The book is divided into five parts: (1) the family; (2) labour; (3) the State; (4) the Government; (5) the Ouang-ming-tse family, in which he gives the history of the life, labours, and pleasures of a family with which he got acquainted in his travels, besides illustrating by a concrete instance how Chinese polity and administration work out in an individual case. With regard to the family, he says that it is at the hearth that the government of the country is carried on. The family has the power of passing judgment on any of its members for an offence, and can sentence the delinquent to whipping, exile, and excommunication. From the decision of the domestic tribunal an appeal is permitted to the ordinary courts of justice, but it is unusual for such an appeal to be made. Such is the respect paid by the Chinese to their traditions that there are few who do not submit at once to the sentence passed on them by their family. No punishment inflicted on a Chinaman can be more terrible than exclusion from the family. Socially he becomes an outcast, and, driven from the shelter of his ancestral home, and the protection of the spirits of his ancestors, he wanders in search of employment over the world, and it is the thousands of these abandoned ones who flood the American labour-markets. In the family, ancestral worship is cultivated, and is one of the strongest incentives to labour and progress: each member looks on himself as the guardian of posterity, toiling for their benefit, and satisfying the ancestors who watch over the family home. Each family religiously preserves the records of its ancestors, their lives and acts; and to the assembled members these records are read by the head of the house at regular intervals. At each meeting one biography is read, then the next, and so on in order, till the last of the series is finished, when a commencement is again made with the first. With regard to these family records, M. Sîmon sees no more noble sign of the honesty and independence of the Chinese than the fact that, when any question is in dispute, an entry in one of these sacred family books referring to the dispute is looked on by the authorities as decisive. To be able to make the entries in this book, and to read it to his family, should he ever become its head, every Chinaman is taught to read and write; of this, in connection with education, we shall speak later on. Property is collective and individual; and the living holders look on themselves as the trustees of posterity. The fee-simple belongs to the community, except in a few fast-diminishing cases, where small portions of land are owned by each family, and are considered inalienable; and he who dares to introduce a stranger into this patrimonial land commits sacrilege, and becomes an outcast. China has been described as a despotic monarchy, but there is perfect liberty to all. Religions of all kinds are tolerated and are never interfered with except for political purposes. All public meetings and expressions of public opinion are freely permitted. To prove this, M. Sîmon says that in 1863 he made in one province a collection of proclamations of great virulence, denouncing the Emperor for agreeing to the treaty with the Europeans after the sack of the Summer Palace and the burning of the great library, and they are very numerous: none of the mandarins, he adds, dared to prosecute their authors. Taxation is very light—not one-hundredth part of what it is in France. With regard to legislation, the Academy of Sciences at Pekin is the only legislative power. If any official thinks that a custom, generally observed in his province, might with advantage be used over the whole country, he sends an account of it to this body, which examines it, and, if it thinks the custom useful, orders it to be tried in the other provinces; if successful there, it is finally adopted, inscribed in the code, and becomes law. Though M. Sîmon reserves a more extensive account of education in China for another work, it is easy to gather his views from the present book. The Government gives full liberty to all to open schools. The children are well taught, and there is scarcely a Chinaman who is not able to read, write, add up accounts, and draw. The foundation of the education is laid in the family. From their earliest years, children are taught their duties and their rights. They are taught respect for others, and hence respect for themselves. Obedience to usages, humanity, justice, and right feeling —these are the foundations of their education. Besides the family education there are two kinds of public instruction,—primary and superior. Primary education is given in the institutions attached to the family temples, where there are such, or in private schools, which anyone is at liberty to open. The education of every child is provided for, apart from Governmental aid, the rich paying for their poorer brethren. Inasmuch as each Chinese sign conveys an idea, the child that is taught to write the Chinese characters learns not only words, but ideas, and he is forced to explain and comment on these to his teachers. And it is to this fact, in addition to the influences of family councils and family readings, with the profuse inscriptions in every public place, that M.

Sîmon ascribes the amazing intelligence and precocity of Chinese children. With regard to higher education, it is open to all. The Government give barely the necessary expenses; the rest is contributed by private donors and by the students themselves, of whom there is always an abundance. The directing staff is paid by Government, the teaching staff by the students. Those who wish to enter the public service are trained and examined at the Hanlin College or University of Pekin. All appointments are given to the graduates according to their degrees; the higher the degree the more honourable and lucrative the post. The graduate takes precedence of all minor officials, and ranks with a minister or viceroy, whose post he frequently fills when he has had a little experience in public life. He has rooms allotted to him in the palatial universities. For these degrees the competition is very severe. All the professions stand on an equal footing, except those of teaching and letters. In no country is the man of letters of such influence as in China. Old age alone makes others as worthy of respect as he. Whenever M. Sîmon found the Chinese distrustful or indifferent to him, he always humoured this opinion of their value of learned men, by seeking out the most learned man in the place and paying his respects to him. The tutor retains a life-long power over his pupil, and frequently the people, when they have had some cause of complaint against an official, have sent long distances to bring his tutor to expostulate with him. The great goal of the literary man is to obtain a public post, such posts being held in high esteem in China. There are few vacancies, however, and the vast majority of candidates being unsuccessful become tutors, public writers, &c.; others turn their talents to commerce and agriculture, and so elevate the educational standard of the industrial classes. Labour is so honourable that handicraftsmen rank as high in public estimation as lawyers and doctors.

M. Sîmon sums up his views of Chinese civilization, of which a few examples have been given here, by stating that the fact which always seemed to him the most wonderful "was the progressive substitution of individual for collective action in all the works of civilization, from the simplest to the most complex, from mental to material. The individual freed from the slavery of collectivity, independent, and free in unity, thanks to that unity, is the salient fact apparent from the study of the relations between the people and the Government in China, and appears to me to justify the theories prevalent there." Very few readers who possess a personal acquaintance with China and the Chinese will be found to agree with all of M. Sîmon's statements of fact, or with all of his conclusions from them. But he has nevertheless produced a book which deserves to be carefully studied, and which will strike the mind by the originality of its propositions and the skill and ingenuity with which they are defended. In these days, when the Chinese are treated amongst many highly civilized communities in different parts of the globe with loathing and scorn, and when elective Legislatures do not hesitate to speak of members of the Chinese race as *hostes humani generis*, it is perhaps well to be reminded, as M. Sîmon forcibly reminds us, that this race has solved, apparently with success, some of the social and political problems before which Western statesmen and philosophers stand helpless.

THE METHOD OF CREATION.

The Creator, and what we may know of the Method of Creation. The Fernley Lecture of 1887. By W. H. Dallinger, LL.D., F.R.S. (London: T. Woolmer, 1887.)

IT is not the province of this journal to deal with theological questions; at the same time, the one discussed in this volume is in such close relation with science, and of such universal interest, that a brief sketch of Dr. Dallinger's argument may be permitted. He deals with a question which takes precedence of those sundering Churches,—one which may briefly be stated thus: Have the recent advances in physical and biological science placed the Theist in an unreasonable position? Obviously this is a fundamental question. If the answer be in the affirmative, all investigations into the minutiæ of theology are less than the shadows of a shade.

Dr. Dallinger commences by pointing out the necessary limits of scientific inquiry. On this he insists, not in any hostile spirit, but only because it is so often forgotten. "The researches of science are physical. The observable finite contents of space and time are the subjects of its analysis. Existence, not the cause of existence; succession, not the reason of succession; method, not the origin of method, are the subjects of physical research. A primordial cause cannot be the subject of experiment nor the object of demonstration. It must for ever transcend the most delicate physical reaction, the profoundest analysis, and the last link in the keenest logic. Absolute knowledge concerning it can only be the prerogative of itself."

This, of course, is a position which many so called Agnostics would frankly accept. But in working out the argument the author indicates that a more definite creed is attainable. Commencing with the physical universe, he shows that whatever discoveries have been made, whatever simplifications introduced into the so-called laws of which it is the result, the physicist is at last arrested by two mysteries—matter and force. But what are these, "the alpha and omega of existence" as some would call them? They are two names, and nothing more. We deal with the properties or qualities of matter, with the consequences of force, but we are no nearer to knowing the one or the other. In addition to these, however, many hard-headed thinkers assert "the existence of a third thing in the universe—to wit, consciousness." Now we may juggle as we please with these terms, we may construct on them elaborate systems explanatory of the universe; but beyond laws either mechanical or vital there lies inevitably, however we may try to smother it by words, the idea of causation; and from this idea that of "volition" cannot be separated. We are, as the author shows in an elaborate argument, reduced at last to this alternative: "either chance or mental purpose gave primal origin to all that is." The former he shows is almost inexpressibly improbable: most men will not hesitate to accept the latter.

Considerable space is next devoted to a discussion of Mr. Herbert Spencer's view that "from matter in motion, and nothing else, the whole universe is supposed to arise; life emerges; and mind in its most transcendent forms comes forth." In this discussion we are again confronted

with an alternative: either the primordial matter was in a state of homogeneity, and so "infinitely incapable of change," or the homogeneity was disturbed by some external force. But an outside influence is not in the philosophic system. "The admission of inability to evolve the universe without it is an admission that the mechanical philosophy fails at the outset. Nor can it serve the emergency to invoke 'force.' A Divine origin of the universe is usually rejected, because the Divinity eludes the methods of science. But we cannot supplant the Divinity by enthroning force. Science can tell us what force *does*, but it can no more find out what force *is* than what an infinite mind is. Force is an irresistible mental inference from matter in motion, but its ultimate nature is defiantly beyond the reach of science."

The phenomena of life, as exhibited in one of the lower and more minute organisms, are then considered. These are "free and self-originating action"; multiplication; and cyclic change in each new organism. Tiny and humble in organization as these creatures are, they differ vastly from chemical compounds of any kind. The force which animates them differs widely from any mode of force which we call physical. So far as we at present know, the break between "life and not life" is abrupt. Hence, whether or not in the remote past the transition from the one to the other may have been what we should call continuous, our present knowledge offers no explanation of it, and the fact is a stumbling-block in the way of a purely mechanical philosophy.

The remainder of the essay is chiefly devoted to a discussion of the theological aspect of the theory of evolution. This, as designed for the non-scientific part of his audience, need not be further mentioned in these pages. It will be enough to say that, as is now generally admitted by the more intelligent among theologians, he maintains that there is no necessary antagonism between their beliefs and scientific theories.

As might be expected from him, Dr. Dallinger is temperate in expression and eloquent in language. Some readers perhaps would have preferred a little more conciseness in style and statement, but it must be borne in mind that the discourse was delivered as a lecture to a non-scientific audience, who required leading gradually, or even alluring, into unfamiliar paths of thought. Among such persons the book cannot fail to do excellent work in allaying needless fear and silencing ignorant clamour; among opponents it will serve to show that the Theist's position is more defensible than they suppose, and that, in their own, unsuspected difficulties lurk beside the seemingly easy path of a euphonious terminology.

OUR BOOK SHELF.

The Harpur Euclid. Book I. By E. M. Langley and W. S. Phillips. (Rivingtons, 1888.)

THE editors are mathematical masters of two Bedford schools under the Harpur Trust; hence the title. For the work itself the title-page further informs us that it is an edition of Euclid's "Elements" revised in accordance with the Reports of the Cambridge Board of Mathematical Studies, and the Oxford Board of the Faculty of Natural Science. Extracts from these Reports are given in a prefatory note: this is the only part of the work which is not strictly adapted for the use of school-boys.

We began our task with no special liking for it, but had not proceeded far when we found that there were new adornments which rendered our perusal of the familiar lines very agreeable. We read on through 102 out of the 120 pages without break, and then ceased, as we had come to some matters which required more careful examination. The editors have kept to the usual sequence, but in many cases have replaced the Simsonian demonstrations by easier ones, and have discarded much of the superfluous matter which has led anti-Euclidians to inveigh so strongly against the "Elements."

We are glad to see that exercises come in right from the outset; these all seem to have been most carefully selected, and are such as a fairly intelligent boy ought to be able to solve from the previous propositions. We refer here to the examples in the body of the book. Frequent reference is made to that excellent, though perhaps hardly sufficiently appreciated, little book of Prof. Henrici, "Congruent Figures," and to the "Syllabus" of the Association for the Improvement of Geometrical Teaching. At the end, as a kind of appendix, are some judicious sections on properties of triangles, on quadrilaterals, on loci, on solving geometrical problems—(1) method of intersection of loci; (2) method of intersection of sets; (3) method of analysis and synthesis. Considerable pains has been bestowed on the arrangement of the text, the selection of the various types, and the drawing of the figures; in fact, the little book is the beau-ideal of a Euclid for boys. We wish we had had such a book in the "auld lang syne," and then our first perusal would not have been so painful. It is the authors' intention to bring out the successive books in like form. We wish them like success, and trust that their venture will find a welcome in many a school.

A Course of Quantitative Analysis for Students. By W. N. Hartley, F.R.S. (London: Macmillan and Co., 1887.)

AFTER the almost infinite number of books, mostly small, "and mostly to meet certain requirements of our own students" on qualitative analysis, it is a relief to meet with a small book for students—beginners—on quantitative analysis, written evidently for beginners, and in a manner to really lead them up from qualitative notions, not by one great bound, but by good sober practice and order, to the appreciation of the care and exactitude, and most important still, the "criticising" state of mind necessary to make a real analytical chemist.

As the author says in his preface: "To be a good analyst does not necessitate a profound knowledge of chemistry;" but any student who has worked at all well through this little book will have a good platform of knowledge under him, and be in a position to enlarge his knowledge with infinitely greater ease, and that very necessary regard for accuracy which is not possible to a student who has not done any quantitative work.

The author begins in a sensible manner by giving the metric weights and measures, with English equivalents, and then the dimensions of various laboratory apparatus, beakers, &c., and all this is very useful. In the introduction, manipulation and reagents are dealt with. The author might have added the use of folded or plaited filters. It is quite as safe and accurate to use them for quantitative purposes as to employ a pump.

Before proceeding to simple estimations of constituents of salts, &c., we have about twenty pages of introductory examples devised with the intention of enabling students to realize the meaning of the atomic and equivalent weights of elements; which they do not always do when put on to determinations without any introduction. This is the most useful and original part of the book. The following exercises, "simple estimations," are fairly in order of difficulty. The middle portion of the book is on volumetric analysis. It is short but workable, and is followed

by a good section on analysis of silicates and some technical products. The book does not attempt to cover all the field of analysis, but what is done will be found really useful by a beginner or a junior student.

W. R. H.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

"A Conspiracy of Silence."

THE Duke of Argyll can scarcely be congratulated upon his latest discovery of a new ground of attack upon geologists. In the year 1862 a very eminent physicist, whose loss we all so deeply deplore, made the somewhat rash suggestion that flint implements are found deep down in the drift, owing to their high density as compared with that of the matrix in which they are inclosed. Seeing that the material in which the implements are found is usually a *flint*-gravel, everyone acquainted with the subject saw that the suggestion was, to say the least, a somewhat unfortunate one, and Prof. P. G. Tait, in seeking for an opportunity to sneer at "advanced geologists," was scarcely kind to the memory of a deceased friend in rescuing such a suggestion from oblivion. But to the Duke of Argyll, the finding of a new basis from which to attack geologists seems to have been a chance which he could not afford to let slip.

The Duke of Argyll now asks when we are going to begin to discuss his magazine-article upon coral reefs. I reply that in the article in question there is not a single new fact or fresh argument—nothing which has not been already brought forward by Mr. Murray himself, or by Dr. Archibald Geikie, and met by Prof. Dana in a singularly exhaustive memoir well known to all geologists. The subject has, moreover, been treated at considerable length by Profs. Prestwich, Green, James Geikie, De Lapparent, and others. Surely no exception can be taken either to the eminence of the authorities who have written on the subject, to the length to which their notices have extended, or to the prominence of the journals or treatises in which these discussions have appeared. If it be said that the general scientific public have not had the matter fully laid before them, it is only necessary in reply to call attention to the pages of NATURE, in which a succession of articles dealing with the subject will be found.

The Duke of Argyll says that he has "nothing to retract." Here I regret to have distinctly to join issue with him. He has asserted that scientific men have refrained from discussing a particular theory, and that in taking this course they have been actuated by the worst of motives—a fear of the truth; he has charged the Geological Society with refusing in the spring of 1885, through its then President, to accept a certain paper from the same cause; and now he adopts and gives fresh currency to an equally offensive charge of a similar kind.

These charges have, each and all of them, been shown to be absolutely destitute of foundation. The Duke of Argyll must judge for himself if the principle of *noblesse oblige* should not lead him, not only to *retract* the charges, but also to *apologize* for having made them. But his Grace may rest assured that, until he does so, the grounds for the deep indignation at his conduct, which is so strongly felt both at home and abroad, will still remain.

JOHN W. JUDD.

On the Constant P in Observations of Terrestrial Magnetism.

I REGRET that Prof. Rücker should have largely misunderstood my last letter. I have not raised the question of fallible observations at all. Referring to the correspondence on pages 127–8 of the present volume of NATURE, my principal contention was and is that the ordinarily accepted formula for P differs by terms of the second and higher orders from Gauss's theory, and that that difference necessarily persists in any rigorous expansion of the formula. By the ordinarily accepted formula for P I mean Prof. Rücker's formula (α); and by Gauss's theory I mean my formulæ (1), (2), and (3). From two observations of $f(u)$, made respectively at the distances r and r_1, the L of Gauss's theory might be found by a direct solution of equations (1) and (2); but instead of that, it is customary to find L from equations (7) and (8) by substituting in them the value of P_0 computed through equation (α). To render the latter procedure rigorous, P should be used in (7), and P_1 in (8). Equation (11) shows that P and P_1 differ by quantities of the second and higher orders, and as the ordinarily accepted value of P_0 lies between P and P_1, it necessarily differs from one or both of these quantities, and therefore from Gauss's theory, by terms of the second and higher orders.

While freely admitting the justice of Prof. Rücker's criticism upon my arbitrary assumption that $P_0 = \frac{1}{2}(P + P_1)$, I cannot assent to the process by which he has deduced equation (γ). Equations (7) and (8) show that we may have either one L and two P's, or two L's and one P. In the latter case these equations become—

$$\tfrac{1}{2}L' = A(1 - P_0 r^{-2}) \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

$$\tfrac{1}{2}L'' = A_1(1 - P_0 r_1^{-2}) \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

and P_0 must be determined so as to make L′ and L″ as nearly as possible identical with L. To that end we must have $2L = L' + L''$; and then, from the difference between (7) + (8) and (15) + (16)

$$P_0 = B(A - A_1)\frac{r_1^2 + r^2}{Ar_1^2 + A_1 r^2} \quad . \quad . \quad . \quad . \quad . \quad (17)$$

Expanding to terms of the second order

$$P_0 = B\frac{(A - A_1)}{A}\left\{1 + \frac{r^2}{r_1^2 + r^2}\left(\frac{A - A_1}{A}\right)\right\} \quad . \quad (18)$$

Whence, by equation (13)

$$P_0 = \frac{r_1^2 r^2}{r_1^2 - r^2}\left(\frac{\log A - \log A_1}{M}\right) - \frac{r_1^2 r^2}{2(r_1^2 - r^2)}\left(\frac{\log A - \log A_1}{M}\right)^2 \quad . \quad . \quad (19)$$

This result agrees better with equation (14) than with equation (γ).

WM. HARKNESS.

Washington, D.C., December 30, 1887.

I AM afraid that the new method of calculating P_0 adopted by Prof. Harkness is not less arbitrary than that which he previously employed. He says that "P_0 must be determined so as to make L′ and L″ as nearly as possible identical with L." If the object is only to deduce a correct value of L by combining equations (15) and (16), this condition is certainly not necessary. For if we substitute from (17) in (15) and (16), and take the mean of the values of L′ and L″, we get by a very roundabout process the same value of L as we should have obtained without using P_0 at all. But we should have reached the same final result if we had started with the assumption that

$$(n + m)L = nL' + mL'',$$

where n and m are any numbers whatever. By properly choosing n and m we could deduce the correct value of L with any assigned value of P_0. It appears to me that the equation $2L = L' + L''$ is based upon the tacit assumption that L′ and L″ are to be combined in accordance with the rules applied to fallible measures, and cannot otherwise be justified if the only object is the correct deduction of L from (15) and (16).

If, however, P_0 is introduced to enable us to calculate another approximate value of L by observing (say) A_2 at some other distance, r_2, the best value to select will depend on circumstances. If r_2 is nearly $= r$ we shall get the best result by writing $P_0 = P$ and so on, so that the equation $2L = L' + L''$ is again arbitrary.

I am quite in agreement with Prof. Harkness as to the fact that if we start from the basis of equations (1) and (2) a small theoretical error is introduced by substituting P_0 for P and P_1. Indeed I think this step can only be justified by our knowledge that the inaccuracy thus caused is less than the error of experi-

ment. It is thus impossible to discuss the proper value of P_0, as Prof. Harkness wishes to do, without raising the question of fallible observations. If it is raised, the method of treatment by least squares follows.

Prof. Harkness tried to show that, although the second term which I introduced brought the approximate value of P_0 nearer to that given by the ordinary formula, it removed it further from another value which he regarded as the standard. I venture to think that I have justified my position by showing that the introduction of P_0 is useless unless the equations are regarded as fallible; that the ordinary value is that given by least squares, and that the standards proposed by Prof. Harkness are founded on assumptions which have no theoretical basis.

In conclusion I may perhaps be allowed to make two remarks, one of which would, I think, from the point of view assumed by Prof. Harkness have strengthened his case. In the first place he is wrong in saying that the ordinary value of P_0 lies between P and P_1. It is smaller than both of them if A is $>A_1$.

In the next place I may point out that by treating a number of fallible expressions of the type of equations (1) and (2) by the method of least squares, a general value of L could be found without the introduction of the small theoretical errors which have caused this correspondence. There is however little doubt that by the introduction of P_0 we obtain a more convenient and practically no less accurate method of dealing with the observations. ARTHUR W. RÜCKER.

Science Schools, South Kensington, January 10.

The Mist-Bow.

IN a letter to the *Times* of January 12, Prof. Tyndall calls attention to a white mist-bow, which he has seen on one or two occasions, and mentions its rarity of occurrence. It may therefore be of interest to record that I witnessed a similar phenomenon on January 9 last. My point of view was an elevated band-stand at the head of Weymouth Pier; the time 11 a.m. The air, as on the occasions mentioned by Prof. Tyndall, "swarmed with minute aqueous particles," *i.e.* was foggy, and on looking away from the sun, which was shining weakly, I saw a well-defined white bow cast upon the mist. The bow appeared to be about 60 feet distant. My point of view being high, a full semicircle was visible. It was, as may be imagined, a beautiful and graceful object. ALBERT BONUS.

St. Leonards, Exeter, January 13.

IN reference to Dr. Tyndall's letter in the *Times* of Thursday last upon the ullao as observed by him, I beg to call your attention to my paper read before the Stockport Society of Naturalists upon the same subject (see pp. 11 and 35). Not having seen the phenomenon described before, I ventured to call it the dew-bow. THOMAS KAY.

Moorfield, Stockport, January 14.

THE character and persistence of the recent fog have been so exceptional that perhaps you may deem the following observations on it worthy a record in NATURE.

I was staying in Mid-Devon at a place in the valley of the River Taw, some 10 miles north of Dartmoor. On Monday, the 9th instant, we were enveloped in a dense, damp, white fog, a rare occurrence in that part of the country. Surmising that the fog had no great vertical thickness, I sallied forth in the afternoon to mount a hill immediately to the eastward. At a slight elevation the sun was already making his appearance, and as I continued my ascent, and the fog became more and more thin, I saw before me on the then pale blue sky a beautiful white bow, similar to the rainbow, only broader and without colour. When the top of the hill was reached, the fog and bow had disappeared, the sky was deep blue, and the sun shining with quite spring-like warmth.

The scene I now had around me was most enchanting. The fog could be traced lying in the river valleys like arms of the sea, with the bordering hills simulating cliffs, and here and there an island appearing in the midst, whilst the distant Dartmoor hills stood out calm in unbroken sunshine. No movement of the air could be detected, but, below, the surface of the fog seemed as if being rolled along by a wind from the east towards the river valley. The white fog-bow is seldom seen, and I imagine owes its absence of colour to the minuteness and close proximity of the water globules, allowing the divided rays to coalesce and so again form white light. C. O. BUDD.

Atmospheric Effects at Sunset.

ON Sunday, January 8, upon leaving the house at half-past four in the afternoon, I observed that the clouds were suffused with a kind of pink or lurid coppery tinge, a sort of angry sunset tint spread over the whole sky. The clouds were of the stratus type which is common in a winter anticyclone, but were moving or rather driving with a swiftness quite unusual under such conditions. The barometer was very high and rising rapidly; but during the afternoon there were several violent and noisy gusts of wind almost amounting to squalls, though during the greater part of the day the atmosphere was still almost to stagnation. The air was mild and intensely humid, and everything was dripping with moisture. In fact the weather was in many particulars the opposite of what we expect during the prevalence of an anticyclone. The diffused sunset effects were quite unlike anything I ever remember to have witnessed before. The gas-lamps had just been lit, and the flames not only appeared of a greenish tint, but seemed to be inclosed in green glass. Several persons stopped me in the street and inquired what it all meant, and one acquaintance said, "What is going to happen?" In the green tint of the gas there is, of course, some suggestion of a colour complementary to the strange red glow which seemed to pervade the atmosphere. But in the absence of all, even the most rudimentary, knowledge of the subject, I should be glad if you or some of your readers can explain the cause to me and to others who witnessed the unaccustomed phenomenon.

CHARLES CROFT.

Prestwich, near Manchester, January 9.

Newton's "Principia."

IT may perhaps interest your readers to know that the 200th anniversary of the publication of Newton's "Principia" was solemnly celebrated on December 20 (old style) by a united meeting of two learned Societies of Moscow—the Imperial Society of Friends of Natural Knowledge, and the Mathematical Society. Prof. Mendeléeff, of St. Petersburg, was Honorary President. Prof. Stoletow (President of the Physical Section in the first-named Society) presented a sketch of Newton's life, and spoke on his optical discoveries; Prof. Zinger (President of the Mathematical Society) treated Newton's mathematical work; Prof. Joukowski pointed out his merits as founder of rational dynamics; and Prof. Ceraski exhibited the creation of celestial mechanics by Newton. The large hall of the Polytechnic Museum, where the meeting took place, was attended by the *élite* of the city. The lectures were illustrated by some optical experiments with electric light and some lantern-slides relative to Newton's biography. A. STOLETOW.

University of Moscow, December 21, 1887 (January 2, 1888).

Meteors.

IN the moonlight on the evening of January 2, at 10h. 58m., a fine meteor, equal in brightness to Jupiter, was observed by Mr. D. Booth at Leeds, and by myself at Bristol. As seen from Leeds, the meteor passed from Musca to the head of Cetus, and terminated its course about 3° east of α Ceti. It moved rather quickly, leaving a long thin train. The fore-part of the nucleus was tinted with red, but the train was yellow. At the finish the motion became slower. At Bristol the meteor was first seen when about 6° S.E. of ζ Draconis, and it travelled some 8° in the direction of β Cephei. Colour yellow, motion very slow. The course was evidently much foreshortened close to its radiant.

Comparing the two paths, it will be found that they intersect each other at $250° + 57°$, so that the meteor was not a member of the January Quadrantids, which attain a maximum on January 2, but belonged to a neighbouring shower of Draconids, which, between January 14 and 19, I have previously observed at $253° + 56°$. The meteor appears to have been observed earlier in its flight at Bristol than at Leeds, for at the latter place the observer was watching the southern sky, and only caught the later part of the course. From a mean of the two observations the height at commencement was 98 miles above a point west of Appleby, Westmoreland, and the end occurred at 60 miles above Chester. The earth-point was near Tiverton, in Devonshire. The real length of path was 109 miles, and it was inclined at an angle of $20\frac{1}{2}°$ to the horizon. The meteor was travelling in a direction from north to south, the bearing of the radiant being N. $8\frac{1}{2}°$ E.

It would be interesting to hear of further observations of this bright meteor. It must have been seen by many persons, as the night was very clear.

The fireball of February 21, 1865, had a radiant at $255° + 55°$, and close to that of the meteor of January 2 last, but the difference of date is too considerable to permit an inference that the wo bodies diverged from the same stream.

January 8. W. F. DENNING.

IN NATURE, November 10, p. 36, it is stated in reference to a meteor that "a Norwegian astronomer" is of the opinion that the track of the meteor must have lain too high to be heard. "He calculates from the reports to hand that the bursting of the meteor occurred at an altitude of about 6000 feet (*sic*), and he thinks that even this figure may be safely doubled."

It may interest some of your readers to know that on the night of July 3, 1884, at 8.27 p.m. standard time of the 75th meridian, a meteor was seen by me, as well as by others, here, and about 5m. 17s. afterwards a sound was heard something like distant thunder, except that it seemed to swell rapidly and steadily to a maximum intensity, and then diminish again in much the same way, but more slowly. I immediately connected the sound with the appearance of the meteor, and stated that it must have been a little over sixty miles distant, and from the estimated angle of elevation about *thirty miles* above the surface of the earth. This estimate was borne out by the accounts from other places of the course of the meteor. The sound I should be inclined to attribute to the rushing together of the air in the wake of the meteor, or perhaps more probably to the sudden compression of the air in front of it, and not to its bursting.

The following account of the meteor was given in the *Canadian Weather Review* of July 1884:—"A magnificent meteor was seen on the night of the 3rd at 8.27 p.m. standard time, passing from south-east to north-west, colours brilliant red and green. Two distinct explosions are reported to have been heard. After the first explosion a sinuous streak remained visible until covered by clouds; the time of flight was from seven to eight seconds, and the apparent size about one-fourth that of the moon. Reports have been received from Listowel, Hastings, Beatrice, Belleville, Lakefield, Pembroke, Peterborough, Kingston, Deseronto, Lindsay, and Huntingdon, all substantially agreeing as to course, size, &c.; it passed two or three miles south of Belleville, and about the same distance north of Lindsay." CHARLES CARPMAEL.

Toronto, December 16, 1887.

The Electrification of the Air.

IN writing upon the electrical condition of the Peak of Teneriffe, the Hon. Ralph Abercrombie (NATURE, vol. xxxvii. p. 31), begins by stating that "the limited number of observations on atmospheric electricity which have been already made all point, with one exception, to a normal positive difference of potential between a point some few feet above the earth and the ground itself;" and farther on he writes: "the electrical conditions of the Peak of Teneriffe [the one exception] were the same as in every other part of the world." As similar statements still find their way into text-books and treatises on electricity and meteorology, I trust you will permit me to point out that, unless a very special meaning be attached to the word "normal," this generalization is decidedly too wide.

In a paper read at the Aberdeen meeting of the British Association in 1885 (printed *Phil. Mag.*, November 1885), I pointed out that, in Madras at least, a negative electrification of the air was a normal, and not an abnormal, condition for many hours of the day at certain seasons of the year. Observations since taken have entirely confirmed the opinion that with a hot, dry, west wind the air at Madras is usually negatively electrified, and often to a very high potential.

With regard to observations made on mountains in the tropics, though perhaps hardly within what Mr. Abercromby terms "the zone of constant electrical discharge," I would venture to call his attention to a short paper on observations made on the top of Dodabetta (8642 feet) in the Transactions of the Royal Society of Edinburgh, vol. xxxii. p. 583.

I may add that during the periods of incessant discharges of sheet lightning which we often experience here the electrification of the air is sometimes positive and at other times negative, but generally positive. C. MICHIE SMITH.

Madras Christian College, Madras, December 14, 1887.

Wind Force at Sea.

PROF. WALDO, in the *American Meteorological Journal* for October, recommends the use of instruments for determining the velocity of the wind at sea. In a paper read before the Meteorological Society, I discussed the comparative results, obtained from a great number of observations under all conditions at sea, between two very simple and small anemometers, showing that, although the two instruments were on entirely different principles, the results obtained differed only by about 10 per cent. In a paper read in March last before the Meteorological Society, "Notes on taking Observations at Sea, &c.," I again urged the desirability of observers using some form of anemometer, so that more uniform results could be obtained, and I gave a table for correcting the apparent velocity of the wind as registered by the instrument for the speed of the ship and for aberration.

For instance, at the present time you may have two sailing-ships close together, one carrying top-gallant sails, the other only reefed top-sails, and the wind will be logged accordingly. Again, two steamers going in opposite directions are very likely to experience apparently different wind velocities, and the senses of officers in steamers are not so acute for detecting differences in wind velocities as are those of officers in sailing-ships. The use of instruments would eliminate these errors.

With instruments similar to those I use—the coefficient of friction of which is slight—the relative velocity of the wind may be obtained fairly accurately; and I contend that this is of more importance than the chance there is of obtaining the estimated true velocity; and, I may add, the trouble attending the use of these instruments is small.

There are two other subjects which, up to the present, have received little attention at sea, viz. the registration of rainfall and the electrical condition of the atmosphere. Observations on both could easily be carried out on board some ships, and the observations would be both valuable and interesting.

DAVID WILSON-BARKER.

A Troublesome Parasite of a Brittle-Starfish.

IN a valuable work on certain parasitic Crustacea ("Contributions à l'Etude des Bopyriens," p. 181), Prof. A. Giard and J. Bonnier have done me the honour of calling attention to my discovery of a Copepod (?) which lives in the body of an Ophiuran, *Amphiura squamata.* They regard the mutual relationship of the Copepod and the Ophiuran as an instance of the castration of the host by the parasite. Although all my observations indicate the correctness of some such an interpretation, I failed to recognize it as a fact until after they had pointed it out. The explanation seems a possible one, and is provisionally accepted, with a few modifications, as the best as far as research has gone. The modifications are important.

The state of knowledge of the subject is as follows. Ova and young of a Crustacean are found in the body of an American brittle-star, identified as *Amphiura squamata.* In some instances an adult Crustacean was also found in the same place. When these ova, young, or adults are found parasitic in the Amphiura, the remains of the ovary of the host appear as an amorphous mass, and there is no possibility of future young of the Amphiura in the brood sac, since the ova have been destroyed.

The conclusion seems inevitable, for observations indicate that the mother Crustacean makes her way somehow into the body of the host (Amphiura), then affects the brittle-star so that the young of the host will not develop, after which she leaves packets of ova to mature in the sacs where normally young Amphiuræ would develop. It thus happens that the products of the ovary of the host are destroyed before the Crustacean ova are developed, or while they are in an early stage of cleavage. Consequently it is legitimate to conclude that if the ova of the host is destroyed it may be done by the adult Crustacean.

If Prof. Giard and Bonnier are right in their interpretation that this is an instance of parasitic castration, as I think they are, we possibly have an interesting case of a parasite destroying the reproductive powers of the host *for the future good of her own offspring.* Such a condition of things is unique, and among Ophiurans the writer recalls but the single instance of the present case of Amphiura. The case of the Crustacean and its brittle star host seems to differ from that of Entoniscus in that in the one instance the destruction of the ovary may be of advantage to the parasite, while in the other the destruction or

modification of the spermary of the host is simply a concomitant circumstance of the parasitism. It seems hard to believe that the simple presence of the packets of Crustacean ova in the brood sac of an Amphiura would lead to a destruction of the ova of the brittle-star, but it does not seem impossible that the adult Crustacean could have spayed the Amphiura.

The character of this phenomenon is so unusual that one hesitates to accept it on insufficient data. There are gaps in my observations which may be serious to the theory. In the first place, it has not been observed that the Crustacean spayed the Amphiura. The ovarian gland of the brittle-star is destroyed, and indications point to the Crustacean as the culprit. Secondly, it is not known that the parasite enters the *brood sac* through the genital slits to deposit the ova. Thirdly, the difficulties of determination whether the ova are in the body cavity, stomach walls, or brood sac, are very great. I believe it is probable that they are in the brood sac. Lastly, the family name of the strange parasite who repays hospitality so ungraciously is unknown. There is no doubt that it is a Crustacean, as I have traced the egg through a nauplius into an adult.

As this condition of life is believed to be a novel one, and needs verification, the writer takes this opportunity to call the attention of marine zoologists to it, and to request correspondence from anyone who may have made similar observations. Before we can definitely accept the conclusions towards which my observations lead, there is a call for re-examination and verification of the observations. The most important question is to determine whether or not the ova of the Crustacean live in the brood sac.

Cambridge, Mass., U.S.A. J. WALTER FEWKES.

Raised Beaches *versus* High-Level Beaches.

IF you can find space for the subjoined list of shells from the ancient beach on the Thatcher rock in Torbay, it may prove acceptable to such geologists as interest themselves in the question recently resuscitated by Prof. McKenny Hughes, as to whether the ancient Devonshire beaches are "raised," as commonly supposed, or merely high-level, as some hold them to be.

Added to the late Mr. Godwin Austen's "Hope's Nose" list, my list runs up the total number of species from the two beaches to forty-six, and this without reckoning Mr. Godwin Austen's *Cardium tuberculatum*, which I think must have been an oversight for *C. echinatum*. This number has not, I believe, been beaten by any British raised beach hitherto.

When the Thatcher beach was accumulated, the northern shell *Trophon truncatus* was abundant in the neighbourhood; so was *Tellina balthica*, a shell which only occurs, I believe, in this vicinity, in or near the tidal harbours of Torbay.

The Thatcher collection evidences the great antiquity of the beach, a considerable change of temperature, differences in the rock-components of the coast-line, and variation in its contour. Of these subjects I hope some day to treat, but in the meantime the facts so far as they have been ascertained are presented to geologists in the following list of shells for them to deal with as they please:—

Ostrea edulis	*Litorina obtusata*
Pinna rudis	*L. rudis*
Mytilus edulis	*L. litorea*
M. modiolus	*Turritella terebra*
Nucula nucleus	*Scalaria turtonæ*
Cardium echinatum	*Natica alderi*
C. edule	*Adeorbis subcarinatus*
C. norvegicum	*Cerithium reticulata*
Cyprina islandica	*Purpura lapillus*
Astarte sulcata	*Buccinum undatum*
Venus exoleta	*Murex erinaceus*
V. fasciata	*Trophon truncatus*
V. gallina	*Fusus gracilis*
Tellina balthica	*F. jeffreysianus*
Lutraria elliptica	*Nassa reticulata*
Mactra subtruncata	*N. incrassata*
Solen vagina	*Pleurotoma striolata*
Mya arenaria	*P. brachystoma*
Saxicava rugosa	*P. turricula*
	Cylichna cylindracea
Patella vulgata	
Trochus zizyphinus	42 species.
Lacuna puteolus	

The shells have been identified in odd lots and at different times by the late Mr. Gwyn Jeffreys, Mr. J. T. Marshall, and Mr. D. Pidgeon, to whom my warmest thanks have been due. The bulk of the work has, however, been done by the last-named gentleman, without whose hearty co-operation, both in searching the beach material and naming the shells and fragments found therein, the list would have been shorn of much of its goodly proportions. A. R. HUNT.

Torquay, December 28, 1887.

Vegetation and Moonlight.

THE letter of your Trinidad correspondent, given in NATURE, vol. xxxvi. p. 586, referring to a Committee appointed to determine moon influence, has a practical interest for me. Among the wood-cutters in Cape Colony, both east and west, there is a fixed belief, which no arguments can turn, that to cut timber at, or shortly after, full moon, is to cut it when the sap is up; and when, consequently, it is out of season. The same belief prevails in various parts of Southern India, notably in Travancore. I have always combated the belief, pending time and opportunity to test it, indulging in the provisional hypothesis that the bush-workers' belief may be due to the fact that they can only work by night at or near full moon; and that at night trees should contain more sap than by day, when watery exhalation is active.

It seems possible that in the habitually cloudless nights of certain countries the moon may exert influences not noticeable elsewhere. It is well known in Cape Colony that fish, pork, and other provisions go bad if left exposed to moonlight; though possibly this may be due to the light acting as a guide to insects. D. E. HUTCHINS,

Cape Colony, December 8, 1887. Conservator of Forests.

Centre of Water Pressure.

DR. ROUTH has done me the favour of pointing out that in the first volume of his "Rigid Dynamics" he has given the following very simple result with regard to the centre of pressure of a triangle occupying any position in a liquid:—"This point is the centre of gravity of three particles at the middle points of the sides, with masses proportional to their depths."

This result of Dr. Routh's is one of many very remarkable theorems of integration published by him in the *Quarterly Journal*, No. 83, 1886. GEORGE M. MINCHIN.

A New Magnetic Survey of France.

IT should not be difficult to do foreigners justice without belittling our own countrymen, and *a fortiori* without robbing any of the latter of their birthright.

In Prof. Thorpe's paper in last week's NATURE there occurs the sentence, "Even the surveys of their own country (France) have been made for them by Germans and Englishmen." This sentence taken in connection with the opening paragraph of the paper conveys the unfortunate impression that Von Lamont, the author of the "Untersuchungen über die Richtung und Stärke des Erdmagnetismus . . ." and of numerous other similar works, was a German, the truth being that he was merely a "Scot abroad" (see NATURE, vol. xx. p. 425). T. M.

Bothwell, Glasgow, January 14.

TIMBER, AND SOME OF ITS DISEASES.[1]

V.

IT has long been known that timber which has been felled, sawn up, and stored in wood-yards, is by no means necessarily beyond danger, but that either in the stacks, or even after it has been employed in building construction, it may suffer degeneration of a rapid character from the disease known generally as "dry-rot." The object of the present paper is to throw some light on the question of dry-rot, by summarizing the chief results of recent botanical inquiries into the nature and causes of the disease—or, rather, diseases, for it will be shown that there are several kinds of "dry-rot."

[1] Continued from p. 254.

The usual signs of the ordinary dry-rot of timber in buildings, especially deal-timber or fir-wood, are as follows. The wood becomes darker in colour, dull yellowish-brown instead of the paler tint of sound deal; its specific weight diminishes greatly, and that this is due to a loss of substance can be easily proved directly. These changes are accompanied with a cracking and warping of the wood, due to the shortening of the elements as water evaporates and they part from one another: if the disease affects one side of a beam or plank, these changes cause a pronounced warping or bending of the timber, and in bad cases it looks as if it had been burnt or scorched on the injured side. If the beam or plank is wet, the diseased parts are found to be so soft that they can easily be cut with a knife, almost like cheese; when dry, however, the touch of a hard instrument breaks it into brittle fibrous bits, easily crushed between the fingers to a yellow-brown, snuff-like powder. The timber has by this time lost its coherence, which, as we have seen, depends on the firm interlocking and holding together of the uninjured fibrous elements, and may give way under even light loads—a fact only too well known to builders and tenants. The walls of the wood-elements (tracheides, vessels, fibres,

FIG. 17.—Portion of the mycelium of *Merulius lacrymans* removed from the surface of a beam of wood. This cake-like mass spreads over the surface of the timber, to which it is intimately attached by hyphæ running in the wood-substance. Subsequently it develops the spore-bearing areolæ near its edges. The shading indicates differences in colour, as well as irregularities of surface.

or cells, according to the kind of timber, and the part affected) are now, in fact, reduced more or less to powder, and if such badly diseased timber is placed in water it rapidly absorbs it and sinks: the wood in this condition also readily condenses and absorbs moisture from damp air, a fact which we shall see has an important bearing on the progress of the disease itself.

If such a piece of badly diseased deal as I have shortly described is carefully examined, the observer is easily convinced that fungus filaments (mycelium) are present in the timber, and the microscope shows that the finer filaments of the mycelium (hyphæ) are permeating the rotting timber in all directions—running between and in the wood elements, and also on the surface, much as in the case shown in Fig. 17. In a vast number of cases, longer or shorter, broader or narrower, cords of grayish-white mycelium may be seen coursing on the surface and in the cracks: in course of time there will be observed flat cake-like masses of this mycelium, the hyphæ being woven into felt-like sheets, and these may be extending themselves on to neighbouring pieces of timber, or even on the brick-work or ground on which the timber is resting. These cord-like strands and cake-like masses of felt, with their innumerable fine filamentous continuations in the wood, constitute the vegetative body or mycelium of a fungus known as *Merulius lacrymans*. Under certain circumstances, often realized in cellars and houses, the cakes of mycelium are observed to develop the fructification of the fungus, illustrated in Fig. 18.

To understand the structure of this fructification we may contrast it with that of the *Polyporus* or *Trametes* referred to in the last article; where in the latter we find a number of pores leading each into a tubular cavity lined with the cells which produce the spores, the *Merulius* shows a number of shallow depressions lined by the sporogenous cells. The ridges which separate these depressed areolæ have a more or less zigzag course, running together, and sometimes the whole presents a likeness to

FIG. 18.—Mature fructification of *Merulius lacrymans*. The cake-like mass of felted mycelium has developed a series of areolæ (in the upper part of the figure), on the walls of which the spores are produced. In the natural position this spore-bearing layer is turned downwards, and in a moist environment pellucid drops or "tears" distil from it. The barren part in the foreground was on a wall, and the remainder on the lower side of a beam: the fungus was photographed in this position to show the structure.

honey-comb; if the ridges were higher, and regularly walled in the depressed areas, the structure would correspond to that of a *Polyporus* in essential points. The spores are produced in enormous numbers on this areolated surface, which is directed downwards, and is usually golden-brown, but may be dull in colour, and presents the remarkable phenomenon of exuding drops of clear water, like tears, whence the name *lacrymans*. In well-grown specimens, such as may sometimes be observed on the roof of a cellar, these crystal-like tears hang from the areolated surface like pendants, and give an extraordinarily beautiful appearance to the whole; the substance of the glistening *Merulius* may then be like shot-velvet gleaming with bright tints of yellow, orange, and even purple.

It has now been demonstrated by actual experiment that the spores of the fungus, *Merulius lacrymans*, will

germinate on the surface of damp timber, and send their germinal filaments into the tracheids, boring through the cell-walls, and extending rapidly in all directions. The fungus mycelium, as it gains in strength by feeding upon the substance of these cell-walls, destroys the wood by a process very similar to that already described (compare Fig. 14, Article III.).

It appears, however, from the investigations of Poleck and Hartig, that certain conditions are absolutely necessary for the development of the mycelium and its spread in the timber, and there can be no question that the intelligent application of the knowledge furnished by the scientific elucidation of the biology of the fungus is the key to successful treatment of the disease. This is, of course, true of all the diseases of timber, so far as they can be dealt with at all, but it comes out so distinctly in the present case that it will be well to examine a little at length some of the chief conclusions.

Merulius, like all fungi, consists of relatively large quantities of water—50 to 60 per cent. of its weight at least—together with much smaller quantities of nitrogenous and fatty substances and cellulose, and minute but absolutely essential traces of mineral matters, the chief of which are potassium and phosphorus. It is not necessary to dwell at length on the exact quantities of these matters found by analysis, nor to mention a few other bodies of which traces exist in such fungi. The point just now is that all these materials are formed by the fungus at the expense of the substance of the wood, and for a long time there was considerable difficulty in understanding how this could come about.

The first difficulty was that although the "dry-rot fungus" could always be found, and the mycelium was easily transferred from a piece of diseased wood to a piece of healthy wood provided they were in a suitable warm, damp, still atmosphere, no one had as yet succeeded in causing the spores of the *Merulius* to germinate, or in following the earliest stages of the disease. Up to about the end of the year 1884 it was known that the spores refused to germinate either in water or in decoctions of fruit; and repeated trials were made, but in vain, to see them actually germinate on damp wood, until two observers, Poleck and Hartig, discovered about the same time the necessary conditions for germination. It should be noted here that this difficulty in persuading spores to germinate is by no means an isolated instance: we are still ignorant of the conditions necessary for the germination of the spores of many fungi—*e.g.* the spores of the mushroom, according to De Bary; and it is known that in numerous cases spores need very peculiar treatment before they will germinate. The peculiarity in the case of the spores of *Merulius lacrymans* was found by Hartig to be the necessity of the presence of an alkali, such as ammonia; and it is found that in cellars, stables, and other outhouses where ammoniacal or alkaline emanations from the soil or elsewhere can reach the timber, there is a particularly favourable circumstance afforded for the germination of the spores. The other conditions are provided by a warm, still, damp atmosphere, such as exists in badly ventilated cellars, and corners, and beneath the flooring of many buildings.

Careful experiments have shown beyond all question that the "dry-rot fungus" is no exception to other fungi with respect to moisture: thoroughly dry timber, so long as it is kept thoroughly dry, is proof against the disease we are considering. Nay, more, the fungus is peculiarly susceptible to drought, and the mycelial threads and even the young fructifications growing on the surface of a beam of timber in a damp close situation may be readily killed in a day or two by letting in thoroughly dry air: of course, the mycelium deeper down in the wood is not so easily and quickly destroyed, since not only is it more protected, but the mycelial strands are able to transport moisture from a distance. Much misunderstanding prevails as to the meaning of "dry air" and "dry wood": as a matter of fact, the air usually contains much moisture, especially in cellars and quiet corners devoid of draughts, such as *Merulius* delights in, and we have already seen how dry timber rapidly absorbs moisture from such air. Moreover, the strands of mycelium may extend into damp soil, foundations, brick-work, &c.; in such cases they convey moisture to parts growing in apparently dry situations.

A large series of comparative experiments, made especially by Hartig, have fully established the correctness of the conclusion that damp foundations, walls, &c., encourage the spread of dry-rot, quite independently of the quality of the timber. This is important, because it has long been supposed that timber felled in summer was more prone to dry-rot than timber felled in winter: such, however, is not shown to be the case, for under the same conditions both summer- and winter-wood suffer alike, and decrease in weight to the same extent during the progress of the disease. There is an excellent opportunity for further research here however, since one observer maintains that in one case at any rate (*Pinus sylvestris*) the timber felled at the end of April suffered from the disease, whereas that felled in winter resisted the attacks of the fungus: internal evidence in the published account supports the suspicion that some error occurred here. The wood which succumbed was found to contain much larger quantities of potassium and phosphorus (two important ingredients for the fungus), and Poleck suggests that this difference in chemical constitution explains the ease with which his April specimens were infected.

It appears probable from later researches and criticism that Poleck did not choose the same parts of the two stems selected for his experiments, for (in the case of *Pinus sylvestris*) the heart-wood is attacked much less energetically than the sap-wood—a circumstance which certainly may explain the questionable results if the chemist paid no attention to it, but analyzed the sap-wood of one and the heart-wood of the other piece of timber, as he seems to have done.

The best knowledge to hand seems to be that no difference is observable in the susceptibility to dry-rot of winter-wood and summer-wood of the same timber; *i.e. Merulius lacrymans* will attack both equally, if other conditions are the same.

But air-dry and thoroughly seasoned timber is much less easily attacked than damp fresh-cut wood of the same kind, both being exposed to the same conditions.

Moreover, different timbers are attacked and destroyed in different degrees. The heart-wood of the pine is more resistant than any spruce timber. Experimental observations are wanted on the comparative resistance of oak, beech, and other timbers, and indeed the whole question is well worth further investigation.

When the spore has germinated, and the fungus hyphæ have begun to grow and branch in the moist timber, they proceed at once to destroy and feed upon the contents of the medullary rays; the cells composing these contain starch and saccharine matters, nitrogenous substances, and inorganic elements, such as potassium, phosphorus, calcium, &c. Unless there is any very new and young wood present, this is the only considerable source of proteid substances that the fungus has: no doubt a little may be obtained from the resin-passages, but only the younger ones. In accordance with this a curious fact was discovered by Hartig: the older parts of the hyphæ pass their protoplasmic contents on to the younger growing portions, and so economize the nitrogenous substances. Other food-substances are not so sparse; the lignified walls inclose water and air, and contain mineral salts, and such organic substances as coniferin, tannin, &c., and some of these are absorbed and employed by the fungus. Coniferin especially appears to be destroyed by the hyphæ.

The structure of the walls of the tracheides and cells of the wood is completely destroyed as the fungus hyphæ extract the minerals, cellulose, and other substances from them. The minerals are absorbed at points of contact between the hyphæ and the walls, reminding us of the action of roots on a marble plate: the coniferin and other organic substances are no doubt first rendered soluble by a ferment, and then absorbed by the hyphæ. This excretion of ferment has nothing to do with the excretion of water in the liquid state, which gives the fungus its specific name: the "tears" themselves have no solvent action on wood.

It will be evident from what has been stated that the practical application of botanical knowledge is here not only possible, but much easier than is the case in dealing with many other diseases.

It must first be borne in mind that this fungus spreads, like so many others, by means of both spores and mycelium: it is easy to see strands of mycelium passing from badly-diseased planks or beams, &c., across intervening brick-work or soil, and on to sound timber, which it then infects. The spores are developed in countless myriads from the fructifications described, and they are extremely minute and light: it has been proved that they can be carried from house to house on the clothes and tools, &c., of workmen, who in their ignorance of the facts are perfectly careless about laying their coats, implements, &c., on piles of the diseased timber intended for removal. Again, in replacing beams, &c., attacked with dry-rot, with sound timber, the utmost ignorance and carelessness are shown: broken pieces of the diseased timber are left about, whether with spores on or not; and I have myself seen quite lately sound planks laid close upon and nailed to planks attacked with the "rot." Hartig proved that the spores can be carried from the wood of one building to that of another by means of the saws of workmen.

But perhaps the most reckless of all practices is the usage of partially diseased timber for other constructive purposes, and stacking it meanwhile in a yard or outbuilding in the neighbourhood of fresh-cut, unseasoned timber. It is obvious that the diseased timber should be removed as quickly as possible, and burnt at once: if used as firewood in the ordinary way, it is at the risk of those concerned. Of course the great danger consists in the presence of many ripe spores, and their being scattered on timber which is under proper conditions for their germination and the spread of the mycelium.

It is clearly an act approaching those of a madman to use fresh "green" timber for building purposes; but it seems certain that much improperly dried and by no means "seasoned" timber is employed in some modern houses. Such wood is peculiarly exposed to the attacks of any spores or mycelium that may be near.

But even when the beams, door-posts, window-sashes, &c., in a house are made of properly dried and seasoned deal, the danger is not averted if they are supported on damp walls or floors. For the sake of illustration I will take an extreme case, though I have no doubt it has been realized at various times. Beams of thoroughly seasoned deal are cut with a saw which has previously been used for cutting up diseased timber, and a few spores of *Merulius* are rubbed off from the saw, and left sticking to one end of the cut beam: this end is then laid on or in a brick wall, or foundation, which has only stood long enough to partially dry. If there is no current of dry air established through this part, nothing is more probable than that the spores will germinate, and the mycelium spread, and in the course of time—it may be months afterwards—a mysterious outbreak of dry-rot ensues. There can be no question that the ends of beams in new houses are peculiarly exposed to the attacks of dry-rot in this way.

The great safeguard—beyond taking care that no spores or mycelium are present from the first—is to arrange that all the brick-work, floors, &c., be thoroughly dry before the timber is put in contact with them; or to interpose some impervious substance—a less trustworthy method. Then it is necessary to aërate and ventilate the timber; for *dry* timber *kept dry* is proof against "dry-rot."

The ventilation must be real and thorough however, for it has been by no means an uncommon experience to find window-sashes, door-posts, &c., in damp buildings, with the insides scooped out by dry-rot, and the aërated outer shells of the timber quite sound: this is undoubtedly often due to the paint on the outer surfaces preventing a thorough drying of the deeper parts of the wood.

Of course the question arises, and is loudly urged, Is there no medium which will act as an antiseptic, and kill the mycelium in the timber in the earlier stages of the disease? The answer is, that mineral poisons will at once kill the mycelium on contact, and that creosote, &c., will do the same; but who will take the trouble to thoroughly impregnate timber in buildings such as harbour dry-rot? And it is simply useless to merely paint these specifics on the surface of the timber: they soak in a little way, and kill the mycelium on the outside, but that is all, and the deadly rot goes on destroying the inner parts of the timber just as surely.

There is one practical suggestion in this connection, however; in cases where properly seasoned timber is used, the beams laid in the brick walls might have their ends creosoted, and if thoroughly done this would probably be efficacious during the dangerous period while the walls finished drying. I believe this idea has been carried out lately by Prof. Hartig, who told me of it. The same observer was also kind enough to show me some of his experiments with dry-rot and antiseptics: he dug up and examined in my presence glass jars containing each two pieces of deal—one piece sound, and the other diseased. The sound pieces had been treated with various antiseptics, and then tied face to face with the diseased pieces, and buried in the jar for many months or even two years.

However, I must now leave this part of the subject, referring the reader to Hartig's classical publications for further information, and pass on to a sketch of what is known of other kinds of "dry-rot." It is a remarkable fact, and well known, that *Merulius lacrymans* is a domestic fungus, peculiar to dwelling-houses and other buildings, and not found in the forest. We may avoid the discussion as to whether or no it has ever been found wild: one case, it is true, is on record on good authority, but the striking peculiarity about it is that, like some other organisms, this fungus has become intimately associated with mankind and human dwellings, &c.

The case is very different with the next disease-producing fungus I propose to consider. It frequently happens that timber which has been stacked for some time in the wood-yards shows red or brown streaks, where the substance of the timber is softer, and in fact may be "rotten": after passing through the saw-mill these streaks of bad wood seriously impair the value of the planks, beams, &c., cut from the logs

Prof. Hartig, who has devoted much time to the investigation of the various forms of "dry-rot," informs me that this particular kind of red or brown streaking is due to the ravages of *Polyporus vaporarius*. The mycelium of this fungus destroys the structure of the wood in a manner so similar to that of the *Merulius* that the sawyers and others do not readily distinguish between the two. The mycelium of *Polyporus vaporarius* forms thick ribbons and strands, but they are snowy white, and not gray like those of *Merulius lacrymans*: the structure, &c., of the fructification are also different. I have shown in Fig. 19 a piece of wood undergoing destruction from the action of the mycelium of this *Polyporus*, and it will be seen how the diseased timber cracks just as under the influence of *Merulius*.

Now *Polyporus vaporarius* is common in the forests,

and Hartig has found that its spores may lodge in cracks in the barked logs of timber lying on the ground—cracks such as those in Fig. 1 (see p. 182). In the particular forests of which the following story is told, the felling is accomplished in May (because the trunks can then be readily barked, and also because such work cannot be carried on there in the winter), and the logs remain exposed to the sun and rain, and vicissitudes of weather generally, for some time. Now it is easy to see that rain may easily wash spores into such cracks as those referred to, and the fungus obtains its hold of the timber in this way.

The next stage is sending the timber down to the timber-yards, and this is accomplished, in the districts referred to, by floating the logs down the river. Once in the river, the wood swells, and the cracks close up; but the fungus spores are already deeply imprisoned in the cracks, and have no doubt by this time emitted their germinal hyphæ, and commenced to form the mycelium. This may or may not be the case: the important point is simply hat the fungus is already there. Having arrived at the

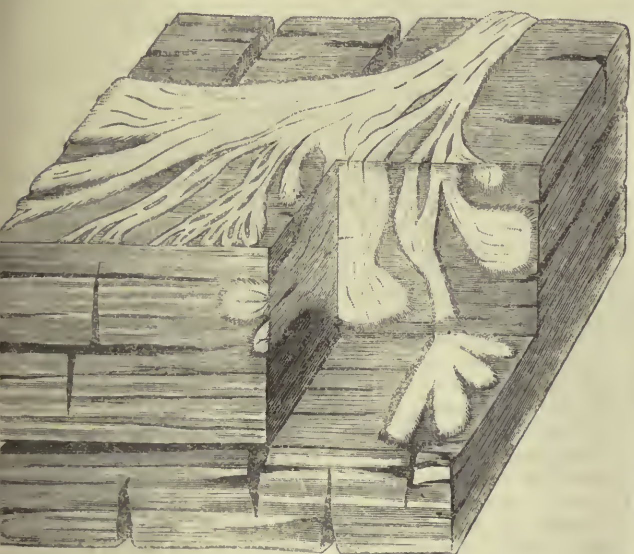

Fig. 19.—A piece of pine-wood attacked by the mycelium of *Polyporus vaporarius*. The timber has warped and cracked under the action of the fungus, becoming of a warm brown colour at the same time; in the crevices the white strands of felt-like mycelium have then increased, and on splitting the diseased timber they are found creeping and applying themselves to all the surfaces. Except that the colour is snowy white, instead of gray, this mycelium may easily be mistaken for that of *Merulius*. The fructification which it develops is, however, very different. (After R. Hartig)

timber-wharves, the logs are stacked for sawing in heaps as big as houses: after a time the sawing up begins. It usually happens that the uppermost logs when cut up show little or no signs of rot; lower down, however, red and brown streaks appear in the planks, and when the lowermost logs are reached, perhaps after some weeks or months, deep channels of powdery, rotten wood are found, running up inside the logs in such a way that their transverse sections often form triangles or V-shaped figures, with the apex of the triangle or V turned towards the periphery of the log.

The explanation is simple. The uppermost logs on the stack have dried sufficiently to arrest the progress of the mycelium, and therefore of the disease: the lower logs, however, kept damp and warm by those above, have offered every chance to the formation and spread of the mycelium deep down in the cracks of the timber. I was much impressed with this ingenious explanation, given to me personally by Prof. Hartig, and illustrated by actual specimens. It will be noticed how fully it explains the curious shape of the rotten courses, because the depths of the cracks are first diseased, and the mycelium spreads thence.

Obviously some protection would be afforded if the bark could be retained on the felled logs, or if they could be at once covered and kept covered after barking; and, again, something towards protection might be done by carting instead of floating the timber, when possible. At the same time, this is not a reliable mode of avoiding the disease by itself; and even the dry top logs in the saw-yard are not safe. Suppose the following case. The top logs of the stack are quite dry, and are cut into beams and used in building; but they have spores or young mycelium trapped in the cracks at various places. If, from contact with damp brick-work or other sources of moisture, these spores or mycelia are enabled to spread subsequently, we may have "dry-rot" in the building; but this "dry-rot" is due to *Polyporus vaporarius*, and not to the well-known *Merulius lacrymans*.

There can probably be no question of the advantage of creosoting the ends of such rafters, beams, &c.; since the creosote will act long enough to enable the timber to dry, if it is ever to dry at all. But the mycelium of *Polyporus vaporarius* makes its way into the still standing timber of pines and firs; for it is a wound-parasite, and its mycelium can obtain a hold at places which have been injured by the bites of animals, &c.: it thus happens that this form of "dry-rot" is an extremely dangerous and insidious one, and I have little doubt that it costs our English timber-merchants something, as well as Continental ones. Nor are the above the only kinds of "dry-rot" we know. Hartig has described a disease of pine-wood caused by *Polyporus mollis*, which is very similar to the last in many respects, and the suspicion may well gain ground that this important subject has by no means been exhausted yet.

H. MARSHALL WARD.

SCIENCE IN ELEMENTARY SCHOOLS.[1]

NOTHING could be more unsatisfactory than the present position of the knowledge and teaching of science in our elementary schools. Notwithstanding all the advantages that have been offered to pupil-teachers for the study of science, as a body they appear to be in a most deplorable state in this respect. Though success in the examinations of the Science and Art Department are now taken into account in placing the students of the training colleges for their teaching certificates, and average school-boys when they have been fairly taught are quite competent for these examinations, yet very few of the teachers have availed themselves of this privilege, and it does not appear that the training colleges have helped them in this respect. Very little, indeed, can be expected while the ordinary pupil-teacher is described, as he is in Mr. Oakeley's report on the working of the Training Colleges, as deficient in many elementary branches, notably mathematics. It is satisfactory, however, to notice that the quality of the candidates for admission to the Training Colleges is improving, and that these institutions are growing in teaching capacity and in popularity. The reports of the examiners for admission are not, with regard to the subject in hand, pleasant reading. One cannot expect good answering in science from candidates who are quite unable to paraphrase an ordinary piece of poetry, or to explain a common English expression. Accordingly we find that in Euclid, algebra, and mensuration, though a few papers were especially meritorious, the vast majority of the answers were very inferior. Few, if any, attempted the easy riders in Euclid, and the examiner remarks that he fears that the pupil-teachers receive but little assistance

[1] "Report of Committee of Council on Education (England and Wales), 1886–87."

from those who superintend their work. It is not easy to say whether this poor teaching or defective early training is at the root of the evil. It is worthy of remark that the metropolitan candidates, in their answers to the questions on Euclid, far surpass their provincial competitors. Many amazing blunders are quite common in the algebra papers, such as subtracting the terms of the numerator from those of the denominator, and completely ignoring the signs, and it is stated that the pupil-teachers at Chester at the end of their apprenticeship were unable to work a simple sum in algebra or to write out an easy proposition Mr. Fitch has a very able report on the Training Colleges for schoolmistresses, and from him it is plain that the same defects exist among the female as among the male pupil-teachers. At the admission examination the work in the arithmetic is satisfactory in point of accuracy, but it displays want of method, failure to appreciate the meaning of the question asked, and ignorance of principles. Thus very few of the candidates were able to give an intelligent explanation of simple arithmetical processes, such as subtraction or division. With them, as with the male pupil-teachers, book-work and memory are wholly relied on, and little attention is paid to the intelligent application of principles. "Scarcely three per cent. are able to do much more in the teaching of arithmetic than work sums more or less correctly on the black-board."

With such material to work on, it is not surprising that the results of the work at the colleges are not what they otherwise might be. Those who are below the average at admission rarely succeed very well in the array of subjects to be learnt in two years' training. With regard to the male students the reports at the close of the first year's training record that the answering of the questions set on the first book of Euclid was disappointing. The students appear to have learnt their propositions by rote, and to have displayed great want of neatness and accuracy. Though the riders were joined to the propositions on which their solution depended, and though all these riders were easy, very few of the papers were satisfactory. This inability to solve the easiest geometrical deductions is commented on again and again, and proves beyond doubt that either the students are negligently taught, or that they commit the book-work to memory without understanding it, and consequently are quite incapable of applying their knowledge to solve the simplest riders. The report for the second year is rather better; few candidates answered very well, and few answered badly, and the majority made a fair percentage of marks; but the same inability to apply their knowledge to the solution of easy deductions in Euclid is recorded. With regard to the answering in algebra and mensuration, there is nothing noticeable except that some students show a discreditable ignorance of the most fundamental questions, while the papers were generally satisfactory.

Summing up the results of the working of our male Training Colleges, Mr. Oakeley gives it as his opinion that the students are over-lectured at some of the colleges, and that the lectures are mechanically reproduced, and transferred as closely as possible to the examination papers. This, of course, is due to the defective early training of the students, and to lectures injudiciously delivered on subjects about which students know absolutely nothing. For instance, one lecturer delivered a very excellent discourse on the corrupt form of Latin used by the Roman soldiers in Britain, its causes and its effects, to a class of which few, if any, of the members knew anything whatever of Latin. Mr. Oakeley also points out one of the greatest defects in the present system of training pupil-teachers when he says that as a rule pupil-teachers see but one school at work; they have no opportunity of comparing the mode of teaching in other schools. This is, however, obviated at Homerton, and partly at Durham, by visiting neighbouring schools during school-hours.

The reports of the examiners on the progress made by the students of the female Training Colleges tell us that in arithmetic, questions on theory and principles are not well done; long problems are inaccurately done, and, as a whole, it is seen that there is yet much remains before it can be said that our present system is satisfactory as regards the knowledge given and the methods adopted. There appears to be among the students a very narrow view of their future work, a desire to regard the obtaining of their certificates as the goal and aim of their existence. The views on science of one of these maidens is worth recording:—"If I am successful in obtaining my certificate, I intend (D.V.) going in for two sciences. At the same time I propose attending a tonic sol-fa class to get my advanced certificate. Should the two sciences 'sound, light, and heat,' and 'electricity and magnetism' prove a success, I shall probably take up the science of hygiene." If the Training Colleges tend to remove the impression that the technical qualification is the end of the pupil-teacher's work, if they awaken a spirit of emulation among the students, aud enable them to teach more thoroughly and intelligently, then they will have fulfilled a large portion of their duties.

This being the stuff of which our elementary teachers are made, let us now glance at the reports of the work done in the schools under their guidance. With masters the majority of whom know little or nothing of even the elements of science the pupils cannot be expected to pass well in these subjects. Thus it is seen in the return of the number of pupils sent up on "specific subjects" (most of which are scientific), that only 16·51 of those eligible for examination have been so examined, and of these nearly one-half were from the London School Board District. One-half of the passes were in algebra and animal physiology. By a new arrangement the ten chief inspectors present biennial reports, five each year, and in the present volume the five divisions reported on are: the North-Eastern, the North Central, the Eastern, the South-Western, and Wales. All these agree that, with the exception of some of the cities and large towns, throughout the elementary schools science is untaught. This we can well imagine, when we have seen that the average teacher is completely ignorant of any of its branches, and it is the average teacher who is sent to the country schools. The explanation of some of the inspectors, that in the country for a great portion of the year the attendance of the children who are fit to be taught these subjects is very irregular, does not meet the question; for, even were the children most regular in their attendance, the subjects could not at present be taught, and until our average elementary teacher is altered they will not be taught. Following the individual reports on the subject, we find in the North-Eastern Division that arithmetic is accurately but unintelligently studied. So utterly mechanical is the teaching that in many schools mental arithmetic is regarded as a separate subject, and not as the adjunct and preliminary of all arithmetic. Having seen the complaints made by the examiners of the quality of the study of the pupil-teachers, it could only be expected that the same defects would show themselves in the scholars under their charge. Elementary science is unknown in the North-Eastern schools, except in Leeds, Sheffield, Bradford, Newcastle, and Sunderland, where algebra and animal physiology are taken up with fair results. But the inspector remarks that physiology is seldom so taught as to be of any practical benefit, and in the teaching of algebra there is a great want of thoroughness. In the North-Central Division, specific subjects are seldom taken; and about one-half the pupils sent up for examination on them passed. These subjects, taking them in the order of the number of pupils sent up on each, are algebra, magnetism and electricity, physiology, agriculture, and mechanics. In this division "arithmetic is always the most unsatisfactory

subject we have to deal with." The teaching of it is dull and mechanical, and the rules are rarely intelligently applied. In this large district there is one bright spot, which shows what can be done by ordinary industry and skill. It is the town of Nottingham, in which 2526 children were examined in specific subjects, of whom four-fifths passed. "Mechanics for boys and domestic economy for girls, are the subjects principally taken by the Nottingham Board Schools, and are taught by a specially qualified science demonstrator and assistant, who visit the various schools in turns, bringing the apparatus with them in a specially constructed hand-cart. The lectures given on these occasions are afterwards gone through again by the teachers of the schools, from notes taken at the time. These lectures are simple and interesting, and are given with great care and skill; the results are remarkably good, both as regards the actual knowledge acquired by the scholars and the stimulus given to the general intelligence. Besides the above-named subjects, physiology and algebra are often taken with very good results, and in one school the principles of agriculture are taught with marked success." This extract from Mr. Blandford's report shows that the neglect of elementary science is due, not to the dullness or irregularity of the pupils, as some of the inspectors would seem to imply, but frequently to the ignorance and incapacity of the teachers. In the Eastern Division specific subjects are rarely taken, but in the Norwich district mechanics, chemistry, and botany have been taught satisfactorily in one or more schools, and "are distinctly a gain to the boys." On the whole, however, this division is rather at a standstill. The quality of the education given has not risen as one would expect, and with regard to scientific and technical education, in the words of Mr. Synge, "there is plenty of room and need for progress in the immediate future, but at the present moment too little sign of its beginning." In the South-Western Division "elementary science has hardly any existence." In fact, except in some of the large towns, it is practically non-existent, and in the whole division, there were only about 600 children presented on specific subjects. In Wales, except in a few higher-grade schools, the teaching of science is unknown.

Some of the causes of this almost total absence of any scientific teaching in our elementary schools have been pointed out. Where science has been well taught it has borne good fruit, and where teachers and managers have set themselves steadfastly to overcome the difficulties in their way a high and encouraging measure of success has been obtained. Thus we have the remarkable testimony of the success of the experiment in Nottingham, and surely there are many other districts in England quite as competent to carry on this work as Nottingham. Why it could not be done in any town in England, it is difficult to see. In many cases where these subjects have been taught, the inspectors have wisely set their faces against them, finding but a wretched smattering amongst the pupils. Nothing else can be expected in remote rural districts, where the teacher, whose whole time is scarcely sufficient for the few rudimentary subjects, is so ambitious as to attempt to cram some of his pupils with the elementary knowledge of a science of which he is himself confessedly ignorant. But in our towns and cities competent teachers are always to be had. If the Board masters do not find themselves fit for the extra labour and extra knowledge required, there should be no difficulty in obtaining a specialist, as has been done at Nottingham. And in no place could the foundations of technical education be more surely laid than amongst the elder children of our elementary schools. In the Minutes and Instructions issued to Her Majesty's Inspectors, managers are requested to aid in every way they can the teaching of one or more specific subjects appropriate to the industrial or other needs of the locality, and the rudiments of two higher subjects to supply a foundation for future work. With this object it is suggested that where the teacher is not competent to do so—and this, according to the reports, is the rule, and not the exception—a specialist might be employed by a number of schools in a district, whose instruction would be supplemented by that of the ordinary teachers. There is only one instance, that of Nottingham, given in the reports of such suggestions having been followed.

Geography.—Where there is "a great absence of culture and general intelligence upon the part of a considerable number of the candidates," it is not surprising to find that, though the answers to the geography papers for admission to the male training colleges were fairly accurate, they were not intelligent. Here, again, the metropolitan candidates are superior to the provincial candidates, particularly in the map-drawing, though, in this particular, there has been a falling away of late. Amongst the female candidates, the geography was not very satisfactory, exhibiting inaccuracies in map-drawing, indefiniteness in the answers, and, generally, marks of defective early training. In the examinations for the first year's certificates the male candidates answered fully and accurately; but usually there was a slavish following of the words of the text-books and the lecturers' notes. At the end of the second year, there is the same report, book-knowledge without intelligence, and abundance of information imperfectly digested. With the females, the result is the same: verbatim reproduction of the books or notes they had read; fairly creditable answering; but "the style of the papers reveals the painful poverty of the general reading of the students, and the utter absence of any individuality, or attempt at description in their own words." In many papers there was a constant iteration of the same words and phrases, suggesting that the candidates had learned off by rote the answers to probable questions. With regard to the elementary schools, all the reports agree in saying that there has been a marked improvement in the teaching of geography. Where it is intelligently taught it is the favourite subject; but too frequently the children are not well grounded. While all divisions report progress in this subject, it is worthy of remark that all the maritime districts, and particularly those of the South-Western Division, including the counties of Hampshire, Dorset, Devon, Cornwall, and Somerset, surpass the inland schools in the knowledge of our country, its colonies, and its trade. And this is only natural. The teacher who would not, in Devonshire, interest a class of boys in the voyages of Drake, or who, in Somerset, would not rivet the attention of his pupils on the victories of Blake, would not be worthy of his post. Though the teachers may be congratulated, speaking generally, on the progress made in geography, there are many faults to be found. In portions of Wales and of the centre of England, geography is only fairly satisfactory. The pupils are weak in questions of latitude and longitude; they do not learn intelligently; because, most probably, they are taught mechanically and unintelligently. It should be within the power of every teacher by the use of an ordinary globe to make this portion of the subject intelligible to any ordinary boy; but few lads could understand a lesson on meridians and parallels, given by a teacher who does not use a globe at all. And yet this is quite common! Hence it is that the map-drawing is very poor, even where there is a good knowledge of geographical facts. Many of the inspectors complain of lack of globes, maps, &c.; and even where there is abundance of general maps, there are no local maps, a want which is very widely felt. In this respect our Board of Education might take a lesson from the Commissioners of National Education in Ireland, who have published local maps, and require each pupil in the higher grades to know, in addition to general geography, the map of his neighbourhood.

NOTES.

LAST week we printed an article advocating the claims of M. Giard to the new Chair of Darwinism in Paris. We are now informed that the appointment will certainly be offered to M. Giard, and that, if he declines it, it will be offered to Prof. Perrier, of the Paris Museum of Natural History. It is generally desired that the Chair should be connected with the Faculty of Sciences in the Sorbonne. M. Liard, the Director of Superior Instruction, in the Department of Public Instruction, is favourable to the whole scheme, and hopes are expressed that the lectures may be begun in the course of two or three months.

MR. G. J. ROMANES has been elected Fullerian Professor of Physiology at the Royal Institution. He intends to devote all the three years of his professorship to one continuous course of lectures on "Before and after Darwin." This year's course—"Before Darwin"—will be an historical survey of the progress of scientific thought and discovery in biology from the earliest times till the publication of "The Origin of Species." Next year's course will be "On the Evidence of Organic Evolution," and the third year's "On the Factors of Organic Evolution."

ON Saturday, the 21st inst., at three o'clock, Lord Rayleigh will deliver, at the Royal Institution, the first of a course of seven lectures on Experimental Optics. The remaining lectures of the course will be given at the same hour on the following Saturdays.

THE annual general meeting of the Anthropological Institute of Great Britain and Ireland will take place on Tuesday, the 24th inst., at 8 o'clock p.m. precisely, Mr. Francis Galton, F.R.S., President, in the chair. The following will be the order of business:—Confirmation of the minutes; appointment of scrutineers of the ballot; Treasurer's financial statement; report of Council for 1887; the Presidential Address; report of scrutineers; and election of Council for 1888.

DR. H. LLOYD SNAPE has been elected to fill the Chair of Chemistry at University College, Aberystwith, rendered vacant by the death of Prof. Humpidge. The new Professor acted for three sessions as Demonstrator of Chemistry at University College, Liverpool. Afterwards he studied at the Universities of Berlin and Göttingen under the direction of Profs. Hofmann and V. Meyer respectively. On his return to England he was appointed Director of the Department of Pure and Applied Chemistry in the Manchester Technical School.

WE regret to announce the death of Mr. Hayden, the well-known American geologist. He died on December 22 last.

MR. ANDREW GARRETT, an eminent American conchologist, died at his residence on the island of Huahine, Society Group, South Seas, on November 1 last, in his sixty-fifth year.

THE Meteorological Council has recently published Part III. of the Daily Synchronous Weather Charts of the North Atlantic and the adjacent continents. Parts I. and II. were respectively noticed in NATURE, vol. xxxv. p. 469, and vol. xxxvi. p. 178. The part just issued, dealing with the period from February 15 to May 24, 1883, comprises the weather for the end of the winter and the early spring. The charts show clearly how very different are the conditions which exist over the Atlantic in the winter from those which exist in the spring. The early charts contain numerous instances of storms, and the barometrical disturbances which accompany them embrace a large part of the North Atlantic Ocean. An interesting case of storm development is shown over the American Lakes on February 19. The disturbance subsequently traversed the Atlantic, and passed about 800 miles to the north of Scotland on the 24th, causing a moderate gale in the north of our islands, and gales generally over the north-west of Europe. There is another instance of rapid storm development off Florida on April 2, the disturbance growing into a severe hurricane when south of Newfoundland on the 4th. A storm-area was formed off the north-west coast of Africa on February 20. This seems to have originated in an intensifying of the northerly wind on the eastern side of the Atlantic anticyclone. On the 22nd the storm was fully developed, and the cyclonic circulation was complete, the barometer registering as low as 29·6 inches. This disturbance travelled to the westward as far as the middle of the Atlantic. On the 25th it was clearly dying out, but on the 26th it apparently gained fresh life, and on February 28 and March 1 it was causing a gale close to the American coast, and to the south of Newfoundland and Nova Scotia. It afterwards travelled eastwards, skirting to the north-west of Iceland on March 3, and finally struck the north-west coast of Norway on the 4th. There is also a case of a double-headed depression travelling to the eastward across the Atlantic between March 25 and 31. These charts show very clearly the explanation of the cold northerly and north-easterly winds experienced over England during the spring, the isobaric lines indicating a general extension of the Atlantic high pressure over our islands at this season.

AT the meeting of the French Meteorological Society on the 6th ult. a paper by M. André, Director of the Lyons Observatory, on the influence of altitude on temperature, was read. The observations were made in the environs of Lyons in the years 1881-84. The mean diurnal range was 18°·5 F. at the lowest station (574 feet), and 12°·3 at the highest station (2050 feet). M. Poincaré submitted a table showing the relation between the barometric movements at lat. 40° and 10° N., and the phases of the moon. M. Renon made a communication on the observation of fog. He considered the present method of observation to be defective, as the observer could only note what exists around him; a knowledge of the conditions at a considerable height above him was necessary, to arrive at satisfactory conclusions. This desideratum was also urged by M. Janssen.

ON January 3, snow fell in Christiania from a perfectly clear sky. After a strong southerly wind with cloudy weather in the morning the weather cleared, but at about noon it again thickened, and snow and sleet fell. In the afternoon the sky again became clear and continued thus, with a storm blowing from the west. Just before 8 p.m., however, thick clouds again gathered, the full moon became obscured, and snow began to fall heavily. A quarter of an hour later the wind swept the clouds away, and the sky became completely clear, with the exception of a few clouds in the east. The stars shone brightly, and the full moon illuminated the landscape; still snow continued to fall thickly for some ten minutes. That the snow could not have originated with the clouds in the east is proved by the circumstance that the wind was westerly. A well-known meteorologist ascribes the phenomenon to the presence at a certain elevation in the atmosphere of a very cold layer of air in which the ascending, comparatively warmer, air became condensed, the moisture being thrown out in the form of snow, but not in sufficient quantities to obscure the blue sky, the stars, and the moon. The great chilling of the layer of air referred to may have been caused by the coldness of the heavy snow clouds which a few minutes previously filled the atmosphere.

ON December 24, at 9.45 p.m., a brilliant meteor was observed in the north-western sky at Örebro, in Central Sweden. The light, variegated in colour, was very intense. The meteor seemed to fall perpendicularly to the earth with a slow motion, and dissolved itself without any report. On December 25, at about 5 p.m., another meteor, shining with an intense bluish-

white light, was seen going in a north-westerly direction at Karlskogo, also in Central Sweden.

ANOTHER important paper upon the synthesis of glucose is communicated by Drs. Emil Fischer and Tafel to the current number of the *Berichte*. They have succeeded in artificially preparing glucose directly from glycerine. It will be remembered that this synthesis was first effected by decomposition of acroleïn dibromide, CH_2Br . $CHBr$. CHO, with baryta water; glycerine aldehyde, CH_2OH . $CHOH$. CHO, being probably first formed, and afterwards polymerizing into glucose. Hence it might be expected that the same result could be achieved by direct oxidation of glycerine to aldehyde and subsequent condensation by means of alkalies. This supposition has been completely confirmed by experiment, and the new method is at once an easier and a cheaper one. A large quantity of glycerine was first oxidized by means of soda and bromine, the temperature being kept down to 10°. The bromine readily dissolved on shaking, and the evolution of carbonic acid gas soon rendered evident the progress of the change. After half an hour the reaction was found to be complete; the liquid was then acidified with hydrochloric acid and a current of sulphur dioxide passed through it until all the bromine was reduced. The liquid, after neutralization with soda, was found to contain a large quantity of glycerine aldehyde. About 1 per cent. more soda was then added, and the solution allowed to stand at a temperature of about 0° for four or five days. As the polymerization proceeded, the liquid gradually lost the power of reducing alkaline copper solutions in the cold, but, like sugar, rapidly reduced them on warming. In order to isolate the sugar thus formed, the phenylhydrazine compound was prepared, as in the former experiments, by neutralizing with acetic acid and adding phenylhydrazine and sodium acetate, heating six hours upon a water-bath. After some time crystals of the phenylhydrazine compound, $C_{18}H_{22}N_4O_4$, were deposited, and after purification were found to possess all the properties of the compound obtained from acroleïn dibromide; in fact, they were identical with it. This compound crystallizes in beautiful yellow needles, melting at 217°; on heating it with zinc dust and acetic acid, a base is obtained which, by the action of nitrous acid and subsequent neutralization with soda, yields, on evaporation, syrupy glucose itself. Not only does this later work of Drs. Fischer and Tafel confirm their former striking results, but it leaves the subject in a much more complete state, and furnishes chemists with a far readier method of preparing artificial glucose in the laboratory.

THE habits of a running spider of Southern Europe, *Tarantula narbonensis*, Latr., studied by Herr Beck, are curious. It makes a vertical round hole in the ground about 10 inches deep, and this, with a small earth-wall sometimes made round the mouth, is lined with web. A little way down is a small lateral hole, into which the spider shrinks when an animal falls into the tube; when the animal has reached the bottom the spider pounces on it. One can readily tell that a tube is tenanted, by the bright phosphorescent eyes of the spider turned upwards. In fight the spider erects itself on its last pair of legs, striking with the others. The bite is not fatal to man, but it causes large swellings. The children in Bucharest angle for these spiders by means of an egg-like ball of kneaded yellow wax tied to a thread. This is lowered with jerks into the hole, and the spider fastens on it and can be pulled out; whereupon another thread is passed round one of the legs, and the animal is played with.

LEMMINGS are very numerous in several valleys in Southern Norway this winter. In many places the snow is furrowed for miles by the march of these little animals on their migration southwards.

IN November last a Runic stone was found at Häggerstalund, in Sweden. A lady happened to notice a long stone in the proximity of a well-known Runic boulder, and having had it turned found that there was an inscription on the other side, which has been interpreted thus:—"Gårdar and Jorund raised these stones after (in memory of) their sister's sons, Ernmund and Ingemund." The newly-discovered stone is of importance, as it supplements the Runic inscription of the other stone, viz.:—"These memorial stones are made after (in memory of) the sons of Inga. She took heirloom after them, but these brothers (referred to on the other stone) will take heirloom after her. Gjad's (?) brothers; they died in Greece." The latter stone is made particularly interesting by the reference to the death of the two men in Greece.

WHILST digging for potatoes late last autumn on the Island of Fredöen, on the west coast of Norway, a man unearthed a flat gold armlet with Runic inscriptions, and bearing on the inside the year 875. On the outside is a large bright stone, but of what kind has not yet been ascertained. This island is rich in historical traditions from the Viking era.

IN a late issue of the *Izvestia* of the Russian Geographical Society M. Krasnoff makes some interesting remarks on the antiquities of Turkistan. He points out that in the stone inscriptions he has seen in the Tian-Shan the men are always represented on horseback, armed with bows, arrows, long pikes with flags, and curved swords. Their dress is like the present *khalat* of the Mongolians and the Turks. The scenes represented mostly relate to hunting, and the men are surrounded by stags, *arkhars* (wild sheep), foxes, tigers, wild boars, and some very big animal with a thick hairy tail, and with tusks like those of the mammoth. In the gorge of the Uzun-su, M. Krasnoff saw the drawing of a camel. There are no inscriptions proper by the side of these drawings; but plenty of wild sheep, like the *tau-tek* of our days, are represented in files along mountain-paths. These drawings are very rapidly obliterated, and will soon disappear. They ought to be reproduced by archæologists.

THE second number of the "Bibliographies of Indian Languages," by James C. Pilling, has just been issued by the U.S. Bureau of Ethnology. It treats of the Siouan stock.

A USEFUL Catalogue of British Mollusca, published by Mr. H. W. Marsden, of Gloucester, has been sent to us. The Catalogue has been compiled by Mr. Charles Jeffreys, from Jeffreys' "British Conchology," with alterations and additions to date.

THE Royal Botanic Garden of Calcutta has just completed the first hundred years of its existence, having been established in the year 1787. The *Times of India*, in reviewing the history of the Garden, points out the many advantages which it has conferred on India. It has practically established and has done wonders to promote the now flourishing tea industry of India. The directors were the first to introduce potato-growing in that country, and they imported the quinine-yielding cinchonas from South America, and thus took the first step towards the establishment of what is now one of the most successful Indian industries. Besides these great successes, India owes to that establishment, the *Times of India* thinks, almost all the efforts that have been made to improve the quality of Indian cotton, and to push its sale in the European markets. The best sugar-cane has been brought from the West Indian Islands, and has been planted in all parts of the country; and flax, hemp, tobacco, henbane, vanilla, coffee, cocoa, ipecacuanha, india-rubber, tapioca, and many other products have been systematically experimented on in the Garden. Nor has horticulture been neglected by the superintendents, for the presence in India

of a large portion of its exotic plants is due to them; and the improved systems of cultivation are in a great measure attributable to their efforts.

THE French Government has commissioned Count Horace de Choiseul, a member of the Chamber of Deputies, to proceed on a voyage of botanical research to Asia and the United States. He will visit the Botanical Gardens at Ceylon, Calcutta, Shanghai, Japan, San Francisco, &c., to collect botanical specimens not indigenous to France.

THE Royal Physical Society, of Edinburgh, seems to be doing much good work. At the second meeting for the present session, Sir William Turner in the chair, Mr. Hoyle read a note discussing the function of the Laurer-Stieda canal in the Trematoda; Mr. J. Arthur Thomson submitted an elaborate paper entitled "A Synthetic Survey of the Influence of the Environment upon the Organism"; the Secretary, Dr. Traquair, communicated a paper on an ornithological visit to the Ascrib Islands, by Mr. John Swinburne; and Mr. Brook gave some valuable notes on the marine Crustacea of the Clyde Estuary.

CAPT. WIGGINS, who successfully performed the sea voyage from Europe to Siberia last autumn in the steamer *Phœnix*, is shortly expected back in this country. He states that at the time of his leaving Yeniseisk, in Siberia, in October, the cold varied from 70° to 80° below zero, and that the mercury was frozen in the bulb.

AT the annual meeting and distribution of prizes at the School of Science and Art at Bromley, Kent, on Tuesday, Sir John Lubbock delivered an interesting address on technical education. He referred to a recent statement of Mr. S. Smith, one of the Commissioners on Technical Education, to the effect that it was not so much the longer hours and lower wages of Continental workmen, nor the tariffs, which were having such objectionable influence on our industries, but rather, in nearly all instances, the great attractiveness of the goods themselves, which had been made by workmen who had received special training in schools. Sir John Lubbock went on to say that if we had spent one tithe of the treasure which we sent abroad every year to buy the produce of the skill of other countries on the training of our own people, we should have been making these goods ourselves and shipping them to the East and West and to every country under the sun. We were constantly crying out for new markets, while there was a new market in every house in the country. We were apt, indeed, to forget how much we owed to science, because many things which were in reality scientific discoveries had become so familiar to us that we looked upon them almost as a matter of course. The electric light was still felt to be a triumph of science, but we forgot sometimes that the common candle was the result of a whole series of chemical discoveries. The Chinese were said to have examined candidates for the army until lately in the use of bows and arrows. We saw the absurdity of this; but we were not free from the same error ourselves.

IN a recent Consular Report there is a complete description of the Technical University of Belgium, which was founded in 1852, as well as a general sketch of the system of commercial and technical training prevailing in that country. Formerly the education in Belgian public schools (*Athénées*) was in the main classical, but in recent years a *section professionelle* (commercial and scientific) has been added, and now takes its place as an integral portion of the public-school system. Here youths intended for commercial pursuits, from the fourth class upwards, receive special instruction, and then pass on to the *Institut*, or University, where the course lasts two years. The number of pupils is 150, a number which would be largely increased, but for the difficult entrance examination, the inability of many parents to keep their children so long at school, and the prevailing idea that a youth intended for commerce cannot enter a counting-house too soon. The course at the *Institut* includes, besides languages, book-keeping, and the ordinary practical work of a merchant's office, a technical description of the ordinary articles of commerce, political economy and statistics, commercial and industrial geography, maritime and Customs' legislation, and the building and fitting out of ships. The fees range from £11 for the second year at the *Institut*, to £3 5*s*. per annum at the public schools. An extensive commercial museum, a chemical laboratory, and a commercial library are attached to the *Institut*. At the end of the course diplomas are given to the successful candidates, entitling them to the degree of *Licencié en Sciences Commerciales*. The rules, and a programme and syllabus of the lectures, are appended to the Report. The new language, *Volapük*, has been added as an experiment, mainly, it would appear, because of its possible utility for telegraphic communication.

THE additions to the Zoological Society's Gardens during the past week include a Mexican Deer (*Cariacus mexicanus* ♀) from the Island of Dominica, presented by Mr. George Anderson; a Water Rail (*Rallus aquaticus*), British, presented by Mr. G. J. Payne; two Black-headed Gulls (*Larus ridibundus*), British, presented by Mr. Thomas A. Cotton; two Common Peafowls (*Pavo cristatus* ♀ ♀) from India, presented by Mr. Richard Hunter; sixty-six Skylarks (*Alauda arvensis*), British, purchased; an Egyptian Vulture (*Neophron percnopterus*) from North Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE MAURITIUS OBSERVATORY.—The report of the Director of the Royal Alfred Observatory, Mauritius, for 1886, shows that the activity of the institution continues to be exhibited in two directions, viz. meteorological and magnetic observations, and the photographic record of the state of the solar surface. The meteorological observations have been extended during the year by the addition to the daily routine, of observations of the duration of bright sunshine, commenced October 1, of maximum and minimum dry and wet bulb thermometers in screens, begun November 1, and of an earth thermometer at 10 feet below the surface of the ground, begun the same day, the necessary instruments having been received from England. The year 1886 was a particularly dry one, the rainfall being below the average in every month, and the annual fall the smallest on record. No hurricane visited the colony; indeed, the last took place so long ago as March 21, 1879; but several cyclones occurred in the Indian Ocean, some of which passed near the island, and storm warnings were issued. Dr. Meldrum gives considerable importance in his report to the connection between the meteorology of the island and its health. It appears that wet years give specially high fever and death rates, the greatest mortality usually following the maximum rainfall by about two months. At the same time there has been a persistent increase in the death rate of late years, which appears to be independent of meteorlogical causes.

The photoheliograph was in constant operation, 533 photographs having been obtained on 353 days, but the sunspots were much fewer and smaller than in 1884 and 1885. Two photographs were also obtained of the solar eclipse of August 29, which commenced at Mauritius a little before sunset.

OCCULTATIONS OF STARS BY PLANETS.—The following lis of possible occultations of stars by planets is in continuation of that given in NATURE, vol. xxxvii. p. 234:—

GEOGRAPHICAL NOTES.

DR. MEYER has been giving an account of his ascent of Kilimanjaro to the Berlin Geographical Society, and from the brief abstract which has appeared his statements are not quite consistent with those made in his letter already referred to. For one thing, Alpinists are doubtful if Dr. Meyer got so close to the summit by a thousand feet as he himself thinks he did; and moreover, from his own statements, his aneroid was quite untrustworthy.

A SPECIAL meeting of the Paris Geographical Society was held on Saturday, to welcome MM. Bonvalot, Capus, and Pepin, who have been journeying in Central Asia. We have already on several occasions referred to this journey, during which the travellers crossed the Pamir, but not for the first time, as they themselves seem to believe. So far it would appear as if the original results of this expedition were of no great value.

THE paper at Monday's meeting of the Royal Geographical Society was by a young engineer, Mr. W. J. Steains, on an exploration of the Rio Dôce and its northern tributaries (Brazil). The Rio Dôce has been in past years a classical region for research in natural history, but for many years it has been neglected. It flows through a region that has scarcely been touched by the influences of civilization, a region which is the home of the Botocudos, one of the most primitive people on the face of the earth. The Rio Dôce lies between parallels 19°–21° S. latitude, and is formed by several small streams springing from the eastern slope of an important range of mountains known by the name of the Serra da Mantiqueira. This range, running in a north-easterly direction, forms a portion of the irregular "coast-range" of Brazil, and forms, so to speak, the "retaining wall" of the series of elevated, undulating tablelands composing the greater portion of Central and Southern Brazil. The total length of the Rio Dôce is a little over 450 miles. That portion of the Rio Dôce basin lying east of the Serra dos Aymôres is a densely wooded lowland, sloping gradually towards the coast from an elevation of about 900 feet. Near the coast this plain resolves itself into a long stretch of low alluvial ground, studded for the most part with small shallow lakes that communicate with each other by means of long, narrow, winding streams, called "vallões." The largest of these lakes is the Lagôa Juparaná, which communicates with the Dôce some 30 miles above its mouth by means of a narrow, tortuous, deep channel 7 miles long. The lake is 18 miles long, and about 2½ miles broad at its southern extremity. It is very deep, and with the exception of some low alluvial ground at its northern and southern ends, is surrounded by high wooded bluffs, composed for the most part of reddish clay overlying a stratum of coarse red sandstone. At the head of the lake is a river—the S. José, which rises in the Serra dos Aymôres, and flows through an unexplored district, inhabited by wandering hordes of wild Botocudo Indians. Throughout the whole of its course, the S. José flows through dense forest abounding in the much sought-after "Jacarandá," or rosewood tree (*Bignonia cærulea*, Will.) The Botocudos number about 7000 people, and among some of the more savage tribes cannibalism still prevails. Mr. Steains stayed several weeks among these people, and is therefore able to add something to our knowledge of them. In appearance Mr. Steains states, the Botocudos can scarcely be called prepossessing. The average height is 5 feet 4 inches. Their chests are very broad, and this accounts for the facility with which they can bend their bows, which are exceedingly strong, being made out of the tough springy wood of the Ayri or Brijaubá palm (*Astrocaryum Ayri*, Mart.). The feet and hands of the Botocudos are small rather than delicate, and these are in fair proportion to their legs and arms, which are lean but muscular. Concerning the colour of their skin, these Indians are of all shades, some being of a dark reddish-brown, whilst others, and especially the women, are quite light. With regard to features, the Botocudos struck Mr. Steains, as they have done

others, as bearing a wonderful resemblance to the Chinese, and if, instead of wearing their hair cut round their heads so as to form a kind of mop, they wore pigtails, the casual observer would scarcely be able to tell where the difference lay. The hideous custom for which the Botocudos have always been so famous, viz. that of wearing huge lip- and ear-ornaments of wood, is fast dying out, and at the present time is only to be met with among some of the older members of the tribes, who retain all the habits and manners of their primitive forefathers intact.

THE January number of *Petermann's Mitteilungen* contains a paper by Count Pfeil, describing his journey last summer in East Africa, from Pangani along the Pangani River, south through Useguha to the Kingani River, and north to Bagamoyo. Dr. Henry Lange briefly describes the region watered by the Rio Tubarao and Rio Ararangua in Brazil. Dr. H. Fritsche contributes a series of astronomico-geographical and magnetic observations at thirty-one places in North-West Russia and North Germany in 1885–6–7, and Mr. S. Brooke gives a short acount of an excursion he made into the West Australian desert, starting from Israelite Bay on the south coast.

IN the January number of the *Scottish Geographical Magazine*, Mr. John Murray publishes the final results of his long research on the height of the land and the depth of the ocean. The paper consists mainly of a series of elaborate measurements giving the detailed data on which he founds his general conclusions. The conclusions to which Mr. Murray comes are of great interest, but they are too important to be stated in a note. The mean height of the land of the globe he estimates at 2252 feet. He finds that 84 per cent. of the land of the globe lies between the sea-level and a height of 6000 feet. The mean depth of the ocean again is 14,640 feet. In contrast with the land, only 42 per cent. of the waters of the ocean lie between the surface and a depth of 6000 feet; while 56 per cent. of the ocean waters are situated between depths of 6000 and 18,000 feet. The total area of the dry land Mr. Murray makes to be 55,000,000 square miles, while that of the ocean is 137,200,000 square miles. The bulk of the dry land above the sea is 23,450,000 cubic miles, and the volume of the waters of the ocean 323,800,000 cubic miles. The amount of matter carried from the land each year in suspension and solution, he estimates at 3·7 cubic miles; it would thus take 6,340,000 years to transport the whole of the solid land down to the sea. Should the whole of the solid land be reduced to one level under the ocean, then the surface of the earth would be covered by an ocean with a uniform depth of about two miles. The volume of the whole sphere, Mr. Murray estimates at 259,850,117,778 cubic miles. With the data now published should be compared Mr. Murray's Aberdeen lecture (NATURE, vol. xxxii. p. 581).

IN the last number of the *Comptes rendus* of the Paris Geographical Society, M. Chaffaujon gives a detailed narrative of his recent journey up the Orinoco. The section of greatest interest is that which relates to the upper course of the river, which M. Chaffaujon found to be all wrong on existing maps. This he has traced with much care. He examined also with care the outlet of the Casiquiare, by which the river is connected with the Rio Negro and the Amazons. He finds the bank of the river here to be mostly gravel, and in the rainy season the river coming down from the mountains with considerable force impinges against the bank, and forces a passage out. He states that the place of outlet seems to be shifting downwards every year.

THE TOTAL ECLIPSE OF THE MOON, JANUARY 28.

A TOTAL eclipse of the Moon offers some special advantages for the exact determination of the diameter and distance of our satellite. Observations of the bright limbs are exposed to considerable errors from the effect of irradiation, and liable to be affected by personal habit in the observer. The method of occultations has, under ordinary circumstances, proved scarcely more successful, owing chiefly to the fact that immersion and emersion so seldom take place under similar conditions. But in a total eclipse of the Moon, the disappearances and reappearances occur at limbs under similar illumination, and since the diminution of the Moon's light allows much fainter stars to be seen close to the Moon than can usually be observed, a much greater number of observations can be made than under ordinary conditions, and the effects of local irregularities of the Moon's circumference can be eliminated by observations made at a great number of points. If, then, as many Observatories as possible would combine to observe the occultations of the small stars passed over by the Moon during its eclipse, the labours of a few hours would give materials for a better determination of its diameter and parallax than could otherwise be obtained from the observations of many years. In view of these advantages, and noting too how hitherto they had been neglected by astronomers, Dr. Döllen, of Pulkowa, published a paper in the *Astronomische Nachrichten*, No. 2615, previous to the eclipse of October 4, 1884, in which he gave a catalogue of 116 stars which would be occulted during that eclipse, and begged for the co-operation of as many observers as possible. Unfortunately, the weather in many places was very unfavourable, and even where the sky was clear an unforeseen hindrance to observation was experienced in the unusual faintness of the eclipsed Moon. The part of the sky, too, through which it was passing was bare of stars above the 9th and 10th magnitudes. Still the results were sufficiently successful to encourage Prof. Struve and Dr. Döllen to repeat the attempt, especially as under several aspects the approaching eclipse of January 28 presents more favourable conditions than that of October 4, 1884: the magnitude of the eclipse will be somewhat larger, and the duration of the total phase a few minutes longer. Accordingly, Dr. Döllen has drawn up a catalogue of 300 stars which will be occulted, whilst Prof. Struve has computed by a graphical method the times of disappearance and reappearance, and the position-angles of the occulted stars, for 120 Observatories, which he has invited to cooperate with him in the work of observation. The experience gained during the 1884 eclipse has led Dr. Döllen to include only those stars occulted during the total phase or immediately before and after, but he has thought it well to give stars down to the 11th magnitude.

Of the 300 stars given in Dr. Döllen's catalogue, the majority of course will not be seen to be occulted from any part of this country. The following, however, may be observed here:—

The positions given are the apparent positions for January 28, 1888, and are expressed for R.A., as well as declination, in degrees, minutes of a degree, and hundredths of a minute.

The following are the times of disappearance and reappearance as furnished by Prof. Struve for the stars which will be occulted

by the Moon at Greenwich. The angles are counted from the true North through the true East as in observations of double stars, &c. :—

Disappearances.

Star's No.	Angle. °	G.M.T. h. m.
148	74	10 23·1
152	107	25·8

201	330	19·4

The following table gives the magnitude of the occulted stars :—

Star's No.	Mag.	Star's No.	Mag.	Star's No.	Mag.	Star's No.	Mag.
100	9·5	150	10	181	10	219	10
108	9·3	153	10	197	10	221	10
126	9·5	157	9·4	198	9·5	225	10
128	9·5	164	8·0	201	8·7	226	10
136	9·5	165	9·4	209	10	236	9·5
142	10	166	9·5	210	9·5	247	9·2
148	10	180	9·5	216	10		

The remaining stars are all of the eleventh magnitude.

It would be advisable for intending observers to make a rough map of the stars they are to observe, and to acquaint themselves as completely as they are able with their configuration. The observations should be rehearsed as far as possible on previous evenings, that the necessary quickness in changing from one point of the Moon's limb to another may be acquired, and a fair acquaintance made with the sequence of the settings. It will be well probably, to somewhat reduce the list of stars for observation ; since some of the phenomena follow each other so closely that some must be lost, and if the work of selection is left for the actual time of observation probably more stars will be lost than necessity demands, and a risk of confusion and mistake will be incurred. The suggestion has also been made that the eye-piece to be employed should not be placed as usual in the centre of the field, but be made to revolve round it at the distance of the Moon's radius. The Moon would then be brought to the centre of the field, and kept there throughout the entire series of observations, and only the eye-piece would be moved. A fairly high power will probably be found the best for the work.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Among the lectures for the present term we note the following:—

Chemistry: Prof. Dewar, on Organic Chemistry; Mr. Pattison Muir (Caius), on Chemical Affinity; Mr. Heycock (King's), on Chemical Philosophy for Natural Sciences Tripos, Part I. ; Mr. Robinson, on Agricultural Chemistry.

Physics: Prof. Stokes, Physical Optics; Prof. J. J. Thomson, Properties of Matter; Mr. Shaw (Emmanuel), Thermodynamics and Radiation.

Geology: Prof. Hughes, Geology of a District to be visited at Easter; Mr. Marr, Principles of Geology.

Botany: Mr. Gardiner, Advanced Anatomy of Plants; Mr. Potter, Advanced Systematic Botany.

Zoology: Prof. Newton, Geographical Distribution of Vertebrates; Mr. Sedgwick, Morphology of Mollucsa and Echinodermata; Mr. Gordon, Morphology of Amniota, recent and extinct.

Physiology: Dr. Lea, Chemical Physiology; Mr. Langley, Advanced Histology and Physiology; Dr. Gaskell, Advanced Physiology of Vascular System.

Prof. Ray lectures on Pathology, and has practical classes; Prof. Latham on the Physiological Actions and Therapeutical Uses of Remedies; Dr. Anningson gives demonstrations in Practical Hygiene.

In Mathematics the following are among the lectures:—Prof. Cayley, Analytical Geometry; Mr. Forsyth, Modern Algebra, symbolical methods and ternary forms; Dr. Ferrers, Elliptic Functions; Dr. Besant, Integral Calculus, Definite Integrals, Mean Value and Probability, Calculus of Variations, and Differential Equations; Mr. Ball, History of Mathematics up to 1637; Mr. Mollison, Discontinuous Functions and Conduction of Heat; Mr. Whitehead, Grassmann's Ausdehnungslehre, with special reference to its applications.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 22, 1887.—"The Early Stages in the Development of *Antedon rosacea.*" By H. Bury, B.A., F.L.S., Scholar of Trinity College, Cambridge. Communicated by P. Herbert Carpenter, D.Sc., F.R.S., F.L.S.

In the orientation of the larva, J. Barrois' suggestion (*Comptes rendus*, November 9, 1886) has been adopted, viz. that the stalk of the Pentacrinoid represents the præoral lobe of other Echinoderms. Besides the right and left body-cavities, an anterior unpaired body-cavity is developed (distinct from the hydrocele), and opens to the exterior by the water-pore in the free-swimming larva.

A larval nervous system is developed, but is lost after fixation.

The vestibule of the fixed larva (Cystid) is formed by invagination, as described by Barrois (*Comptes rendus*, May 24, 1886).

The water-tube (stone canal), by opening into the anterior body-cavity (now very small), places the water-vascular ring in indirect communication with the exterior.

The anus opens in the same interradius as the water-pore.

In the skeleton, besides the parts already known, three underbasals are present, which are of great phylogenetic interest.

Geological Society, December 21, 1887.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On the correlation of some of the Eocene strata in the Tertiary basins of England, Belgium, and the north of France, by Prof. Joseph Prestwich, F.R.S. Although the relations of the several series have been for the most part established, there are still differences of opinion as to the exact relation of the Sable de Bracheux and of the Soissonnais to the English series; of the Oldhaven Beds to the Woolwich series; and of the London Clay and Lower and Upper Bagshots to equivalent strata in the Paris basin. The author referred to the usual classification of the Eocene series, and proceeded to deal with each group in ascending order. The Calcaire de Mons is not represented in England, but may be in France by the Strontianiferous marls of Meudon. It contains a rich molluscan fauna, including 300 species of Gasteropods, many of which are peculiar, but all the genera are Tertiary forms. The Heersian are beds of local occurrence, and the author sees no good reason for separating them from the Lower Landenian or Thanet Sands. He gave reasons for excluding the Sands of Bracheux from this group. Out

twenty-eight Pegwell Bay species, ten are common to the Lower Landenian, and five to the Bracheux Sands, which present a marked analogy with the Woolwich series. These Sands of Bracheux are replaced in the neighbourhood of Paris by red and mottled clays. Out of forty-five species at Beauvais, only six are common to the Thanet Sands, and ten to the Woolwich series. Out of seventy-five species in the Woolwich and Reading Beds, nineteen occur in the Bracheux Beds, if we add to these latter the sands of Chalon-sur-Vesles. Respecting the Basement Bed of the London Clay (Oldhaven Beds in part), the author would exclude the Sundridge and Charlton fossils, which should be placed on a level with the Upper Marine Beds of Woolwich. He allowed that the former were deposited on an eroded surface, but this involves no real unconformity, whilst the palæontological evidence is in favour of this view, since, out of fifty-seven species in the Sundridge and associated beds, only sixteen are common to the London Clay. He therefore objected to the quadruple division. Either the Oldhaven should go with the Woolwich or with the Basement Bed. He admitted that the term "Basement Bed" is objectionable, and preferred Mr. Whitaker's term for the series, as he would limit it. The Lower Bagshot Sands the author would call "London Sands," whose Belgian equivalent is the Upper Ypresian, and the French the Sands of Cuise-de la-Motte, forming the uppermost series of the Lower Eocene. A group of fossils has been discovered in the Upper Ypresian sands of Belgium, which leaves no doubt of their being of Lower Eocene age, and consequently the Lower Bagshots must be placed upon the same horizon. There is no separating line of erosion between the London Clay and the Lower Bagshots, the upper part of the former is sandy, and the lower part of the latter frequently argillaceous. Similarly no definite line can be drawn between the Upper and Lower Ypresian; but in both countries this series is separated from overlying beds by a well-marked line of erosion. So also in France the base of the Calcaire Grossier (Bracklesham Beds) is a pebbly greensand resting on an eroded surface of the Sands of the Cuise-de-la-Motte. In Belgium, in Whitecliff Bay, and in the Bagshot district the Upper Eocene rests upon an eroded surface of the Lower Eocene. The reading of this paper was followed by a discussion in which the President, Mr. Whitaker, Dr. Evans, Dr. Geikie, and others took part.—On the Cambrian and associated rocks in North-West Caernarvonshire, by Prof. J. F. Blake.

PARIS.

Academy of Sciences, January 9.—M. Janssen, President, in the chair.—Remarks on M. Cornu's last note regarding the synchronizing of time-pieces, by M. C. Wolf. The author points out that M. Cornu has misunderstood the language of the English physicist, Mr. Everett, whose theory is shown to be perfectly applicable to the Vérité method of synchronization. The efficiency of this system has received a remarkable confirmation from the circumstances attending an accident by which the synchronizing apparatus was recently put out of order in the city of Paris.—Researches on ruthenium, by MM. H. Debray and A. Joly. In continuation of previous studies of this rare metal, the authors here deal with its oxidation and the dissociation of its bioxide. From these researches it appears that hyperruthenic acid must now be added to the list of compounds which are easily destroyed by heat, although obtained at such high temperatures that their existence was long considered problematical. Their formation at these temperatures is analogous to the dissociation of bodies that were supposed to be incapable of decomposition before H. Sainte-Claire's discovery.—Researches on the breath of man and other mammals, by MM. Brown-Séquard and d'Arsonval. These researches make it evident that the air exhaled by mammals, even in a healthy state, contains a very powerful toxic element, to which should probably if not certainly be attributed the bad effects caused by breathing a close atmosphere.—Variation of temperature of a condensed or expanded vapour while preserving the same quantity of heat, by M. Ch. Antoine. An easy method is given for calculating the final tension that results from the variation of a given temperature, and the final temperature that results from a given degree of condensation or expansion.—On the influence of temperature on the magnetic state of iron, by M. P. Ledeboer. Although it has long been known that a magnet raised to a red heat loses its magnetic properties, no successful attempt had hitherto been made to determine by direct measurement the actual degree of temperature at which iron ceases to be a magnetic body. The experiments here described now show that iron remains magnetic up to 650° C., after which a rapid variation is observed in its magnetic condition. At 750° the magnetic properties are scarcely perceptible, and at 770° they disappear altogether, returning in the same way as the metal cools down. This presents a remarkable analogy to the conclusions of M. Pionchon, who, in his recent paper on the specific heat of iron at high temperatures, has shown that this metal undergoes a sudden change of state between 660° and 720°.—On the present value of the magnetic elements at the Observatory of the Parc Saint-Maur, by M. Th. Moureaux. The absolute values, as deduced from the mean of horary observations recorded by the magnetograph are as follow: declination, 15° 52'·1; inclination, 65° 14'·7; horizontal component, 0·19480; vertical, 0·42245; total force, 0·46520; longitude of the Observatory, 0° 9' 23" E. of Paris; N. lat., 48° 48' 34".—On the employment of sulphureted hydrogen for purifying the salts of cobalt and nickel, by M. H. Baubigny. The experiments here described clearly show that from a mixture of the salts of these two metals it is impossible to obtain a pure sulphuret either of nickel or of cobalt by the action of sulphureted hydrogen. Dellfs' statements regarding the action of hydrogen on the salts of the heavy metals are thus shown to be groundless.—On a new method of quantitative analysis for the nitrites, by M. A. Vivier. This method consists in using the reaction discovered by Millon for the analysis of urea, but with absorption of carbonic acid and measurement of the nitrogen liberated in the process.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Treatise on Algebra: Charles Smith (Macmillan).—The Nervous System and the Mind: C. Mercier (Macmillan).—Reports on the Mining Industries of New Zealand, 1887 (Wellington).—The Ethic of Freethought: K. Pearson (Unwin).—Year-book of Pharmacy, 1887 (Churchill).—An Elementary Text-book of Physiology: J. M'Gregor Robertson (Blackie).—Bergens Museums Aarsberetning for 1886 (Griegs, Bergen).—Zoological Record, vol. 23, 1886 (Gurney and Jackson).—A Course of Lectures on Electricity: G. CONTENTS.

THURSDAY, JANUARY 26, 1888.

ODIUM MEDICUM.

NO one will deny the truth of the saying, "All men are mortal," but very few have any definite feeling that it applies to them personally so long as they are in the possession of health and strength. Almost everyone, however, has either suffered at a former time, is suffering now, or is afraid of suffering at some future time, from ailments of some sort; and therefore the treatment of disease has a personal interest for everyone. On this account the discussions which have been going on for about a month in the *Times* regarding homœopathy have attracted a good deal of attention; but it is difficult for lay readers to understand the merits of the discussion thoroughly unless they know something about the "pathies" generally. The fundamental idea of the "pathies" is that the body does not readily tolerate more than one diseased process at the same time, and therefore one morbid condition may be driven out by inducing another.

The nucleus of our present medicine may be said to consist of the accumulated experience in the observation and treatment of disease possessed by the priests of Cos, and recorded by Hippocrates, who is justly regarded as the father of medicine. His treatment was based upon empiricism, and was not governed by any absolute rule, for, although he stated that in general diseases are cured by their contraries, he also allowed that disease might sometimes be relieved by medicines which produced similar symptoms, and mentioned that under certain circumstances purgatives will bind the bowels, astringents will loosen them, and substances which cause cough and strangury will also cure them.

The principle that contraries are cured by contraries, *e.g.* that constipation is cured by purgatives, attained so much importance under Galen and his followers, that the other principle of like being cured by like was nearly lost sight of, and so the antipathic school had for a long time the preponderance. But the use of evacuants, which formed a large portion of the practice of Hippocrates and of medical practice down to the present day, could not always be brought under the head of antipathy, and so it came to be admitted that one abnormal condition in the body might be relieved by inducing another, which was neither of the same kind as itself, nor of an opposite kind, but was simply of a different nature, and this is the allopathic form of treatment. As an example of this we may take the fact that a pain in the head may be cured by a medicine which does not act on the head at all, but upon the bowels.

The antipathic and the allopathic systems of medicine were in vogue in the time of Hahnemann, and their imperfections were very evident to a man of his mental power and acuteness. He saw clearly that the enormous doses which were given in his time were often productive of great harm, and in experimenting with smaller doses he found that his results were better. He also found, what had been noted before by Hippocrates, that he obtained curative effects from small doses of remedies which in large doses produced symptoms similar to those of the disease. In the recognition of this fact Hahnemann agreed with Hippocrates; but, while the father of medicine, testing everything by experiment and relying simply on the result of experience, regarded the rule "*similia similibus curantur*" as only of partial application, Hahnemann converted it into a universal rule. He began at first by relying on experiment, and spoke of pure experience as the "only infallible oracle of medicine," but he afterwards quitted this sure ground, and committed himself unreservedly to a belief in his theoretical opinions, whether supported by facts or not, and said in regard to his doses that the maxim as to the very smallest being the best is "not to be refuted by any experience in the world.' The essence of his system of homœopathy consisted in the universal application of the rule regarding the similar action of the drug to that of the disease, and in the smallness of the dose.

Some modern homœopathists are inclined to regard the minute dose as not essential to homœopathy, but Hahnemann says: "The appropriation of the medicine to any given case of disease does not depend solely upon the circumstance of its being perfectly homœopathic, but also upon the minute quantity of the dose in which it is administered." The extent to which he carried the dilution of his medicines was extraordinary, and he imagined that the more they were diluted the more potent did they become. Thus he says in his "Materia Medica Pura" (Dr. Dudgeon's translation) that the curative power of aconite is marvellous when it is given "in the dose of a thousandth part of a drop of the decillionth development of power." But even this astoundingly minute dose was unnecessarily strong in some cases, in which he thought "a single momentary olfaction at a phial containing a globule the size of a mustard-seed, moistened with the decillionth potency of aconite, is quite sufficient." But it is difficult for those who have not studied the action of potent drugs like aconite to form any definite judgment regarding their effect in large and small doses; so that it may be worth while to give his views regarding vegetable charcoal, a substance about which everyone can form an opinion. Most people will be surprised to hear that Hahnemann gives no fewer than 720 symptoms as being caused by a few grains of vegetable charcoal diluted a million-fold with milk sugar. These symptoms are of the most varying nature, from aching of the corns to headache, palpitation, and rheumatism, with sometimes a peevish temper, and at other times an excessively cheerful one. The variety and severity of these symptoms clearly show that they were not due to the vegetable charcoal at all, but would have occurred whether the charcoal had been taken or not. But the most remarkable instance of a fallacy in Hahnemann's conclusions appears in his famous experiment on the action of cinchona bark in producing ague, which has been regarded by homœopathists as one of the most important proofs of the truth of the system. Hahnemann, at one time of his life, had suffered from ague, as we learn from Ameke's "History of Homœopathy," but he had probably been free from it for some time before he made his experiment with cinchona. It is well known that persons who have once suffered from ague are apt to have it return when their digestion is disturbed, or when they are subject to depressing influences. The dose of powdered cinchona bark which Hahnemann took was

very large, and similar doses have produced in other people vomiting and gastro-intestinal irritation. In Hahnemann it produced symptoms of ague, but instead of concluding that the cinchona had simply brought back an attack of his old enemy, by acting as an irritant to his stomach, he concluded that cinchona bark had a specific power to produce ague. Others who have tried the experiment, and who have not had ague before, have naturally failed.

Hahnemann's system was greatly ridiculed and opposed both during his life and since, and yet, in spite of its absurdities in regard to dose, it has a number of adherents. The reasons of this are perhaps not very hard to find. For instead of homœopathic medicines being disagreeable to the patient, as those of regular practitioners too often are, they are given in a form which is rather pleasant than otherwise, and Hahnemann's rules of diet and regimen were very different from those followed by regular practitioners of his time. While they were apt to consider that anything that seemed agreeable to the patient was dangerous and to be forbidden, Hahnemann, placing full reliance on the influence of his infinitesimal doses, allowed the desire of the patient for food and drink to be gratified within proper limits, and the temperature of the chamber as well as the quantity of the bed-clothes to be regulated according to the wishes of the patient. There can be no doubt that the attention given by Hahnemann and his followers to diet and regimen have been of great service, not only to the patients they have treated, but to the whole medical profession. It is obvious that such a system as Hahnemann's—gratifying the desires of the patient so far as it was judicious, giving remedies in such minute doses as could at all events do no harm, and at the same time encouraging the patient with the positive assurance that the infinitesimal doses were of the utmost potency to effect a cure—had a great advantage over the system of allopathy. This advantage was to a certain extent shared by antipathy, inasmuch as both it and homœopathy acted on a definite plan, and chose their drugs according to what they supposed to be fixed laws.

Although so far behind the other two in some respects, allopathy had this great advantage over them, that it depended simply on the results of experiment; and although it might be influenced, and was influenced at times, by prevailing fashions, its followers were still searching after truth, while the others falsely supposed they had already found it. With the development of pathology and a truer insight into the nature of disease, the term allopathy has fallen to a great extent into disuse, and most of what we might term the orthodox practitioners of the present day object to range themselves under any "pathy" whatever, but aim at a rational practice founded on the one hand upon the knowledge of the nature of disease, and on the other of the action of remedies. Where these are insufficient to guide them, they fall back simply upon empiricism; expecting, however, that before long, wider knowledge may increase their power to cure their patients. Their power is no doubt very greatly on the increase; and we have only to look at the fact that within the last few years they have been able by the use of substances belonging to the aromatic series of chemical compounds to regulate the temperature of their patients, so that whereas formerly physicians were obliged to stand by idly while their patients died of high fever, they can now prevent the temperature from rising too high with almost perfect certainty, and thus save their patients' lives. Every day fresh contributions are being made both to the physician's knowledge of the nature of disease and his power to modify it or prevent it.

Yet still the regular physician is but a seeker after truth, and as yet no infallible rule by which to select his medicines is known to him. He cannot lay down with dogmatism that the medicine which he is about to administer is the only one or the very best one that can possibly be given, as a homœopath might do. He is therefore to a certain extent at a disadvantage as compared with the homœopath, especially in the treatment of those cases where the disease is not extremely severe, and where the effect upon the mind of the patient counts for as much or more than the action of the medicine itself. The want of a definite rule on the one hand affords an opportunity for the homœopath to sneer at the regular practitioner, while at the same time he complains that the regular practitioner refuses to have any dealings with him. But there seems to be no other course open to the regular practitioner, for he considers that the homœopath must do one of two things: he either believes in homœopathy, or he does not. If he believes in homœopathy as founded by Hahnemann, and prescribes for his patients infinitesimal doses with a conviction that he is actually modifying the disease from which they suffer, the regular practitioner regards him as a fool; while he would apply a still stronger term to the man who does not believe in Hahnemann's system, and uses powerful drugs in large doses, but nevertheless professes to treat his patients homœopathically. It is as useless for a regular practitioner to treat a patient along with a believer in homœopathy as it is for a modern chemist to undertake a joint research with a believer in phlogiston; and therefore the regular practitioner refuses to meet him in consultation so long as he holds homœopathic doctrines. But if the homœopath gives up his belief in infinitesimal doses, and in the universal application of the rule "*similia similibus curantur*," he has given up the essentials of homœopathy, and has no more title to the name of homœopath than Hippocrates had. If he has given up the thing he should give up the name and join the ranks of orthodoxy, but if he still retains the name for the sake of gain he can hardly expect to be welcomed by the orthodox part of the medical profession. It is very unfortunate that the "*odium medicum*" should exist, but the homœopaths seem more to blame for it than the followers of rational medicine.

DARWINISM AND ETHICS.

The Ethical Import of Darwinism. By Jacob Gould Schurman, M.A., D.Sc., Sage Professor of Philosophy in Cornell University. (London: Williams and Norgate, 1888.)

Morality and Utility. By George Payne Best, B.A., M.B. (London: Trübner and Co., 1887.)

WE will consider these two little books together, as in some measure the latter, although earlier in publication, answers the former.

More than half of Prof. Schurman's essay (which altogether extends to but about 250 small octavo pages) is occupied with a preliminary discussion of Darwinian principles *per se*, or without special reference to ethics. Here his object is to argue in favour of "teleological variation" along "beneficial" or "predetermined" lines—supporting this argument in the usual way by denying that natural selection is a cause of organic change. Natural selection can only act on the materials supplied to it by variation: it does not itself create these materials, and therefore leaves where it was before, the question as to the *origin* of the fittest. This argument always appears to us transparently fallacious; but, as our object at present is to consider what Prof. Schurman has to say on "the ethical import of Darwinism," we will not occupy space by discussing the weaker half of his work. In ethics, however, he is strong; and, in our opinion, has produced one of the best defences of the intuitional side which has appeared since the publication of the "Descent of Man."

He begins by pointing out the distinction between the utilitarianism of Bentham and of Darwin—viz. the difference between "pleasure-giving and power-giving," or hedonism and life-serving. Next, he provisionally allows that the Darwinian theory furnishes a proximate or natural explanation of the "innateness, immutability, and universality of moral conceptions." He also allows that, at all events to a large extent, this theory is able to explain the authoritativeness of conscience. But, having thus frankly conceded all that the Darwinist has to demand, he turns upon him as follows:—

"Is it forgotten that, even if goodness be an end in itself—the sole end worth living for—it still remains true that honesty is the best policy, that honest acts are the most advantageous acts, and that they will accordingly be preserved through natural selection in the struggle for existence? All that natural selection requires is that something shall be useful; *what else it may be*, what other predicates it may have, natural selection knows not and seeks not. Be virtue a proximate or an ultimate end, natural selection tells us it will be preserved and perpetuated if it be useful; and it tells us no more. It is, accordingly, a gratuitous assumption which our exponents of evolutionary ethics make, when they decline to allow more than a merely relative value to morality."

The first thing to notice about this position is, that the Darwinian, *quâ* Darwinian, has nothing to do with it. All that the Darwinian, as such, undertakes to show is, that conscience and the moral sense, in all its protean forms, admit of being explained as proximately due to natural causes. Whether or not these natural causes are themselves the results of a final cause, intelligent and moral—this is a question which Darwinism leaves the ethical philosophers to wrangle about.

But now, suppose that a man is not only a Darwinian, but also an ethical philosopher, what is he to make of Prof. Schurman's conclusion that "it is a gratuitous assumption which our exponents of evolutionary ethics make, when they decline to allow more than a merely relative value to morality"? Surely such a man must feel that the burden of proof here lies with the intuitionists. It is they who affirm a supernatural quality of the moral sense, over and above the natural origin of it which (as agreed) the Darwinian has explained; therefore it is for *them* to show that *their* "assumption" of the *absolute* value of morality is other than "gratuitous." This burden Prof. Schurman seeks to discharge as follows:—

"In opposition to this mechanical theory of conscience, we hold that it is an ultimate function of the mind, and that in germ, as in full fruition, it must be regarded, not as an action, but as *an ideal of action*. . . . This view of the subject may be affiliated to Darwinism as readily as the other. For an abiding ideal of action is, to say the least, quite as beneficial as a chance action; and wherever there is an advantage, there natural selection may operate."

Now, without question, "an ideal of action is quite as beneficial as a chance action"; but is it not evident that the Professor is here proving too much? The more he can show that "an ideal of action" admits of being developed in the race by natural causes on account of its utility to the race, the more is he playing into the hands of his opponents, so long as they do not agree to assume with him that morality is of any absolute or ultra-human signification. But it is precisely this assumption which he is required to justify; and the above attempt to discharge his burden of proof, far from making "in opposition to the mechanical theory of conscience," is merely a re-statement of that theory, *plus* his original assumption.

Mr. Best is not nearly so matured a thinker upon ethical problems, and yet upon this important matter he displays a clearer vision than Prof. Schurman. He shows that the intuitive (or instinctive) side of conscience is everywhere an "ideal of action"; but he also shows that where it stands alone, or without reasoned perceptions of utility, it is everywhere an ideal impossible to realize. With considerable originality and success, he argues that the moral ideal, in all phases of its development, is essentially irrational, inasmuch as it could only realize itself completely in a population all the members of which "are equal, asexual, and immortal." He then goes on to ask:—

"Suppose such an idea should become actually operant, and endeavour to realize itself in thought, or in action, in this world of inequality, sexuality, birth and death, what kind of phenomenon might we expect to arise from the conflict between idea and fact? Might we not expect to find in those in whom the moral intuitions were best developed a constant protest against things as they are? Might we not expect to find a hankering after equality? Might we not expect to find some, in reaction against that inequality which, in the form of wealth, obtrudes itself before their eyes, take refuge in voluntary poverty; might we not expect others to endeavour by force or contrivance to bring about the reign of equality? Might we not expect the dim picture of an asexual world to make men revolt against sex and sexual relations, and cry up celibacy as the holiest condition possible?" &c.

Thus, then, the moral ideal is more or less out of joint with actual fact; and although it is easy enough to understand why such should be the case if it is but of relative significance—or of no further meaning than that which arises from its utility to the race—we cannot so well understand why such should be the case if it be of absolute significance. And, if we extend our view beyond the human race, we are met by a similar difficulty. Not only man, but the whole creation, groans in pain and travail—that is to say, the unmoral as well as the moral;

and, therefore, the creatures whose pain and travail cannot possibly serve any moral purpose. Yet the moral sense of man, in its most "intuitive" or least rational form, is outraged even by the practice of vivisection with a view to an ultimate amelioration of sentient life.

Our object in saying this much is to show that Prof. Schurman does not appear to have perceived the basal difficulty against which he has to contend. The question which he undertakes to answer is whether the moral sense is of absolute or only of relative significance. But this question he merely begs on behalf of the intuitionists. Of course, if it be thus assumed that the moral sense is of absolute significance, it is reasonable enough to show that the fact of its utility is not opposed to the assumption. But where the validity of this assumption is the matter in dispute, an intuitionist only plays into the hands of the utilitarian by arguing that in his view of morality "an ideal of action may be affiliated to Darwinism as readily as any other." Nevertheless, although we thus deem Prof. Schurman's essay a failure in its argument against the mechanical interpretation of conscience, it is otherwise an able contribution to the literature of ethics; and anyone who is already an intuitionist may properly accept the work as proving that there is nothing in Darwinism, *per se*, which can be logically regarded as inimical to his theory.

GEORGE J. ROMANES.

AN INDEX-CATALOGUE.

Index-Catalogue to the Library of the Surgeon-General's Office, United States Army. Vol. VIII., Legier—Medicine (Naval). (Washington, 1887.)

THE regularity with which the large annual volumes of this great work reach us is most reassuring, and now its completion in some six more years may be looked upon as practically certain, considering the vast resources of the United States, and the energy which its editors have shown. It still remains unique among printed catalogues in its immense lists of articles from every species of periodical literature, arranged under subject-headings, and drawn from more than 3400 Journals, Reviews, Transactions, &c. It has added to its list last year 165 new periodicals, and its tastes are sufficiently catholic to include such as the *Revue Philosophique*, which contains important matter bearing on the fundamentals of physiology and psychology, but hardly touching on any professional details.

The entries are carried up to the end of 1886; the volume has a few words of preface dated June 1887. When it is considered that the papers of Delhi, Madras, and Adelaide, for example, take some weeks to reach Washington, and that any of these may contain entries which should take a place in any part of this book of 1078 closely printed quarto pages, there seems to us certainly to have been no loss of time in publication. There are many entries, in this volume, of Chinese and Japanese books, magazine articles, and manuscripts, which the editors insert in English characters, and are kind enough to translate for us. Of the European languages also, Hungarian, Russian, and Polish are as a rule translated, much more freely than in the last volume; but Swedish and Danish rarely, and Portuguese, Dutch, Spanish, Italian, and Greek not at all. A very commendable practice has sprung up, though it is not found everywhere possible, of putting the date of birth after a living author's name. Thus we read Lussana (1820—), Luys (1828—), &c. It would be very convenient if this could be further extended, though of course the difficulties in the way are obvious. There are some very large collections of entries under such words as Liver (70 pp.), Lungs (30 pp.), Lithotrity and Lithotomy (40 pp.), and the extent of the bibliography is well illustrated when we find 213 books and 646 articles entered under such a simple heading as Measles. By far the largest aggregation, and one as yet unfinished in this volume, is under Medicine, which in the present volume occupies 288 pages. It is a heading under which the subdivisions have been difficult to arrange; but the large bulk of matter has, on the whole, been well distributed. Under such a subdivision as Medicine (Anecdotes, Curiosities, &c.), we naturally find strange companions, such as "Uriel to his Compeers; adapted by Ithuriel"; "The Doctor, by the Author of 'Betsy Lee'"; "Sniggers (J.), Gnihtontuobaodahcum," the last a *Spiegelschrift* in print. Under Medicine (Systems, Theories, and Practice), we find a large group of the elder writers who are chiefly of historical interest, extending from "Averrhoes: Incipit Liber de medecina Averoys qui dicitur Coliget, &c., imp. folio, Venetiis, 1482 (Gothic letter), to the writers of the last generation, such as Dr. C. J. B. Williams (1842), and, curiously enough, containing only one small volume among the modern hand-books, "Elements of Practical Medicine, by A. H. Carter, 1881," which might have come more appropriately among Medicine (Manuals) or Medicine (Practice of), along with the mass of modern text-books. Groups are chronicled under Medicine (Magical, Mystic, Spagyric) of some 300 books, and of some 250 under Medicine (Chronothermal, including the Thompsonian system), which serve to remind us of the chequered history and varied principles of the healing art. To the accuracy of this vast body of references, amounting to more than 40,000 in all, it is Time that will bear the best testimony, as it has borne to those of the earlier volumes. A first testing on such detail as is practicable shows the figures right, and the text sometimes—as, for instance, in the case of M. Luys—more accurate than that of the author's own publisher in his advertisement columns. It is a mistake, we must allow, but we trust a very pardonable one, to have spelt the name of a distinguished living physician as "S. Wilkes"; and it is a pity that, under the record of Hospital Reports (London), we should find mention only of those of the Hospitals of St. Thomas and St. George. But these are trifles; when we close the heavy volume we cannot help feeling a hearty admiration of so much hard and careful work well spent, not on the aggrandizement of any individual fame, but on the steady and strenuous advancement of learning.

A. T. MYERS.

OUR BOOK SHELF.

A Vertebrate Fauna of Sutherland, Caithness, and West Cromarty. By J. A. Harvie-Brown and T. E. Buckley. (Edinburgh: David Douglas, 1887.)

THIS is a good type of all that a hand-book on local natural history ought to be from a naturalist's point of view. While it appears to be as exhaustive as any two

workers can make it of the fauna of which it treats, its honest tale is not only plainly but also briefly told. In other words, we are spared those poor attempts at poetical prose and all the allied sins which seem so easily to beset the field naturalist. This is another way of saying that the work has been undertaken and executed in a purely scientific spirit. After a few introductory chapters on the geography, topography, physical aspects, &c., of the area, the authors proceed to give a systematic catalogue of the entire vertebrate fauna, beginning with the mammals and ending with the fish. In this catalogue everything relating to distribution, habits, &c., which can possibly be of any interest is likewise set forth in terse phraseology. The whole catalogue covers between 200 and 300 octavo pages, and is everywhere indicative of painstaking labour. Several well-executed plates embellish the volume, which throughout displays good taste as well as sound judgment. We are, therefore, particularly glad to read in their preface that the writers intend this to constitute "the first volume of a series, which, unlike most local faunas, lays aside to a great extent political boundaries, and is marked out by others, much more natural, such as watersheds." We trust that this first volume will meet with the recognition which it deserves; and in any case congratulate the writers on having so successfully accomplished so extensive and valuable a piece of work.

G. J. R.

Gospel Ethnology. By S. R. Pattison. (London: Religious Tract Society.)

THE author observes that the many-sided investigations of ethnologists do not seem to have included a study of the way in which Christianity has been received by different races. The problem suggested is undoubtedly an interesting one, but the present volume does not do much to solve it, being mainly made up of a series of anecdotes which go to show that the Gospel, in the form in which it is set forth by Protestant missionaries of the Evangelical school, has found a response in the hearts of individuals of almost every known race. It is reasonable to infer from this that the particular type of Christianity to which Mr. Pattison confines his attention contains motives that appeal to men in almost every stage of social development and culture. But so far as one can judge from the anecdotes, which are not chosen with a view to facilitating scientific analysis, it seems probable that in every case the really effective element in the missionary teaching lay in the Gospel story itself, not in the dogmatic construction built on it by missionaries of a particular school. At any rate, it is plain that no discussion of the problem which Mr. Pattison deals with can claim to be of scientific value so long as it deals only with the reception given to one form of Christian teaching. Nor is it enough to know that *individuals* of almost every race are capable of becoming sincere Christians of a particular school: the ethnologist, from his point of view, is much less concerned with individuals than with masses. A serious inquiry into the fitness of Christianity to become the religion of *societies* that have not come under the influence of the civilization of the Roman Empire would be extremely useful, but such an inquiry cannot be made to any purpose if one starts by identifying Christianity with one of its local and particular types.

There is not really any ethnology in the book before us. There is, indeed, a chapter which professes to give a survey of the races of mankind, but it is so badly done that the book, which is really, as has been said, a collection of anecdotes, would have been better without it. There are some good woodcuts of people of different races.

The British Journal, Photographic Almanac, and Photographer's Daily Companion for 1888. Edited by J. Traill Taylor. (London: H. Greenwood and Co., 1888.)

To all those who are engaged in the art of photography either as amateurs or as professionals this work will be extremely useful. Besides all the ordinary information, such as that of developing, toning, &c., there are articles of the most practical and theoretical nature—written by such men as Captain Abney, F.R.S., Rev. S. J. Perry, F.R.S., &c.—on subjects which are most interesting, and of great service to those who have attained the higher branches of the art.

All the various tables and formulæ are here added, together with a list of all the Photographic Societies at home and abroad.

Two pictorial illustrations are given, one being of the famous yacht *Thistle*, printed by Messrs. Morgan and Kidd on their argentic bromide paper (360 being able to be printed from one negative in an hour) from a negative by Mr. A. H. Clark; the other being a callotype by Messrs. Waterlow and Sons from a negative by Mr. T. B. B. Wellington on a Pall Mall plate, entitled "You naughty boy."

For the sake of young photographers the Editor has written twelve chapters to present in simple language a few lessons in the practice of the art.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

"A Conspiracy of Silence."

WHEN I read Prof. Judd's letter in your issue of last week, I felt as if one of the Eocene volcanoes of the Isle of Mull, which he has described so well, had broken out afresh and covered a great extent of country with erupted matter, decidedly, by a wonderful phenomenon, of the "acid series."

I have a very short reply to give:—

First, it is not the fact that I have made any attack on geologists. The fathers of British geology were among my dearest and most intimate friends, and I have the highest respect for many of the (comparative) specialists among whom, by the division of labour, the science is now divided. Among the most eminent of these I have always reckoned Prof. Judd himself.

Secondly, it is not the fact that I have accused anyone of conscious indifference to truth. I attacked the undue influence of authority in science, and in doing so I used the well-known formula "conspiracy of silence," which, on the face of it, is a metaphorical and rhetorical expression, but which has been used in his latest writings by Prof. Huxley precisely in the same sense, and has been applied by him to the most distinguished scientific body in the world—the French Institute.

Thirdly, it is not the fact that I have challenged discussion on my September article upon "Coral Reefs." I have challenged discussion upon the subject, and on the question of Darwin's theory—of which my paper was a mere popular abstract, and nothing more.

Recent discoveries by the staff of the *Challenger*—the observations of Prof. Semper—the papers of Mr. John Murray, and of Mr. L. Agassiz—and lastly, the recent admirable observations of Dr. Guppy, have, in their combination, afforded ample ground and materials for a review of the whole question; and I have a distinct opinion, which I repeat, that the influence of Darwinian authority and prejudice is one of the causes which has retarded, and is now retarding, any acknowledged solution of the question.

I have heard with extreme regret that Dr. Guppy, the most recent witness to facts irreconcilable with Darwin's theory, has felt compelled to resign his position as member of the London Geological Society—for what reason I do not fully know, but for some reason connected with his views on this subject.

Inverary. ARGYLL.

On some Unapparent Contradictions at the Foundations of Knowledge.

An argument parallel to that by which Mr. Tolver Preston proposes to prove that Space is nothing will prove with equal cogency that Time is nothing. But if Space is nothing and Time is nothing, then he has the choice of two alternatives, neither of which will he find particularly acceptable. If Space and Time are both nothings, they are identical. If Space and Time are not identical, then they are two nothings which differ. What is the difference between two nothings?

I would suggest that Mr. Preston should read Mr. Herbert Spencer's views on "The Relativity of Knowledge," contained in Chapter IV. of "First Principles." On his carefully thinking this out, and understanding it, I am willing to hope that the title I have adopted for this letter may appear to him appropriate to the subject-matter which he has brought under the consideration of your readers. F. Howard Collins.

Churchfield, Edgbaston.

Extraordinary Fog in January 1888, at Shirenewton Hall, Chepstow.

The recent fog has been so remarkable that it seems desirable to record its principal features. From the 7th to the 14th the air was completely saturated with moisture. The most notable feature was that of cold air passing over a warm ground, for from the 11th to the 15th the greatest cold on the grass did not descend to that read at 4 feet. Such a condition of the air as this has not been noticed since I commenced observations in 1838.

The following readings of the thermometers will illustrate this:—

Date.	Temp. 4ft. 10 a.m.	Diff. bet. wet and dry.	Min. 4 ft.	Min. grass.	Diff.
Jan.	°	°	°	°	°
7	43·3	0·0	40·0	34·5	−5·5
8	45·6	0·0	42·1	37·2	−4·9
9	41·2	0·0	37·0	30·3	−6·7
10	34·3	0·0	32·8	28·1	−4·7
11	36·7	0·0	33·3	37·3	+4·0
12	29·8	0·0	29·3	30·5	+1·2
13	28·3	0·0	26·7	28·3	+1·6
14	32·0	0·0	25·0	29·5	+4·5
15	33·9	1·0	28·0	30·0	+2·0
16	30·0	0·5	27·0	27·0	0·0
17	30·5	1·0	29·7	29·7	0·0
18	28·6	0·0	27·0	27·0	0·0
19	31·7	0·4	26·4	24·8	−1·6

Throughout the 12th after 9 a.m. the temperature on the grass was above 32°, whilst it was a frost from the height of 1 foot upwards; at 10 a.m. the temperature on grass was 32°·8, at 4 feet 29°·8, and at 10 feet 28°·6.

The fog lasted from the evening of the 6th till 3 p.m. of the 14th. On the 7th the clouds moved rapidly in W. current, and on the 8th they moved rapidly in S.W. current; on the 9th nearly calm and cloudless overhead; from the 10th to 14th overcast (except from 11 a.m. on the 12th till 12.40 p.m.). The chief direction of the wind was: 8th S.S.W., 9th S.S.E., 10th W.S.W., 11th and 12th calm, and from 13th to 18th between N. and N.E., and on the 19th E.S.E.

The fog was wet and yielded much moisture, viz.:—

7th ·079, 8th ·008, 9th ·015, 10th ·017, 11th ·031, 12th ·013, 13th ·020, 14th ·020, 15th ·023.

The barometer was very high, and almost stationary, reaching a maximum on the 9th at 10h. 30m. a.m., viz. 30·75 inches corrected and reduced to the sea-level.

On the 11th the fog cloud moved in a south current till 3 p.m., when it became north, and continued so throughout the 12th. On this day on the side facing the fog current every leaf and twig had a horizontal deposit of ice, increasing in length from half an inch at 4 feet above the ground to fully an inch at 10 feet; the outside edge of this ice being as thin as the fine edge of a knife; and the whole upper surface of all laurel and other large leaves that were horizontal had a coating of ice, so thin (although it could be detached without breaking) as almost to resemble gold-leaf, on which were transparent impressions of every irregularity, however minute. On the side of trees opposite to this current, instead of rime there were nearly pear-shaped transparent drops of frozen water, of various sizes, mostly as large as one-eighth of an inch in diameter; they were situated *not quite* at the point of every leaf; no leaf was without a frozen drop, and this had an extraordinary appearance, more especially amongst the crowded leaves of such plants as *Pinus insignis*, *Abies Webbiana*, &c. On the opposite side of these fir-trees the appearance was equally singular, as each leaf looked like a knife-blade of one-sixth of an inch in width, with a square apex. The ground-temperature being above 32°, the vivid green of the grass was a great contrast to the ice on the trees. E. J. Lowe.

"The Art of Computation for the Purposes of Science."

In a paper with the above title, in Nature, vol. xxxvii. p. 237, Mr. Sydney Lupton refers to some of our work as affording a good example of "the natural tendency of the human mind . . . . to exalt the accuracy of one's own experiments."

The experimental work referred to was a determination by the dynamical method of the vapour pressures of liquid benzene. A curve was drawn to represent these relations; three points were chosen, and the constants for the formula $\log p = a + ba^t$ were calculated. Mr. Lupton finds fault with the number of decimal places given for these constants, and makes three statements which are intended to put the experimental work in as unfavourable a light as possible so as to heighten the contrast with the extreme accuracy of the calculations. Mr. Lupton says: "Nine places of decimals are given with apparent confidence, when (1) only three of the whole number of experiments were made even in duplicate." We do not quite understand this statement, for on reference to the original paper (*Phil. Mag.*, Jan. 1887) it will be seen that the last six experiments in Series I. overlap the first six in Series II., while the last seven of Series II. are within the same limits of temperature as the first four of Series III. The second statement is that "the last pressure, 755, was obtained not by experiment at all, but by extrapolation from a freehand curve, the highest experiment being 79°·6 and 743·1 mm." We would point out that the experiment referred to is not the highest, for on the preceding page in our paper the boiling-point 79°·9 at 753·4 mm. is given. Again, the curve was not drawn by freehand, but by means of engineers' curves, which give very much more accurate results. It is quite true that the last pressure was obtained by extrapolation, but an extrapolation of 0°·1, or even of 0°·4 does not seem very excessive with a range of 80°. Mr. Lupton states, thirdly, that "a difference of $\frac{1}{9}$° at low temperatures produced no change in pressure which was appreciable by the apparatus used." But, as a matter of fact, at 0° a difference of 0°·1 corresponds to a difference of pressure of 0·15 mm., which is quite appreciable on our gauge. Perhaps, however, Mr. Lupton refers to the experiments at 36·15 mm., in which at the same pressure two *different* thermometers registered temperatures which differed by $\frac{1}{9}$°.

Mr. Lupton lastly gives much simpler constants, calculated from our data, and compares the pressure at 60°, calculated from them and from our constants, with the pressure given by Regnault. It happens that the number obtained with the simpler constants exhibits greater concordance with Regnault's value. Now while we would agree with Mr. Lupton in classing Regnault (as far at least as some of his work is concerned) with the select few who are entitled to an extra number of decimal places, yet we would point out that Regnault did not always succeed in obtaining perfectly pure substances to work with, and some of his results are rendered almost valueless on that account. In this case, for instance, the melting-point of Regnault's sample of benzene was 4°·44, whereas after the most careful purification we find that it melts at 5°·58, and the value obtained by Fischer (*Wiedemann's Annalen*, xxviii. 400) is almost exactly the same as ours. Again, Regnault failed to observe the existence of a difference in the vapour pressure of solid and liquid benzene (and other substances) at the same temperature, while this difference has been measured by Fischer by the statical and by ourselves by the dynamical method.

We are quite willing to admit that our decimal points are carried further than is necessary for the calculation of the vapour pressures, but we have frequently had occasion to calculate the values of $\frac{dp}{dt}$ for various substances, and we have found that in order to obtain regular values a large number of decimal places are required; if a smaller number are employed the

values of $\frac{dp}{dt}$ themselves require smoothing, which involves additional labour.

But if—since vapour pressures only are given in our paper—we have gone to one extreme, we think that Mr. Lupton has gone to the other, for at 79°·9 the pressure calculated from his constants differs by 3·8 mm. (= 0°·16) from that calculated from ours, and by 3·1 mm. (= 0°·13) from our observed pressure, and this difference is certainly too great.

It might also be supposed from Mr. Lupton's constants that the value of b in the formula $\log p = a + b\alpha^t$ could generally be expressed by a very simple number such as the one he gives (− 3·3), but this is not so. It happens that our constant differs only very slightly from the number − 3·3; it is − 3·30062, and by striking off the two last figures in this constant and making a corresponding slight alteration in the value of a, a much greater simplification is possible than would usually be the case.

Mr. Lupton gives five decimal places for log α, and we are unable to appreciate the advantage of using a table of four-figure logarithms where five places are required.

While recognizing the advantage of methods of computation, may we suggest, in conclusion, that, as a rule, only experimentalists are capable of judging the limits of accuracy of experiment, and that they may be trusted to save themselves trouble where trouble may be saved without sacrificing accuracy?

W. Ramsay.
Sydney Young.

"The Mammoth and the Flood."

The question raised in my previous letter is too important and is being too widely discussed to allow me to let it go by default, and as it has a certain freshness I cannot help thinking that it will prove interesting to many of your readers.

Your critic disposes of Sir Andrew Ramsey in a very unceremonious fashion. To describe the head of the Geological Survey, and the former President of the British Association and the Geological Society, as *an irrational uniformitarian* is to get rid of my attack in a very simple way. Surely some of his scholars or some of his subordinates will have a word to say for their late chief, and, if they cannot maintain his position, will offer some alternative. To the great mass of scientific men who are not geologists, teaching from such a source is naturally accepted as authoritative.

To pass on, however. Your critic speaks of my invoking a series of catastrophes to explain the difficulties surrounding the extinction of the mammoth. This is most inexplicable to me, and points to his not having read my book at all, which was neither fair to you nor me. My book is a perpetual protest against such a series of catastrophes, and an argument in favour of one catastrophe only. May I quote one statement among others?

"If we are to summon some normal cause not now operating for these facts, it certainly seems more reasonable that, with effects so completely alike over such a wide area we should summon *one cause*, and not *several*, and attribute the aberrant conditions showing so much uniformity to some uniform impulse. Here, again, the burden of proof is upon those who deny this view, and treat the remains not as the result of some widespread catastrophe, but as evidence of as many catastrophes as there are skeletons.

"It would be as unreasonable to invoke a separate storm and a separate date for the death of each one of the myriads of razor-bills and guillemots that strewed the western coasts of Britain on a fatal occasion a few years ago, and whose remains were all fresh and in the same condition, as to do the same for the myriads of fresh skeletons of mammoths, rhinoceroses, bisons, &c., in Siberia or in Europe. These debris of a former world have every sign that they formed parts of a contemporaneous fauna destroyed at one time, and are not the wreckage of centuries of deaths."

I now come to what is more important; namely, the theory which your critic resuscitates, after it has been given up by all the Russian inquirers, save one, for many decades—namely, the notion that the mammoths have been floated by the rivers from some undefined land and buried by river action, where they are now found.

Dr. Bunge, who has recently returned from a protracted residence on the Lower Lena, and has described his researches in detail before the St. Petersburg Academy, tells us expressly that mammoth remains are found very seldom indeed in the delta of the Lena, and very seldom also near that river. It is in the higher land separating the great rivers that the remains abound, and especially, as Wrangell and others showed long ago, and as Bunge has recently confirmed, in the mounds and low hills of the tundra. When found near rivers, it is near the short rivers, like those of North-Eastern Siberia, or near the head streams of the Lena, the Yenissei, &c., which could not float such carcasses.

In the next place, Northern Siberia is not a country of mountains and small valleys, but a vast, continuous, nearly level waste covered with moss, called a tundra, diversified by mounds and rounded hillocks, and threaded here and there by rivers running in deep channels—rivers which are frozen fast for a large part of the year.

When the late spring comes, and the ice in the upper reaches melts, while that lower down is still locked fast, there is no doubt a considerable flood in the estuarine parts of the Obi and other rivers, but this is temporary and transient, and it only covers the low lands where mammoth remains are most infrequent. It never covers and cannot cover the higher land. There is not supply of water to do it. To cover the higher points where the mammoth and other remains abound would require such a supply as would put the whole northern part of the continent under water, and thus destroy all animal life there every spring flood. Even if we could postulate river floods of this kind as I have shown, quoting a most experienced geologist, Schmidt, the Siberian rivers deposit no warp that could cover in the mammoths as they are found covered in, by deep beds of clay and gravel, not when lying on their sides only, but when standing upright, as they have several times been found. They must have been covered in by more than two yards of deposit also in a single year in all parts of Siberia, since the ground melts to that depth in the summer, which melting would destroy their soft parts. Appeals to river-floods therefore involve appeals to transcendental causes which are obsolete in other sciences than geology.

Lastly, why is this river portage invoked at all? We have not merely the mammoth carcasses to account for, but the trees found with these great beasts *still rooted*, and the land and freshwater shells showing a different climate when he lived.

Where are we to bring these debris of a former life from? We cannot go outside of Siberia; for the mammoth, so far as we know, has never been found in Asia outside that province. We cannot bring the mammoths found in Kamchatka, and the peninsula of the Chukchi, and the Liachov Islands (which are 150 miles from the mainland), from Central Siberia. Again the remains are very infrequent there compared with their abundance further north, while the mammoths from the north and south of Siberia can be discriminated. There is no sign of rolling on the bones, and the epiphyses are still attached. Evidence of every kind converges therefore upon the conclusion that the mammoths lived and died where their remains are found, and the problem that has to be faced is, how they were exterminated simultaneously from the Obi to Bering Straits, of all ages and sizes, and mixed with various incongruous beasts; how they were buried in the hillocks and high ground under vast, undisturbed, and continuous beds of gravel and clay; and how, lastly, their flesh was subsequently preserved. If all this can be explained without some appeal to the forces I have invoked, then *one factor out of many* in my argument can be answered. If not, it is no use going to Wonderland for hypotheses which only arouse ridicule among students of those sciences which claim induction for their basis. I am most anxious for an answer. Henry H. Howorth.

Bentcliffe, Eccles.

Is Hail so formed?

I noticed here yesterday a curious phenomenon—one that has not before come under my observation.

I was standing under a pine-tree that was laden with moisture from the foggy atmosphere; drops were falling to the ground from the branches, but what struck me was the fact that although most of the drops reached the ground in a liquid state, some of them were converted in their descent into *pellets of ice*.

It was very cold, but I had no reliable means of ascertaining the temperature at the time; it could not, however, have been far off freezing-point.

I was quite unable at first to account for the fact that some drops were frozen while others were not; it occurred to me later, however, that the drops which reached the ground as pellets of ice had been derived from the *topmost* branches, while those remaining uncongealed had fallen from the *lower* ones.

I based my conclusion on the assumption that the drops from the top of the tree in falling a greater distance, and in travelling more rapidly, than those beneath them, consequently suffered a greater loss of heat by more rapid evaporation, and hence were converted into ice before reaching the ground; but it seems to me nevertheless a most remarkable thing that such a result should depend upon so small a difference in altitude (10 ft. at the most), and the atmospheric conditions favourable for the production of such a phenomenon must have been so unusual as to make its recurrence very unlikely.

I have heard of a railway train becoming coated with ice after travelling through an atmosphere above freezing-point and laden with mist, but we can easily grasp the phenomenon when occurring on so large a scale.

"British and Irish Salmonidæ."

ALTHOUGH calling in question statements made by reviewers is generally a thankless task, still, when an author believes himself to have been misquoted as well as erroneously corrected, a deviation from the usual course may sometimes be excusable. Acting under such an impression, and feeling sure that the Editor of NATURE, and the reviewer of my "British and Irish Salmonidæ," would be equally unwilling to promulgate errors to the public, I must ask for a small space with reference to the review of my work which appeared in your last issue.

Purporting to quote a sentence of mine (p. 31) as an example of my "originality in sentence construction," the reviewer has rendered it misleading by omitting five words which I have here re-inserted in italics and within brackets. Alluding to the water containing the recently expressed eggs and milt, he makes me say as follows:—"This is gently stirred with the hand (*and then allowed to stand*) until the eggs harden, or 'frees' as it is termed, being a period from one-quarter to three-quarters of an hour," &c. If newly expressed eggs and milt were thus stirred up from fifteen to forty-five minutes they could not "set," and would therefore have no occasion to "free," as the Americans have termed it, but such misplaced energy in the operator (which I never proposed) would assuredly destroy their vitality.

The reviewer says, "the description in the text of the mode of packing eggs which has been perfected at Howietoun seems to be erroneous, . . . while in a quotation in a footnote the correct account is given—namely, that the ova lie in direct contact with the damp moss, and are covered by another layer of the same, the muslin being only used in order that the layer of moss may be lifted and moved." The reviewer has here confused the text, or general principles as laid down, with the note (p. 42) of the mode pursued at Howietoun, which he asserts to be "the correct account"; but had he read the quotation to the end he would have seen that, besides the plan adopted at Howietoun for packing eggs going *long distances* when no muslin is used, a second mode is employed for those going *lesser journeys*, and was described as follows: "For shorter journeys eggs are thrown off the frames on to swans' down, which takes little more than half the time, and greatly facilitates the unpacking at the end of the journey."

The reviewer observes that "no reference is given to any work where the correct description of *S. namaycush* as a char can be found." If this remark is seriously made under the impression that the fish is not a char or a *Salvelinus*, I would refer among others to *Salvelinus namaycush*, Jordan, Bull. 16, U.S. Mus. 1883, p. 317; Bean, "Fish Com. Report," 1884, p. 1042; Garman on the "American Salmon and Trout," Boston, 1885, p. 5; to Brown Goode in his "Game Fishes of the United States," and his more recently published account in the "Fisheries and Fishery Industries of the United States," 1884, p. 485, &c. In this last work he observed of the *namaycush* that "the Lake trout is in fact a member of the same group of the salmon family with the chars," while I referred to his statements at p. 249.

PHYSICAL SCIENCE AND THE WOOLWICH EXAMINATIONS.

IN June 1884 we called the attention of those who are interested in science and in the science-teaching in our public schools to some new regulations for admission to Sandhurst which had lately been announced, and to efforts that had been made by the President of the Royal Society, and others, to induce the authorities at the War Office to reconsider their scheme, which appeared likely to seriously handicap those public schools in which real attention to science is given in the regular school work, and to be unjust to young men of scientific ability.

Whilst we wrote, those regulations were already undergoing revision, and they were subsequently replaced by others in which certain improvements had been made, but in which the mark value of science was still so low as to be likely to do harm. In a second notice of the subject in August of the same year, whilst admitting that improvements had been effected, we expressed our opinion that even in their new form the regulations would tend to check freedom and progress in education, and act unfavourably on the work of those public schools which have aimed at widening the basis of education by introducing the study of physical science into the regular school work of all, or nearly all, their pupils.

We regret to add that this view has proved to be, to a considerable degree, correct. We hear, for example, that almost directly after the issue of the amended regulations at least one large school decided to omit all work in science from the instruction given to boys *at once upon their deciding to become candidates for Sandhurst.* In the interests of the subsequent career of the boys this was, and is still, considered to be almost invariably necessary. And we find that at the last four examinations only about 2 per cent. of successful Sandhurst candidates have offered a knowledge of some branch of physical science ("experimental science" in the regulations), whereas formerly the very moderate but much larger proportion of 8 per cent. did so. In the case of physical geography and geology the corresponding proportions are 19 per cent. during the four years that preceded the date of our article, and about 8 per cent. during the last two years.

No doubt the candidates for Sandhurst are not, as a rule, drawn from the class of boys to whom the study of science is particularly attractive, and it is not impossible that to some extent the present regulations for admission to Sandhurst may have had the effect of inducing scientific boys to enter more freely for the scientific branches of the army, to which admission is gained through Woolwich.

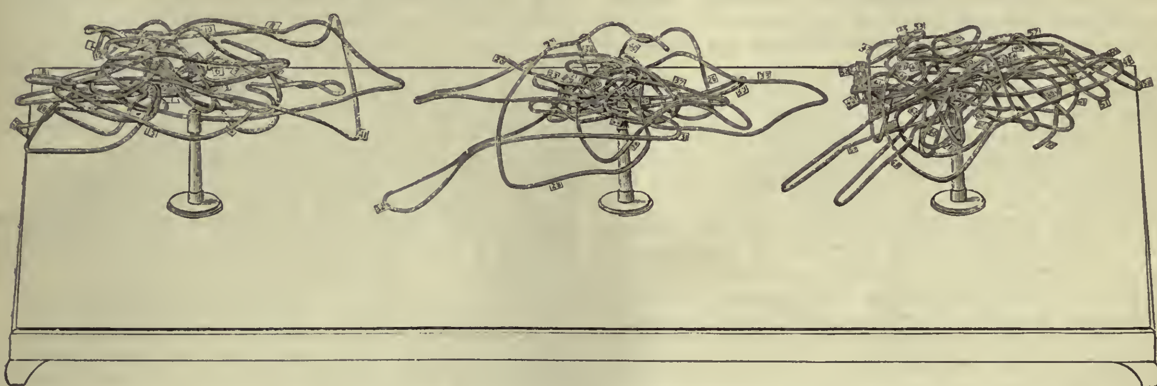
In the examinations for Woolwich, science has hitherto met with more liberal treatment than at Sandhurst, and has been taken up by a fair, but not excessive, proportion of the successful candidates, which has lately tended to increase in the case of chemistry and physics. It is therefore with the greatest regret that we learn that new regulations for admission to Woolwich are to come into effect in November, which will be likely to seriously further discourage the teaching of physical science. These regulations correspond pretty closely to those for Sandhurst, which we have previously discussed; it will be sufficient, therefore, to say that compulsory mathematics, optional mathematics, Latin, French, and German, form Class I., have each of them an allotment of 3000 marks; that Greek, English history, chemistry, physics, physical geography and geology, form a second class, to each of which 2000 marks are allotted; and that candidates may take all the subjects of Group I.,[1] or may substitute one subject from Group II. in place of one of those in Group I.

[1] They may also take any or all of Group III., viz. English composition, freehand and geometrical drawing, to each of which 500 marks are allotted.

Hitherto the mark values of all subjects, except mathematics, have been equal in the Woolwich examination, and free choice of subjects has been permitted to candidates. This has been fair to young men of different orders of ability; it must have secured officers of varied powers, and has satisfied the schools by leaving them free to do for each boy that which was best for him. In one respect the new scheme is better than the old—viz. in the grouping of the physical science subjects. But with such a bribe as will now be offered for Latin and modern languages, we cannot think that it will often be worth while even for boys of more than average scientific capacity to adopt the study of science if they desire to enter Woolwich. It is evident that, other things being equal, those who do so will come out lower in the list of those who succeed, and be more likely to find themselves amongst those who have failed, than will be the case with such as are of equal ability in the study of languages. We do not believe that it is the intention of the War Office authorities thus to partly bar the way into the scientific branches of the service against young men of more than average promise in the experimental sciences, subjects that will afterwards form a very important a part of their work in the Royal Military Academy; and we trust that leaders in science, and the representatives of those schools which are doing their best for their scientific boys, as well as for their unscientific boys, will not fail to unite in calling attention to the inevitable results of the final adoption of the present scheme. The reception that such representations met with in 1884, and the position accorded to physical science in the course of study for the cadets after having entered Woolwich, cause us to feel sure that such representations will not be without effect, especially if they be not too long delayed.

A MODEL OF AN EARTHQUAKE.

IN the latest part of the Journal of the Science College of the University of Tokio, Prof. Sekiya describes a very curious and remarkable model he has made to exhibit the manner in which a point on the earth's surface moves during an earthquake. Readers who have followed the recent progress of seismometry in Japan are aware that the motion which is recorded at an earthquake observatory is a prolonged series of twists and wriggles of the most complicated kind, so that the path pursued by a point on the surface of the soil has been aptly compared to the form taken by a long hank of string when loosely ravelled together and thrown down in a confused heap. Prof. Sekiya has taken advantage of a very complete earthquake record obtained by him with a set of Prof. Ewing's seismographs to follow out this path step by step, and to represent it, in a permanent form, by means of stiff copper wire. The earthquake he has modelled in this way took place on January 15, 1887, and was unusually severe, for Japan. It has been already described in NATURE (vol. xxxvi. p. 107), and we have given there a copy of the seismographic record by help of which the model has been constructed. The seismogram shows the vertical displacement and two rectangular components of the horizontal displacement, instant by instant, throughout the disturbance.



Professor Sekiya's Model of an Earthquake.

It was only necessary to go through the laborious task of compounding the three displacements in order to find the actual path. This, Prof. Sekiya has done for the first seventy-two seconds of the earthquake—a period which embraces all the most interesting features, although large movements in a horizontal plane continued for a minute more, and small movements for a still longer time.

After the seventy-second second, however, the vertical component of motion had virtually disappeared, so that the later part of the disturbance might be represented by a curve drawn on a horizontal plane. To avoid confusion, the model (a sketch of which is given above) is constructed in three parts: the first and second parts each refer to twenty seconds, the third to thirty-two seconds. The parts are mounted together on a lacquered stand 3 feet long, genuinely Japanese as to its legs, as the sketch will show. The model represents the absolute motion of the ground magnified fifty times. Little metal labels are attached to the wire to mark successive seconds of time, from 0, where the shock begins, to 72, where the model ends.

Prof. Sekiya is to be congratulated on his patience and skill. The model will serve to show at a glance the real character and enormous complexity of earthquake motion; it may also serve to open the eyes of seismologists of the older school to the perfection to which earthquake measurement has now been brought. We learn by a Japanese advertisement that a native firm (Seirensha and Co., Tokio) has undertaken to sell copies of Prof. Sekiya's model, lacquered stand and all, at a price so low that it should induce many private persons, not to speak of curators of museums and others officially interested in scientific novelties, to possess themselves of this pretty and instructive Japanese "curio."

ANTON DE BARY.

ON January 19, after a painful illness, died Anton De Bary, for many years the Professor of Botany in Strassburg. He had been suffering for some time since his visit to this country in September, and had undergone an operation which entailed the removal of parts of the face, but he did not recover.

He was born in Frankfurt in 1831, and studied in Berlin under Alexander Braun. From an early age he showed extraordinary powers as an original investigator, and was successively Professor of Botany in Freiburg, Halle, and Strassburg, having held the latter distinguished post since 1872. His indefatigable labours as the editor of the *Botanische Zeitung*, since 1867, are well known; and English agriculturists knew him from his admirable exposition of his investigations of the potato disease, in 1861, and in the Journal of the Royal Agricultural Society for 1876.

De Bary's influence on the progress of biology has been enormous, and in attempting to form an estimate of the value of his contributions to science, we must try to picture the state of botany in 1850 or thereabouts, when his labours began.

Little was known of the Thallophytes beyond the apparently endless species-making, which was coming into shape, however, under the discriminating hands of Agardh, Harvey, and Kützing; Fries, Léveillé, Berkely, and Corda: the zoospores of Vaucheria had been seen, and the conjugation of Spirogyra was known. Thuret and Nägeli were at work: Hofmeister was publishing his illustrious work on the embryology of the Phanerogams and Cryptogams: von Mohl was creating a new school of vegetable anatomy.

Surrounded by these influences, De Bary was working at the structure and development of the Fungi causing "Rusts" and "Smuts," and in 1853 he published his first book on this subject: Thuret observed the details of the fertilization of Fucus in the same year.

De Bary was also occupied with the Algæ, and in 1854 published his observations on *Œdogonium* and *Bulbochæte*: Pringsheim's papers on *Vaucheria*, *Œdogonium*, *Saprolegnia*, and *Coleochæte* appeared in 1855-58. The great botanical questions of the day centred around the development of the lower Cryptogams.

Then came De Bary's researches on the *Conjugateæ*, published in 1858, where the essentials of sexual reproduction are described with wonderful accuracy; and this was followed by his observations on the germination of *Lycopodium*, a piece of work so good that although we have only come into possession of most of the remaining facts quite recently, his old figures have been found worth reproducing.

But, as is well known, De Bary abandoned this newer pursuit of the green plants to return to his earlier love, the Fungi; and from about 1860 onwards he sent forth memoirs and books into the world of a nature to shake the tottering hypotheses of the day to their foundations, building up in their place the beginnings of what is rapidly becoming a mighty and coherent superstructure.

Until about 1850 little was known of Fungi beyond the mycelium and spores of the larger forms. The Tulasnes were at work, and had described several of the "Rusts," &c., before De Bary's book came out, and by 1853 the development of the Ergot of rye had been observed. Then followed their brilliant descriptions of the development and germination of the spores of *Cystopus*, *Puccinia*, *Tilletia*, *Ustilago*, and in 1861-65 Tulasne's "Selecta Fungorum Carpologia" appeared.

De Bary was already bringing forward the methods which distinguish his work so eminently from the anatomical method of his predecessors, and by 1863 he had not only cultivated many forms of Fungi, and repeatedly seen the sexual organs of the *Peronosporeæ*, but he showed that the fructification of the *Ascomycetes* is also to be traced back to the interaction of sexual organs. These may be regarded as the starting-points of the long series of researches into the sexuality of the Fungi which have already led to such remarkable results, and with which the names of De Bary and his school are so intimately associated.

In 1864, De Bary published the second edition of his book on the *Myxomycetes* (the first edition was in *Zeitschr. für Wiss. Zool.* 1859), and we ought to point out that the first edition of this work, coming at the time when the observations on zoospores by A. Braun, Thuret, Nägeli, Pringsheim, and De Bary himself, were astounding the botanical world, helped much towards clearer conceptions regarding the "sarcode" of the zoologists, and the protoplasm of the botanists.

This year (1864) also saw the first number of the celebrated "Beiträge zur Morph. u. Phys. d. Pilze," and in 1865 were produced the startling results of his further cultures of parasitic Fungi, in which he showed how—by regarding a parasite as an organism to be cultivated on its proper medium, just as we regard wheat as an organism to be grown on suitable soil—its life-history can be followed without those large breaks in continuity which render so much of the anatomical evidence worthless. By means of these researches De Bary proved the entrance of the parasitic Fungus into the host, and its progress in the tissues, so conclusively that any doubts still lurking on the main subject were for ever dispersed. The importance of these results cannot be rated too highly: they not only entirely altered the position of the agriculturist towards his fungoid enemies, but they introduced a new era in medicine. Their bearings on science were simply beyond valuation. From this point onwards the continuous observations of cultures under the microscope became extensive; and in the hands of those who were not too readily deterred by the technical difficulties and the laborious patience of such researches, there sprang up the beginnings of that knowledge of the diseases of plants which is now taking shape under the action of workers trained by De Bary himself.

Nor was this all. The startling facts of heterœcism were at the same time put before the world, and on such evidence that none could reject the phenomenon: De Bary proved that the so-called *Æcidium* of the Berbery is only a phase in the life-history of the *puccinia* of the rust of wheat. The repeated confirmation of this in later years, and the numerous similar cases which have been discovered since, sufficiently attest the accuracy of the original work; while its practical importance is obvious.

In 1866 was published the first edition of the "Morphologie und Physiologie der Pilze, Flechten, und Myxomyceten," a book which gave definiteness to the scattered knowledge of these organisms, and enabled the scientific world to see clearly the remarkable power of the man. His unflinching honesty and rigorous self-criticism and modesty had already attracted the attention of all who came in contact with him or his work; now, however, was seen the marvellous grasp of details, and the power of logical generalization which he possessed, and thenceforward the name of De Bary was associated with the leadership of the modern school of biologists he was himself creating.

As evidence of his untiring industry, it may be pointed out that not only did he publish the second number of the "Beitrage zur Morph. und Phys. d. Pilze" this year, but he had already taken in hand that monument of laborious investigation and critical reading, the "Comparative Anatomy of the Phanerogams and Ferns," which was not finished until 1877. The years 1869, 1870, and 1871 show indications of his new labours—undertaken, it should be mentioned, because the original plan had been interfered with—in articles in the *Botanische Zeitung*, on the epidermis, on *Cycads*, &c. Nevertheless the third number of the "Beiträge" appeared in 1870, full of new work, and important, on the *Erysipheæ* and *Ascomycetes*.

During 1874 and 1875 he published two papers on the fertilization and germination of *Chara*, and a memoir on *Protomyces*. In 1877 was published his and Strasburger's joint memoir on *Acetabularia*, and the book above referred to—the "Comparative Anatomy of the Ferns and Phanerogams"—was finished. The influence of this work has been enormous: criticism has been cast on the plan and mode of treatment, but probably all botanists

capable of judging are unanimous in praising its extreme accuracy, justice, and completeness. 1878 and 1879 saw the publication of the essays on Apogamy, and on Symbiosis, two bright and suggestive papers, which have had a wide influence on succeeding work, and which connect De Bary's name paternally with new doctrines in biology.

In 1881 he was busy with the promulgation of his new facts and deductions in connection with the *Peronosporeæ*, and the phenomenon of apogamy in the Fungi. In addition to articles in the *Botanische Zeitung* on the classification of the Thallophytes generally, and of the Fungi in particular, he published extended and important observations on the *Saprolegnieæ* and *Peronosporeæ* (the 4th number of the "Beitrage zur Morph. u. Phys. d. Pilze."), and the philosophical scheme of classification of the Fungi which forms the basis of our present system. Space will not admit of our referring further to his other memoirs, and it is impossible to even mention the numerous illuminating ideas and suggestions which are scattered through his papers, for we must proceed to the passing enumeration of his last two books, either of which would have sufficed for the reputation of an ordinary great man.

In 1884 was published his "Comparative Morphology and Biology of the Fungi, Mycetozoa, and Bacteria," and the best idea of De Bary's influence can be obtained by comparing this work with his "Morph. u. Phys. d. Pilze, Flechten, u. Myxomyceten," published eighteen years previously.

In 1885, De Bary brought together a series of lectures on Bacteria, since published in the form of a book: it is in his best style, and brings before the reader by far the clearest trustworthy general account of this astonishing and fruitful subject. Here, as everywhere, to take a subject in hand was to aid it: had De Bary done no more for "bacteriology" than observe and clearly describe the development of the spores of *Bacillus Megaterium*, his influence would have been felt; and the student is especially indebted for his careful sifting of the literature, and his suggestive indications.

One of his latest efforts was on the subject of infection, particularly with reference to certain *Pezizæ* and Sclerotia: he placed firmly on record the discovery that some of these Fungi may be harmless saprophytes until they have been cultivated—educated up to a higher degree of power—and then they can enter into and destroy a living host, which resisted them previously.

It should also be remembered that he was for many years editor of the *Botanische Zeitung*, and lent his aid to the forwarding of numerous botanical projects.

The above sketch may serve to convey some idea of the labours of the great Strassburg botanist. But, although they give a glimpse of the specialist's results, they afford no insight into his keen appreciation of all good work; of his humorous and never malicious disposition, in the laboratory, and in his writings; and of his sharp, but always just, criticism of anything pretentious. Nor is it possible to enter here into his abundant knowledge of species: he was one of the first to grasp Darwin's teachings, and perhaps never misapplied them. His close acquaintance with species and even local varieties of the plants around Strassburg, at any rate, could only be known to those who have walked with him; and the delight of those walks in Alsace!

As a lecturer he was not brilliant: he appeared shy and nervous when on the daïs, but in spite of his low voice and restless fingers he kept his hearers interested, and always taught clearly. Quaint he often was, in speech and manner, but the impressive truthfulness of his nature, the earnestness of his teaching, and the absence of any striving after effect, gave to his very quaintness a charm and dignity the influence of which will never be forgotten so long as his pupils live. H. MARSHALL WARD.

NOTES.

WE print to-day a leading article on "Odium Medicum." As the questions to which it relates have already been fully discussed in the *Times*, it may be well to state that we do not intend to publish any correspondence on the subject.

SOME time ago the Australian Governments, through Sir Graham Berry, represented to the Home Government the fact that in their opinion much good might be done by an "Antarctic *reconnaissance*," preliminary to an expedition for the thorough exploration of the Antarctic regions. In order that this suggestion might be carried out, the Australian colonies offered to contribute £5000, on condition that a like sum should be given by the mother country. The proposal was supported by the Colonial Office, by the Royal Society, and by the Royal Geographical Society; nevertheless, the Treasury has announced that it does not see its way to the granting of an Imperial contribution. The objects to be attained do not seem to it to justify the payment of even so small a sum as £5000. There will, of course, be much disappointment in the Australian colonies, but it may be hoped that the idea of a joint Antarctic Expedition will not be abandoned. Perhaps a larger scheme than the one which has just been rejected would have had a better chance of success.

THE scientific education of the mining population of Cornwall was for many years in the hands of the Miners' Association of Cornwall and Devon—an institution founded in 1859, at the suggestion of the late Mr. Robert Hunt, F.R.S. Some time ago this body was amalgamated with another Cornish institution, and the united organization took the name of the Mining Association and Institute of Cornwall. A movement has just been set on foot for increasing the efficiency of this Association by the formation of a Museum of Mineralogy, to be established at Redruth, or elsewhere, in the heart of the great tin and copper mining district. It is held that such an institution will in no way interfere with the existing museums in the county—such as those of the Royal Institution at Truro, and of the Royal Geological Society at Penzance. The new museum, instead of seeking to exhibit attractive specimens, will be essentially practical and educational—a place for the earnest student rather than for the casual visitor. It will endeavour to collect characteristic samples of ores, and typical specimens of such other minerals as are of interest to the miner or to the geologist. In recognition of the services which Mr. Robert Hunt rendered to Cornwall by his persistent advocacy of the necessity of giving the young miners a scientific training, it is proposed that the new museum shall bear his name. The Committee appeals for contributions, either in money or in minerals, and for suggestions as to the development of the scheme. Communications should be addressed to Mr. T. C. Peter, Town Hall, Redruth.

MR. J. E. HARTING has been appointed Librarian and Assistant Secretary to the Linnean Society at Burlington House, in the place of Dr. Murie, resigned. Mr. Harting has for some years past been engaged in fulfilling the duties of Zoological Librarian at the Natural History Museum, South Kensington, where he has organized what is now the best zoological library in this country, although possibly not the largest in regard to the number of volumes. The new appointment has been made opportunely at the expiration of the Government grant for the purchase of books at South Kensington, and has given general satisfaction.

THE forty-first annual general meeting of the Institution of Mechanical Engineers will be held on Thursday, February 2, and Friday, February 3, at 25 Great George Street, Westminster. The chair will be taken by the President, Mr. Edward H. Carbutt, at half-past 7 p.m. on each evening. The discussion on Mr. John Richards's paper, on "Irrigating Machinery

on the Pacific Coast," will be resumed. The following papers will be read and discussed, as far as time permits:—"On the Position and Prospects of Electricity as applied to Engineering," by Mr. William Geipel, of Edinburgh; "Third Report of the Research Committee on Friction: Experiments on the Friction of a Collar Bearing."

THE 1888 Conference of the Camera Club, the central institute for amateur photographers, will be held in the theatre of the Society of Arts on Tuesday and Wednesday, March 13 and 14, under the presidency of Capt. W. de W. Abney, F.R.S.

THE eighth annual general meeting of the Essex Field Club will take place at the Public Hall, Loughton, Essex, on Saturday evening, January 28, at seven o'clock. Mr. T. Vincent Holmes will deliver the annual Presidential address, taking as his subject "The Subterranean Geology of South-Eastern England."

A PUBLIC Conference on the Sanitary Registration of Buildings Bill will be held at the Society of Arts, John Street, Adelphi, on Saturday, February 4. The chair will be taken at 4 o'clock by Sir Joseph Fayrer, F.R.S.

A NATIONAL Hydrographical, Meteorological, and Climatological Congress is to be held at Madrid in February.

THE American Society of Naturalists held its annual meeting in the Peabody Museum, New Haven, on December 27 and the two following days. *Science* explains that this Society, composed of professors and specialists, leaving to other scientific associations the function of presenting and discussing results, devotes itself to the publication of new methods, improved apparatus, and aids to science-teaching. The work of the Society falls into two sections—biology and geology—and a day of each meeting is devoted to each of these topics, while the third day is given over to a general discussion on some attractive subject. The attendance at the recent meeting was large, and, according to *Science*, the proceedings were both interesting and profitable.

THE *Monthly Weather Review*, published by the Chief Signal Officer of the United States for October 1887, contains a discussion of the movements of high barometer areas over the North Atlantic Ocean for the year 1885. Fifty-two well-defined areas passed off the coast, of which seven traversed the ocean to Europe, and three moved north-easterly, to the vicinity of Iceland. The average time occupied by the fifty-two anticyclones in advancing from the 90th meridian to the coast was about one day and a half, this rate of progression being considerably greater than the average velocity of cyclonic areas over that region. These areas of high pressure have an important influence on the paths of storms. During October 1887 the paths of sixteen depressions are also traced; four advanced eastward over Newfoundland, one of which traversed the ocean from coast to coast.

THE Meteorological Council have published the observations taken at stations of the second order during the year 1883 (218 pp. large 4to). Observations taken twice a day are printed *in extenso* for thirty stations, and monthly and annual summaries and extremes for forty-four stations. The positions of the stations are shown upon a key-map, but the map also shows that considerable districts in the west of Scotland and Ireland, and even on the east coast, for instance between Dundee and Seaham, are still unrepresented. The barometer observations (reduced to mean sea-level) are given to the nearest ·01 inch, instead of the ·001 inch as heretofore. There is also a useful summary of the hours of bright sunshine for the stations which are furnished with sunshine-recorders, but the yearly values are not calculated.

WE have received a sheet on which are three photographs of the total eclipse of the sun, August 19, 1887, taken at Yōmeiji-yama (long. 138° 59′ 23″ E., lat. 37° 37′ 13″ N., alt. 115 metres), Echigo, Japan, by M. Sugiyama, the observer of the Tokio Observatory, under the direction of I. Arai, the Director of the Tokio Observatory and the chief of the Expedition. The photographs were taken in the following order: L.M.T. 3h. 40m. 36·5s. (1m. 8s. after beginning of totality); L.M.T. 3h. 41m. 25·4s. (1m. 57s. after beginning of totality); L.M.T. 3h. 42m. 6·2s. (34s. before end of totality). In sending us these photographs, Mr. I. Arai writes to us:—"While bad weather prevented nearly all the observations at other stations in our country, I was very fortunate, my station being entirely free from clouds, at least during the totality. But I regret to inform you that, as we were not equipped with complete instruments, and the telescope used was only of small size and not sufficient for photographic purposes, the result was not very satisfactory, because some of the coronal rays, extending outside of the field of the telescope, do not appear in the photographs. I did not, however, like to make the least modification, neither in size, nor in shape, believing that it would be best to leave the actual phenomena just as represented by the photographic apparatus."

SEVERE earthquakes are reported from Ontario and Quebec on January 11, but no damage was done. Shocks are also reported from Columbia (South Carolina), Summerville, and Charlestown. According to a telegram sent from New York on January 23, three shocks had occurred at Newburyport, in Massachusetts.

MESSRS. MACMILLAN have arranged to publish in their "Student's Series" a new biological text-book, "Lessons in Elementary Biology," by Prof. T. Jeffery Parker, of the Otago University, New Zealand. The book will be written on a modification of the "type" system, the earlier chapters consisting of detailed accounts of the morphology, physiology, and life-history of selected examples of the lower organisms. Briefer accounts of important types of the higher animals and plants will be given, but, as the work is intended for the study and not for the laboratory, it will not be necessarily limited to readily accessible forms, and the plan will sometimes be adopted of omitting certain points of structure, development, &c., which from their complexity or aberrant character are unsuited to an elementary work. The book will be written throughout in such a way as to bring clearly before the student the fundamental principles and generalizations of biology, and will be fully illustrated. It is hoped that it may serve to supplement the lecture-notes of a student attending an ordinary junior University course of biology, and, in the case of one working independently, to supply the connected narrative which is not readily obtained in suitable form either in a laboratory manual or in the ordinary text-books of zoology and botany.

THE "Zoological Record" for 1886 has just been issued. For sixteen years the annual volume of this most useful work was issued by the "Zoological Record" Association, which was aided by grants from various sources. At the close of 1886 the Association failed to obtain the renewal of some of these grants; and, being unwilling to carry on the publication of the "Record" any longer, it came to an agreement with the Zoological Society, by which the task was undertaken. The Council of the Zoological Society appointed a Select Committee to superintend the new enterprise, and Mr. F. E. Beddard was made editor. In the preface to the present volume Mr. Beddard explains that the only change he has made is the introduction of a section devoted to general subjects. This includes text-books and works of a general nature, many of which are again recorded under the several groups with which they are more especially concerned.

UNDER the title "A Year's Insect-Hunting at Gibraltar," there appears in the January number of the *Entomologist's Monthly Magazine*, a valuable paper by Mr. James J. Walker,

on the entomology of Gibraltar, concerning which subject next to nothing had previously been written. Mr. Walker, as an officer of H.M. gunboat *Grappler*, stationed there, had ample opportunities for studying the insect-fauna. His observations are mainly confined to *Lepidoptera* and *Coleoptera*. He says there is scarcely a day throughout the year on which butterflies may not be found; and he enumerates fifty-five species for the limited district, thirty of which have occurred on the isolated Rock itself. *Coleoptera* are very numerous, and he has already found 900 species, and is almost daily adding to the number. Apart from its purely entomological interest, the introductory portion is of great value, being a lucid *résumé* in a few pages of the topography of the Rock and the immediate neighbourhood, with sketches of the chief botanical, zoological, geological, and meteorological features, not forgetting the Barbary apes, which, reduced a few years ago to less than a dozen individuals, are now so numerous as to cause serious depredations in the gardens.

WE have received the volume for 1886 of the Journal and Proceedings of the Royal Society of New South Wales. Among the contents may be noted the Presidential Address by Prof. Liversidge, F.R.S.; description of an unrecorded Ardisia of New Guinea, by Baron von Mueller, F.R.S.; a comparison of the dialects of East and West Polynesian, Malay, Malagasy, and Australian, by the Rev. G. Pratt; preliminary notes on some new poisonous plants discovered on the Johnstone River, North Queensland, by T. L. Bancroft; notes on the process of polishing and figuring 18-inch glass specula by hand, and experiments with flat surfaces, by H. F. Madsen; notes on the theory of dissociation of gases, by Prof. R. Threlfall.

A LARGE number of new aromatic fluorine substitution products have recently been prepared by Drs. Wallach and Heusler (*Liebig's Annalen*, Band 243, Heft 1 and 2), the properties of which point to some interesting conclusions regarding the physical nature of fluorine itself. It is found that in all cases the specific gravity of a compound is raised by the introduction of fluorine instead of hydrogen. Thus while benzene at 20° has the specific gravity 0·8846, fluorbenzene, C_6H_5F, at 20° possesses a specific gravity of 1·0236. But, on the other hand, the substitution of fluorine is found to have a remarkably small effect in raising the boiling-point; for instance, fluorbenzene enters into ebullition at 85° C., a temperature only 5° higher than that of boiling benzene. What is, however, still more interesting is the fact that the difference between the boiling-points of corresponding iodine and bromine substitution products, and again between those of bromine and chlorine is smaller than that between the substitution derivatives of chlorine and fluorine. Whilst this difference of boiling-point between corresponding bromides and chlorides amounts to 20–23°, that between chlorides and fluorides approaches 40°. This fact, coupled with the small influence which the substitution of fluorine exerts upon the boiling-point, indicates the interesting probability that the boiling-point of free fluorine itself lies very much below that of chlorine (–33°·5), and that fluorine much more nearly approaches the volatility of hydrogen. Indeed, it appears likely that fluorine is one of the so-called permanent gases, and might form a worthy object for the attentions of those who have been so successful in inducing the other "permanent" gases to reveal their boiling-points; the difficulties in the way would of course be immense, but, in face of what has been done, are not perhaps insuperable. Under all circumstances fluorine attaches itself to carbon with far greater tenacity than any of the other halogens, as was clearly shown by leaving one of the new fluorides, bromfluorbenzene, C_6H_4BrF, in cold ethereal solution in contact with metallic sodium. After eight days a considerable quantity of sodium bromide had formed, but not a trace of the fluoride of sodium. The fluor-compounds themselves form a most valuable contribution to organic chemistry, and fill up a gap which has long been noticeable in the literature of the subject.

MR. J. A. CROWE, Her Majesty's Commercial Attaché for Europe, reports to the Board of Trade that the French Legislature has recently passed a law enacting that a prize will be given to the discoverer of a simple and practical test to ascertain the presence in spirits and alcoholic drinks of substances other than pure and ethylic alcohols. The conditions under which the award is to be made will be determined by the Academy of Sciences of the French Institute.

IN the last number of the *Zoologischer Anzeiger*, Dr. Otto Zacharias earnestly recommends the establishment of a zoological station on a German lake for the observation and study of the freshwater fauna.

THE other day three ladies in India received the degree of B.A.,—two at the University of Calcutta, and one at the University of Bombay.

A SEAM of good coal is reported to have been discovered in Cashmere. An officer of the Indian Geological Survey is to be sent to examine it.

RECENTLY an elk was shot in Galicia. It is now 130 years since the last of these animals was killed in Austria. It is believed that the one referred to had come from Lithuania.

IT is generally believed that the Polar bear cannot be tamed. Last autumn, however, a Norwegian skipper brought one of these bears with him from the Arctic Sea to Tromsö, and it has become quite tame. The bear plays like a dog with the crew of the vessel, and follows its master everywhere. It is nearly full grown.

THE Spitzbergen whale-fisheries have been more remunerative during the last two years than at any time during the past quarter of a century. Last year 1311 animals were killed. The whalers are English, Russian, and Norwegian.

A MAGNIFICENT gift has lately been received by the Ethnological Museum at Leipzig, from Dr. Alphonse Stübel (Dresden), Dr. Wilhelm Reiss (Berlin), and Consul-General Benedix Koppel (London). It consists of a rich collection of articles illustrating the culture and industry of ancient and modern South American races. The collection is divided into two parts: the first being objects belonging to the period before the Spanish conquest, the second being modern. There are many figures, vessels, weapons, and implements of stone and clay, found in the old Columbian, Bolivian, and Peruvian tombs, as well as ancient silver, copper, and bronze ornaments from Ecuador and Peru. The Columbian antiquities, and the ancient gold objects of the Chibchas, are specially noteworthy.

THE additions to the Zoological Society's Gardens during the past week include two Snow Finches (*Montifringilla nivalis*), European, presented by the Lord Lilford; two Cockateels (*Calopsitta novæ-hollandiæ*) from Australia, two Pale-headed Parrakeets (*Platycercus pallidiceps*) from North-East Australia, presented by the Hon. Stormont Finch-Hatton; an African Buzzard (*Buteo desertorum*) from Africa, presented by Mr. Sydney H. Carr, four Barbary Turtle Doves (*Turtur risorius*) from North Africa, presented by Mr. John Biehl; two Herring Gulls (*Larus argentatus*), British, presented by Mr. Thomas A. Cotton; a Common Barn Owl (*Strix flammea*), British, by Mr. Hugh Bromley; a Moorish Gecko (*Tarentola mauritanica*) from France, presented by Mr. J. C. Warbury; two Viscachas (*Lagostomus trichodactylus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CAPE OBSERVATORY.—The second portion of the data upon which the forthcoming Cape Catalogue for 1885 will be founded has recently appeared. The first portion, containing the results of the meridian observations made during the years 1879, 1880, and 1881, was published by Dr. Gill some time ago, and the present volume gives the results from the beginning of 1882 to February 8, 1885, when, the programme for the observation of the fundamental stars of Schönfeld's *Durchmusterung* —which stars will form the most important part of the Catalogue —having been completed, further work with the transit instrument was suspended. An additional reason for the interruption of the meridian observations lay in the desirability of re-polishing the object-glass, and of replacing the micrometer screws of the circle microscopes, which were of gun-metal, by steel screws. The investigation of the errors of the screws used in the present observations forms the most important portion of the introduction, for the effect of wear upon them has attracted Dr. Gill's special attention, and has already formed the subject of a lengthy paper by him in the *Monthly Notices* of the R.A.S., vol. xlv. The transit instruments of the Cape and Greenwich Observatories are almost exactly alike in construction; it is therefore interesting to note that there are evident differences in their behaviour; thus the mean horizontal flexure of the Cape instrument, as determined by the collimators, amounts to nearly half a second—0″·462—whilst that of the Greenwich telescope is almost insensible.

The introduction is followed by 144 pages giving the separate determinations of the various instrumental corrections, the readings of the transit-circle thermometers, &c. The ledgers and catalogues for the years 1882, 1883, and 1884 occupy the remaining 400 pages, the catalogues for the three years containing respectively 863, 444, and 1301 stars, reflex or sub-polar observations of stars being counted separately.

THE PARALLAX OF MARS.—We have received a letter from Mr. C. G. Stromeyer, calling attention to the fact that Mars is stationary on March 4, and urging the desirability of determining its parallax by the diurnal method, the rather that it will then be near two sixth-magnitude stars, as will be seen by the following positions:—

	Mag.	R.A. h. m. s.	Decl. ° ′ ″
95 Virginis	... 6	... 14 0 48	... 8 46 47 S.
94 Virginis	... 6	... 14 0 22	... 8 21 27 S.
Mars	..	... 13 56 16	... 9 2 20 S.

Unfortunately, however, the parallax is small—only 11″·3, and only part of this is practically available for the diurnal method, as the planet cannot be observed through a longer period than eight hours at the utmost.

THE LONGITUDE OF ODESSA.—The *Astronomische Nachrichten*, No. 2820, gives the result of the determination, by Dr. E. Becker and Prof. Block, of the difference of longitude between Berlin and Odessa, which was carried out in July and August 1876 by the telegraphic method. The deduced distance in longitude of the centre of the axis of the Repsold meridian-circle of the Odessa Observatory to the east of the centre of the great dome of the Berlin Observatory is given as 1h. 9m. 27·29s.

THE WINKLER OBSERVATORY.—Herr Winkler notifies, in No. 2821 of the *Astronomische Nachrichten*, the transference of his private observatory from Gohlis, near Leipzig (N. lat. 51° 21′ 35″·1; long. E. from Greenwich, 0h. 49m. 29·65s.), to the neighbourhood of Jena. The growth of the city of Leipzig rendered the old site no longer a favourable one for observation. The transit-instrument and small 4-inch refractor are already temporarily mounted. The co-ordinates of the new observatory are taken at present as being N. lat. 50° 55′ 35″·6; long. E. from Greenwich, 0h. 46m. 20·8s. Herr Winkler publishes at the same time some observations of occultations and eclipses of Jupiter's satellites made in the first half of 1887, which were the last observations made at Gohlis.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 JANUARY 29—FEBRUARY 4.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 29

Sun rises, 7h. 45m.; souths, 12h. 13m. 19·9s.; sets, 16h. 41m.: right asc. on meridian, 20h. 46·1m.; decl. 18° 0′ S. Sidereal Time at Sunset, 1h. 14m.

Moon (at Last Quarter on February 4, 19h.) rises, 16h. 20m.*; souths, 0h. 15m.; sets, 8h. 1m.: right asc. on meridian, 8h. 46·0m.; decl. 17° 56′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′
Mercury..	8 16 ...	12 46 ...	17 16 ...	21 18·8 ...	17 39 S.
Venus ...	5 20 ...	9 23 ...	13 26 ...	17 55·5 ...	21 47 S.
Mars ...	23 32*...	5 0 ...	10 28 ...	13 31·9 ...	7 2 S.
Jupiter ...	3 13 ...	7 30 ...	11 47 ...	16 1·6 ...	19 45 S.
Saturn ...	15 51 ...	23 45 ...	7 39*...	8 19·8 ...	20 6 N.
Uranus ...	23 1*...	4 33 ...	10 5 ...	13 4·5 ...	6 9 S.
Neptune..	11 29 ...	19 8 ...	2 47*...	3 41·6 ...	17 54 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich).

M signifies maximum; *m* minimum.

GEOGRAPHICAL NOTES.

GENERAL PRJEVALSKY has begun to print his narrative of his fourth journey in Central Asia. It is expected to appear in May, and we may hope that it will find an English translator.

WE are glad to learn that the French explorer of the Gran Chaco, M. Thouars, is safe. The Bolivian Government succeeded in rescuing him from a perilous position among hostile Indians.

A SCOTCH merchant captain, Mr. Strachan, has just returned from New Guinea, many hitherto unexplored parts of which he seems to have visited. It is expected that he will be able to give information that will seriously modify the cartography of the Fly River region. He maintains that the forests in New Guinea are confined to a fringe along the banks of the rivers, and that the bulk of the interior is covered with grass. Captain Strachan has brought home with him a young Papuan boy.

THE steamer *Essex*, of the United States Navy, has been making a series of soundings between Cape Guardafui and Ceylon. In the Indian Ocean, between 60° and 70° E. long., a uniform depth of about 2000 fathoms is almost constantly met with, gradually decreasing as the coast is approached. The greatest depth met with was 2705 fathoms, off the coast of Africa, 160 miles from Cape Guardafui. To the east of this

maximum, the sea-bed rises suddenly to a depth of only 857 fathoms below the surface.

THE new part of the *Mittheilungen* of the Hamburg Geographical Society contains several papers of interest. Dr. Sievers concludes the long series of papers describing the results of his journeys in Venezuela with some remarks on his original route map of the Venezuelan Cordilleras, which are accompanied by an admirable reproduction of this map. In addition to this, Herr Frohberg arranges and discusses the barometric results obtained by Dr. Sievers. Dr. Zintgraff describes the Lower Congo from Banana to Vivi, and insists on the importance of the Congo for the exploration of the region behind the German Cameroons protectorate. Herr Weisser gives a fairly complete account of German New Guinea and the Bismarck Archipelago; and Herr Hernsheim does the same for the Marshall Islands.

As a supplement to the Indian Survey Report for 1885–86, there has just been issued the narrative of the journey of a native explorer, M—H, through Eastern Nepaul into Southern Tibet, as far as the town of Dingri, and westwards and southwards through Central Nepaul. M—H has succeeded in rectifying in many points existing information on the hydrography of the region traversed, and gives many useful notes on its physical geography and its flora, as well as on the people.

OUR ELECTRICAL COLUMN.

THE additional facts added to our knowledge of electricity in 1887 are not very numerous, but the impetus given to its practical applications was very encouraging. One of the most important scientific discoveries was that of Prof. J. J. Thomson, which formed the subject of the Bakerian Lecture, viz. that sparks in tubes dissociated iodine, bromine, and chlorine. In iodine the dissociation produced at 214° C. was as much as that effected directly by Victor Meyer at 1570° C.

PROF. EWING showed that there was apparently no limit to the magnetization of iron in strong magnetic fields when we increased the magnetizing force, and Prof. Roberts Austen showed that it was impossible to separate the elements of alloys by means of electric currents.

IMMENSE improvements have been made in the construction of dynamos, motors, accumulators, and secondary generators, and in consequence electric lighting and working of railways and tramways are upon a commercial and useful stage. Many other causes besides restrictive legislation have retarded electric lighting in England, but there are now many signs that this useful industry is in more senses than one about to commence a very bright career.

SEVERAL useful constants have been added to our notebooks during the past year. Dr. John Hopkinson is pursuing his examination of the specific inductive capacity of oils and other liquids.

MR. PREECE has determined the coefficient of self-induction of straight iron telegraph aërial wires to $0{\cdot}005 \times {\cdot}10^9$ centimetres per mile, while that of copper wire is practically *nil*. He has also measured the current which will just actuate a Bell telephone, and he found it to be 6×10^{-13} ampere.

THE application of powerful electric currents to smelting, as in the Cowles process for producing aluminium, and to welding, as proposed by Elihu Thompson, is gaining rapid progress, while the use of enormous dynamos for the deposition of pure copper from impure ores is gaining ground with giant strides. Messrs. Bolton, at Widnes, and Messrs. Vivian, as well as Messrs. Lambert at Swansea, are each depositing from forty to fifty tons of copper per week by currents of from 5000 to 10,000 amperes.

THE Society of Telegraph-Engineers and Electricians has decided to change its title to that of the Institution of Electrical Engineers—a change for the better. Mr. Graves, the new President, gave an exceedingly interesting address on the industrial importance of electricity, and he brought out the remarkable fact that there are at least 300,000 persons in the United Kingdom depending upon electrical industry for their daily bread.

SOME of our prominent workers in the field of electricity, such as Lord Rayleigh, Sir William Thomson, and Prof. Hughes, are conspicuous by their absence during the past year, although the two former have been by no means idle in other directions.

A NOTE ON VALENCY, ESPECIALLY AS DEFINED BY HELMHOLTZ.[1]

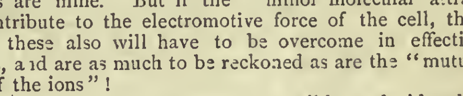
VERY little has been either said or written of late on the subject of valency—not because the topic is admitted to be exhausted, nor because our views can be regarded as reposing on a fixed basis of fact, but more I believe on account of the feeling being almost universally entertained that little is to be gained by continuing the discussion from our present standpoint.

My purpose in this note is to call attention to the extreme importance of reopening the discussion on account of the intimate bearing that it has on the work in which the Electrolysis Committee, jointly appointed by Sections A and B, are now engaged; and to urge that it is time that the gage thrown down by Helmholtz in the Faraday Lecture (Chem. Soc. Trans., 1881, p. 277) was uplifted by chemists.

We are told by Helmholtz that it is a necessary deduction from the fundamental law of electrolysis established by Faraday, that definite, as it were atomic, charges of electricity are associated with the atoms of matter; that, in fact, a monad bears a single charge, a dyad two, a triad three; and that when combination occurs the charges are still retained by the atoms but neutralize each other—"the atoms cling to their charges, and opposite electric charges cling to each other." I cannot help thinking, however, that Helmholtz deprives his statement of much of its force and simplicity by adding: "But I do not suppose that other molecular forces are excluded, working directly from atom to atom." He is led to do this apparently by being aware of the distinction which it is usual to draw between atomic and molecular compounds. The attempt should at all events be made—and in my paper on "Residual Affinity" I have already ventured the first step—to include both classes of compounds, molecular as well as atomic, in the discussion; indeed it is somewhat difficult to reconcile the passage above quoted with the following statement which occurs previously in the lecture: "The law of the conservation of energy requires that the electromotive force of every cell must correspond exactly with the total amount of chemical forces brought into play, not only the mutual affinities of the ions, *but also those minor molecular attractions produced by the water and other constituents of the fluid.*" The italics are mine. But if the "minor molecular attractions" contribute to the electromotive force of the cell, then conversely these also will have to be overcome in effecting electrolysis, and are as much to be reckoned as are the "mutual affinities of the ions"!

It is obvious that if it should prove possible to decide what number of charges are necessarily associated with any particular atom, the conception of valency will have acquired a definiteness which cannot possibly be attached to it as long as the views that have hitherto guided us are adhered to. A decision must involve the discussion of the question of the existence of molecular as distinct from atomic compounds.

To cast the apple of discord without further preface, I would direct attention to the insufficiency of the evidence on which it is usual to rely as proof that nitrogen, for example, is a pentad; nay more, I would assert that this very evidence should be interpreted as proof that nitrogen is not a pentad. It is commonly held that the behaviour of the alkyl tetra-substituted derivatives of ammonium is such as to negative the idea that these are "molecular compounds" of triad nitrogen, and that it must be assumed that the elements of the binary compound which are added to the ammonia derivative are *distributed* in the ammonium derivative; for example, that in the formation of tetramethylammonium iodide from trimethylamine and methyl iodide the methyl and iodine of the iodide part company and separately attach themselves to the nitrogen, thus:—



But I contend that the properties of tetramethylammonium iodide and hydroxide prove that such is not the case: the iodide, it is well known, can be boiled for hours with the strongest caustic potash solution without undergoing change; there is not a single

[1] A Paper read by Prof. Henry E. Armstrong, F.R.S., in Section B of the British Association at Manchester. Communicated by the Author.

case on record, however, of any haloid compound other than an alkylic compound behaving in this manner; the chlorides, bromides, and iodides of every element except carbon are almost at once converted into hydroxides by such treatment, and a nitrogen iodide would surely be acted on. The behaviour of the iodine is much more nearly that of iodine in methyl iodide, and, it may be said, exactly that of the iodine in iodobenzene; indeed it would seem that in the alkyl-ammonium haloid compounds the halogen is always less easily displaced by the action of alkalies than it is in the parent haloid alkylic compound.

The remarkable resemblance of the tetra-substituted ammonium hydroxides to potassium hydroxide has led to their being regarded as in every respect analogous to this latter, and would appear to preclude the idea that they are molecular compounds of an alcohol with an ammonium derivative. But attentive consideration of their properties will suffice, I think, to show that the apparent discrepancies are not only explicable, but that they actually support the molecular compound hypothesis. Thus it might be said to be improbable that tetramethylammonium hydroxide should behave as a powerful base, and have the same heat of neutralization as potassium hydroxide, if methyl-alcohol were one of its proximate constituents; but it is to be remembered that the salt which results from the action of an acid on methyl-alcohol is liable to suffer reconversion into the alcohol by the action of the water produced in the interchange; also that in many cases the methyl salt is insoluble in water, or nearly so. The heat developed on neutralizing methyl-alcohol therefore falls far short in amount of that which would be evolved if the interchange were complete, and if the product were capable of interacting with water, and perhaps also with itself in the way that apparently is possible in the case of metallic salts. In the case of the tetramethylammonium hydroxide, the action of acids is total as the change is irreversible, or almost so, under the conditions which obtain during the formation of the salt, just as in the case of the conversion of potassium hydroxide into a salt; moreover, the product is easily soluble, even when acids like muriatic are used. Why the methyl-alcohol, or other methyl derivative, retained in the ammonium compound behaves so differently as compared with the unassociated methyl derivative, is a question which, for the present, we must be content to put aside unanswered. I am also of opinion that in discussing their constitution no particular weight can be attached to the mode in which the tetralkylic ammonium hydroxides undergo decomposition when heated, as the products in some cases are an amine and an alcohol, but in others an olefine and water, instead of an alcohol; in the case of the phosphonium salts the diversity is still greater (Chem. Soc. Proceedings, 1886, p. 164). That amines may act as "dehydrating" agents in the manner required if the molecular compound hypothesis be adopted, appears by no means improbable.

What is here stated of the tetramethyl compounds is true of tetralkylic ammonium haloid compounds generally, in the sense that they are all less readily acted on by alkalies than are the parent alkylic haloid compounds; but just as these latter are more readily attacked by alkalies and other agents the more complex the alkyl, so are the tetralkyl ammonium compounds; in no case, however, do they manifest a reactivity at all comparable with that of simple metallic or non-metallic haloid compounds—always excepting those of carbon.

The argument used above would apply equally to the phosphonium and sulphine compounds; indeed with greater force.

In many other respects the behaviour of nitrogen in aminic compounds is altogether peculiar and irreconcilable with the assumption of pentadicity. Thus it is commonly pointed out that the basic properties of aniline, for example, become lessened and ultimately almost annulled by the introduction of chlorine or bromine into the phenyl radicle; and that acetamide, $C_2H_3O \cdot NH_2$, and other similar compounds formed by the introduction of acid radicles into ammonia are all but destitute of basic properties; the power to form ammonium compounds, therefore, is not a simple function of the nitrogen atom, but is largely dependent on the nature of the radicles associated with the nitrogen atom. Other illustrations are afforded by the hydrazines. Thus phenyl-hydrazine, $C_6H_5 \cdot NH \cdot NH_2$, although it contains two atoms of (triad) nitrogen, forms with hydrogen chloride the compound $C_6H_5 \cdot N_2H_3 \cdot HCl$, which crystallizes unchanged from fuming muriatic acid, in which, moreover, it is almost insoluble. Ethyl-hydrazine, however, forms a dichlorhydride, $C_2H_5 \cdot N_2H_3 \cdot 2HCl$, but on evaporating the aqueous solution of this salt a monochlorhydride is obtained; and unsymmetric diethyl-hydrazine, $(C_2H_5)_2N \cdot NH_2$, is a monobase like phenyl hydrazine.

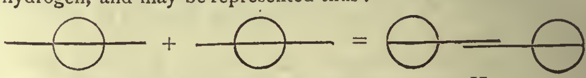
Hence it may well be argued that we have no reason to assume that nitrogen is pentad in the ammonium compounds, or phosphorus pentad in the phosphonium compounds, or sulphur tetrad [1] in the sulphine compounds; but that these are all to be reckoned as molecular compounds.

What then is the valency of the elements in question? and what is a molecular compound?

In answer to the first of these questions, the proposition may be advanced that gasefiable hydrogen compounds are the only compounds available for the direct determination of valency, and that the valency of an element—the number of unit charges necessarily associated with its atom—is given by the number of hydrogen atoms combined with the single atom of the element in its gasefiable hydride.[2] In cases where such hydrides are unknown, the determination of valency is very difficult; it can be but provisionally effected, and only by most carefully weighing all the evidence relating to the constitution of the compounds available for discussion.

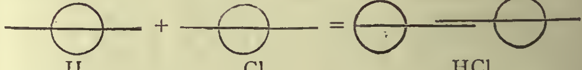
But if it be granted, for example, that nitrogen is a triad, and that iodine is a monad, how are we to explain the fact that the methyl compounds of these two elements unite to form so well characterized a molecular compound as tetramethylammonium iodide? how are such molecular compounds constituted? My own view has long been that the nitrogen and iodine in such a case are both possessed of a certain amount of *residual affinity*; and I would define a molecular compound as one formed by the coalescence of two or more molecules, unattended by redistribution of the constituent radicles, and in which the integrant molecules are united by residual affinities. In other words, the unit charge must be capable in certain cases of directly promoting the association, not merely of two, but of at least three, atoms. To put this hypothesis in terms which cannot be misunderstood, let unit valency or charge be represented by a unit line, and further be it supposed that the charge *penetrates the atom*, then the atom with its unit charge may be represented thus:—

i.e. the unit charge may be held to consist of three portions, the buried portion a, and the free portions $f + f'$. The facts, as they present themselves to me, also appear to necessitate the assumption that, in the case of different elements, the charge penetrates the atom—and in the case of some polyad atoms, different directions in the atom—with varying degrees of freedom.[3] The union of two atoms may then be pictured as an overlapping of the unit lines. If the atoms are freely penetrated by their charges, each atom may tend to move out to the end of the line, leaving either no portion, or but a very small portion, free; a conception of this order would appear to apply in the case of hydrogen, and may be represented thus:—



H. H. H_2.

But if the atom be not easily penetrated by its charge, it will not move out to the end of its line, and the resulting compound molecule will possess more or less "residual affinity;" this conception would appear to apply to the non-metals generally, and to some of the metals; it may be illustrated thus:—



H. Cl. HCl.

I have thought it permissible to state my views in this form merely in order to advance the study of molecular compounds

[1] Probably one of the strongest arguments in favour of the conclusion that sulphur is divalent may be based on its inactivity in the closed-chain compound *thiophen*, which does not unite with methyl iodide, nor does the sulphur in it or its homologues permit of oxidation in the manner that is characteristic of the element in thioethers.

[2] If this be granted, it follows that the maximum number of charges which an atom can carry is four; in other words, that the possible maximum valency is attained in the case of carbon.

[3] This is practically but a modification of Helmholtz's statement that "the phenomena are the same as if equivalents of positive and negative electricity were attracted by different atoms, and perhaps also by the different values of affinity belonging to the same atom, with different force."

by the introduction of a working hypothesis, an *absolutely artificial* mode of expression such as is here adopted being perhaps pardonable in the absence of any explanation which may serve to guide us in extending our inquiries as regards the structure of such compounds, a knowledge of which is all-important to a rational conception of the nature of chemical change generally. Moreover, I do not hesitate to affirm that, from the chemical point of view, it is impossible to adopt the Helmholtz explanation of valency, unless physicists are prepared to grant the possibility of the "division" of the unit charge somewhat in the manner here suggested; and it is in order to impress this that I have ventured to give utterance to these speculations.

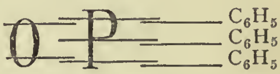
To return to the consideration of the compounds previously referred to, it may be supposed that the nitrogen of trimethylamine and the iodine of methyl iodide are possessed of residual affinity, and hence the two molecules unite to form the molecular compound tetramethylammonium iodide, which may be represented thus:—

The phosphonium and sulphine iodides may be regarded as similarly constituted. It is well known that the ammonium haloid compounds and their analogues are also capable of forming still more complex molecular aggregates with the halogens, &c.: they are therefore to be regarded as possessed of residual affinity; and that polyad elements, *e.g.* nitrogen, phosphorus, and sulphur, should still exhibit residual affinity in such compounds is not surprising in the light of the hypothesis advocated in this note; but it is scarcely compatible with the assumption that the halogen in the ammonium haloid compounds serves as the bond of union. On the other hand, if it be assumed, as I think it should be, that the formation of double metallic chlorides, &c., is the outcome of the possession of residual affinity by the halogen, the complete analogy which appears to exist between the ammonium haloid compounds and those of the alkali metals would seem logically to involve the inference that the halogen of the ammonium compound does not serve as the bond of union. I see but one mode of escape from this conflict of evidence, and that is to call in question the time-honoured assumption that the radical ammonium is the true analogue of potassium and sodium, which, be it remarked, is of necessity subject to doubt if the hypothesis that the ammonium salts are molecular compounds be entertained; and evidence which supports the conclusion that the per-haloid compound is formed by the addition of the halogen to the nitrogen (phosphorus or sulphur) is afforded by the observation that not only *haloid* ammonium and sulphine compounds, but also the *sulphates*, combine with halogens (Dobbin and Masson, Chem. Soc. Trans., 1885, p. 56; 1886, p. 846).

It is now proved by abundant experimental evidence that, whatever the order in which the radicles A, B, C, D are introduced in forming a tetralkylic ammonium compound N(ABCD)X, one and the same end product always results. This is commonly regarded as proof, not only that nitrogen is pentad, but also that the five affinities of the nitrogen atom are of equal value, and it would appear to favour the conclusion that the ammonium salts are in truth "atomic" compounds; but I see no reason why isomeric change should not occur at the moment of formation of a molecular compound—why the integrant molecules, in fact, should not interchange radicles. If the statement be confirmed[1] that the compound formed from dimethyl sulphide and ethyl iodide is different from that obtained on combining methylethyl sulphide and ethyl iodide (Krüger, *Journ. pr. Chem.*, 1876, xiv. p. 193), it will follow, not that sulphur is a tetrad, and that the four affinities are of unequal value, but that there is little or no tendency for isomeric change to occur in the formation of sulphines. The possible occurrence of isomeric change in the formation of molecular compounds, however, is a subject which certainly deserves careful study at the present time.

In the case of phosphorus, the existence of the highly stable gaseous pentafluoride PF_5, discovered by Thorpe, is undoubtedly regarded by many as final proof of the pentadicity of this element; but the existence of compounds such as H_2F_2, HFFR, &c., which clearly belong to the class of molecular compounds, is an indication of so marked a tendency on the part of fluorine to combine with itself, that for this reason alone (as Naumann and others have asserted) the pentafluoride is by no means necessarily regarded as an atomic compound. And I would here add that stability affords no criterion as between atomic and molecular compounds, every degree of stability being met with even among those of the former class.

An argument in favour of the pentadicity of phosphorus which apparently cannot be disposed of by any explanation based on conventional considerations has, however, been advanced by La Coste and Michaelis (*Berichte*, 1885, p. 2118), who have shown that the compounds obtained from diphenylchlorophosphine, $PCl(C_6H_5)_2$, and phenol is not identical with the triphenyl-phosphine oxide, $OP(C_6H_5)_3$, obtained by oxidizing triphenyl-phosphine, as it should be if the latter were a compound of the formula $(C_6H_5)_2P . OC_6H_5$; this last corresponding to the formula $Cl_2P . OCl$, which has been suggested as that of phosphorus oxychloride, and which appears to derive considerable support from Thorpe's observations on the specific volume of the oxychloride (Chem. Soc. Trans., 1880, p. 388). It is, however, conceivable that the oxygen and phosphorus are united by residual affinities, thus:—



Michaelis and Polis (*Berichte*, 1887, p. 52) have argued in the case of bismuth, which also is a member of the nitrogen group, that the pentadicity of this element is proved by the existence of the triphenyl dibromide, $(C_6H_5)_3BiBr_2$. But the mere production of such a compound proves nothing so long as its constitution is undetermined; it at most serves to strengthen the conviction gained from the general study of the element, that bismuth is a member of the nitrogen-phosphorus group.

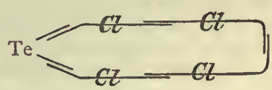
In other cases also it is possible that undue importance may have been attached to the existence of alkylic compounds of particular types: thus lead, judging from its general chemical behaviour, would appear to be a dyad; yet the existence of the tetrethide $Pb(C_2H_5)_4$, is commonly held to be a proof that it can function as a tetrad. But the properties of lead are such that I am tempted to suggest that it is one of the metals in which the "charges" have but a small degree of freedom; and it is conceivable that the tetrethide is actually a compound of dyad lead, each charge serving to bind two ethyl groups, thus:—

The same may be true of tin, although in this case the fact that we are dealing with an element of the carbon-silicon family tend to favour the conclusion that it may be a tetrad.

Also too much importance must not be attached to the existence of stable volatile chlorine compounds: thus tellurium *tetra*chloride may well be a compound of dyad tellurium, thus:—

Iron, and the other members of the family which boron heads, in like manner, I feel convinced, are triads even in their *ic* compounds: recent vapour-density determinations all support this conclusion.

It is even conceivable that chlorine may form *closed-chain* compounds, and that a tetrachloride may exist, such as is represented by the formula:—



I think it is especially noteworthy that so many well characterized and comparatively stable double chlorides exist formed by the union of chlorides of which one at least is *per se* very unstable; the tin-sulphur chloride, $SnCl_4 . 2SCl_4$, and the remarkable series of aurous compounds recently described by Lepetit (*Ann. Chim. Phys.*, 1887, p. 11) may be cited as examples.

[1] The number of *Liebig's Annalen* last issued contains a valuable paper by Klinger and Maassen disproving Krüger's statement.

If my contention in this and previous papers be correct, that residual affinity thus plays a far more important part than has hitherto been supposed, and that it must be taken into account in all discussions on valency, it follows of necessity that our views regarding the constitution of the majority of compounds at present rest upon a most uncertain basis: the constitution of the paraffins, of the benzenes, and of the haloid compounds and alcohols derived from the hydrocarbons of these series, may be regarded as determined with a degree of precision almost amounting to certainty; but in the vast majority of other cases we have as yet no secure method of arriving at conclusions which in any sense approach finality. There can be little doubt that in framing our modern conceptions of valency we have been too much influenced by the graphic symbols which have been so widely made use of. In the future it will be necessary to attach a more liberal interpretation to the facts, and it may be hoped that it will some day be possible also to take into account differences depending on the relation of the different forms of matter to the pervading medium.

The properties of compounds being demonstrably dependent on the intramolecular conditions, it is difficult for a chemist to resist the feeling that the peculiarities manifested by the different elements are also very probably the outcome of differences in structure; such an assumption indeed affords at present apparently the only explanation that can be given of the relationship manifest between different elements when these are classified in groups of "homologues" in accordance with the suggestion originally made by Dumas, which has now found full expression in the so-called periodic system of classification. There appears to be an increasing weight of evidence to favour the assumption that the influence exercised by compounds in cases of chemical change is local in its origin: that it is exercised more by a particular constituent or constituents—in particular directions, in fact—than by the molecule as a whole. The suggestion above made that "affinity" acts in particular directions in elementary atoms, and perhaps with different degrees of freedom in various directions, is therefore but an extension to elements of what is more or less generally recognized as the case in compounds. Some such hypothesis is certainly required to account for the existence of allotropic modifications both of non-metals and of metals; for the remarkable changes in magnetic and other properties which iron undergoes with change of temperature; for the different values of the dielectric constant—along the several axes in sulphur crystals; for the difference in electric conductivity of bismuth in two different directions in bismuth crystals; for the existence of planes in crystals in which cleavage takes place with special readiness, &c.—all these are instances which apparently afford evidence of atomic dissymmetry. May not valency after all depend—not in the number of "charges" carried by the atom, but—on the number of directions in which the ever-present "lines of force" are free to act?

WORK OF THE KEW OBSERVATORY IN 1887.

THE Annual Report of the Kew Committee, just issued, shows that the activity of the staff of the Kew Observatory is still well sustained, and the various departments devoted to observations—magnetic, meteorological, and solar—verification of scientific apparatus of various kinds, rating of time-pieces, and experiment, all show a considerable turn out of work. In addition to the regular periodical magnetical observations, the main results of which are given in a concise form in the appendixes, assistance was rendered to Profs. Rücker and Thorpe in respect to their valuable magnetic survey of Great Britain, which we are glad to learn they have now completed, after having devoted the greater portion of their vacations to the task for the last four years. The labours of the Krakatão Committee of the Royal Society, the Magnetic Committee of the British Association, the late Prof. Balfour Stewart, and other investigators, have also been supplemented by aid afforded by the Kew staff.

The meteorological staff have during the year recorded, principally on behalf of the Meteorological Council, who defray the expenses attendant on the work, some 57,126 observations averaging over 150 per diem; the resulting monthly and annual means are, by permission of the Council, published as appendixes.

The multiplication of Observatories engaged in solar photography at home and abroad having rendered unnecessary the co-operation of Kew in that branch of science, so energetically carried on there by the present Chairman, Mr. De la Rue, and the late Prof. Balfour Stewart, twenty years ago, the photoheliograph has only been employed of late years as an ordinary telescope, by means of which the counting of new sunspot groups is continued after Schwabe's method.

An appendix shows that during the last year 44 new groups were catalogued, and that on 60 days out of 180 days of observations the sun's surface was free from spots.

Under the heading "Experimental Work" we find a good deal of attention has been devoted to the photography of high cirrus clouds simultaneously from two points, with the view of determining their position and motions; and to the question of the proper construction of black bulb thermometers; and also to preparatory operations with the Indian Government pendulum apparatus, preliminary to repeating the observations made at the Observatory by Basevi, Heaviside, and Herschel.

There is a long list of various instruments compared and certified during the year in the verification department, which shows that nearly 14,000 articles belonging to one or the other of twenty-seven different classes have undergone treatment; as instruments newly brought within the influence of the verifier, attention is directed to range-finders for the use of the Army and Navy, telescopes of the Admiralty pattern, and surveying aneroids.

The popularity of the Kew certificates, as to the time-keeping of watches, shows that the demand for a guarantee as to the accuracy of performance of a watch other than the maker's name actually exists, and no less than 510 watches and 27 marine chronometers have been submitted to the rating department since the last report was issued.

An appendix showing the behaviour of the best of the watches during the test is given, and it is found that places in this list are being strongly contested for by watch manufacturers, as the blue ribbons of the trade. In consequence of the growth of the work done at Kew, steps have been taken to obtain the permission of Her Majesty's Chief Commissioner of Works and Public Buildings to enlarge the Observatory, which at present remains almost in the same condition as it stood 130 years ago when originally erected as His Majesty George III.'s private Observatory at Richmond.

THE TOTAL ECLIPSE OF THE MOON, JANUARY 28.

BY the kindness of the Astronomer Royal for Scotland, Mr. Gledhill, of Mr. Crossley's observatory at Bermerside, and Mr. Stothert, all of whom took part in the observation of the eclipse of October 4, 1884, we are enabled to give Prof. Struve's times and position-angles for the stars that will be seen to be occulted by observers stationed at Edinburgh, Halifax, and Bath. A comparison of these tables will enable intending observers in other parts of England to form a sufficiently correct list for their own locality.

The following ten stars, not included in the list given in NATURE for January 19, will be occulted as seen from Edinburgh:—

Star's No.	R.A.	Decl.	Star's No.	R.A.	Decl.

The Chief Assistant, Royal Observatory, Greenwich, Mr. H. H. Turner, will be obliged if successful observers will write or telegraph to him, *immediately* after the eclipse is over, the number of immersions and emersions observed, and the character of the night for observing.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. Sylvester is not to lecture this term; Mr. Es on will give for him courses on Higher Plane Curves and on Involution.

Prof. Pritchard promises two lectures on Modern Methods of determining Stellar Parallax, besides a longer course on Lunar and Planetary Theories.

In Physics, Prof. Clifton is giving only an elementary lecture; Mr. Walker lectures on the Polarization of Light, treated mathematically, and Mr. Baynes is to take up Fourier's Theorem and its Application to the Conduction of Heat.

In Chemistry, besides the usual systematic courses, Prof. Odling is lecturing on the Paraffins, and Mr. Veley on Physical Chemistry.

In the absence of Prof. Moseley, Dr. Hickson is lecturing on the Morphology of the Chordata; Mr. Hatchett Jackson lectures on Parthenogenesis.

Prof. Burdon Sanderson is treating of the Nervous System, and Prof. Bayley Balfour of the Algæ.

Dr. Tylor is giving Anthropological Elucidations of Greek and Latin authors, and the Reader in Geography is continuing the courses which he began last term.

The Professorship of Geology is to be filled up in the course of this term: applications will be received by the Registrar up to February 1.

The Radcliffe Fellowship will be awarded this term; also the Burdett-Coutts Scholarship, as soon as the Professor of Geology is appointed.

The number of men reading Medicine is steadily increasing, and now that it is possible for a man to pass his B.A. examinations and his first M.B. examination in four years, there can be little doubt that the increase will continue.

CAMBRIDGE.—Mr. H. D. Rolleston, B.A., M.B., of St. John's College, has been appointed Demonstrator of Pathology.

Sir F. A. Abel, F.R.S., has been appointed to deliver the Rede Lecture this year.

The Disney Professor (the Rev. G. F. Browne) will lecture on Tuesdays this term on Sculptured Stones of pre-Norman type in the British Islands. The inaugural lecture will be given in the Senate House on January 31.

Dr. F. Warner's lectures on the Growth and Development of the Intellectual Faculty began on January 25. The lectures aim at describing and analyzing the action of the brain of a child, with special application to educational methods.

SCIENTIFIC SERIALS.

THE most important article in the numbers of the *Journal of Botany* for December 1887 and January 1888 is one by Mr. S. Le M. Moore, "On Epidermal Chlorophyll," in which he shows that the presence of chlorophyll-corpuscles in the cells of the epidermis is of much more common occurrence than is usually stated in text-books, and that these chlorophyll-corpuscles very commonly contain starch-grains. The other articles relate to botanical nomenclature and to the distribution of British plants. In addition, Mr. J. G. Baker continues his "Monograph of the Tillandsieæ," and Colonel Beddome contributes a paper on Ferns of Perak and Penang.

IN the *Botanical Gazette* (Crawfordsville, Indiana) for December 1887 is an interesting paper by Mr. Byron D. Halsted, showing that under certain conditions pollen-grains may contain three nuclei, instead of the two usually found in them.

Bulletin de l'Académie Royale de Belgique, November 1887.—Action of the acids on the taste, by J. Corin. The object of these researches has been to ascertain what relation there may exist between the acid taste and chemical composition. The author arrives at the curious result that acidity increases with the quantity of basic hydrogen contained in the acid molecule, and decreases with the weight of the molecule itself.—Physical observations on Saturn, by Paul Stroobant. These observations, extending over the period from January 27 to April 20, 1887, show that the famous divisions of Encke and Struve appear to be subject to great modifications, especially as regards the actual position occupied by them. No doubt the state of the terrestrial atmosphere, the proximity of the moon, and other outward circumstances, must exercise a considerable influence on the character of the manifestations. But the changes here recorded, such as the disappearance of Encke's division while that of Struve is still visible, make it evident that other and more recondite causes are at work in producing these shifting appearances.—Experimental researches on the sense of vision in the Arthropods (second part), by Felix Plateau. In this section the author passes from a study of the Myriapods to that of the higher order of the Arachnidæ, and arrives at the general conclusion that in all the sub-groups of the Spiders, Scorpions, and Phalangidæ the visual sense is very feebly developed. They exhibit in general a vague perception of movement acting on their nervous system, rather than a clear sight of any definite object. In the case of *Epiblemum scenicum*, distinct vision does not seem to extend beyond a distance of 1 centimetre, while *Tegenaria domestica* and others seem unable to distinguish form at all. Even in the closest proximity they rush with equal avidity on true or false objects of prey. The scorpions also show little evidence of sight, shunning the light and awaiting, rather than pursuing, their prey, which they fail to detect except at very short distances. The same remark applies to the Phalangidæ, which compensate the defect of vision by the exquisite tactile sense of their extremities.

Rivista Scientifico-Industriale, November 1887.—On the heating of metallic points when discharging their electricity, by Prof. Eugenio Semmola. Some experiments are described scientifically demonstrating the fact that heat is generated while metallic points discharge their electricity, the points themselves becoming at the same time heated. It is suggested that this fact, now for the first time verified, might under certain conditions be utilized as a new means of studying atmospheric electricity.—On the anæsthesis and poisoning of plants, by Dr. Flaminio Tassi. An analysis is given of the researches and experiments carried out by Prof. T. Caruel, tending to show that certain plants really possess a property analogous to the irritability, excitability, sensitiveness, or contractibility of animals, as it is variously called; that this property is not derived from any particular nervous system, but from the vegetable protoplasm itself; that certain organic substances are alike fatal to plants and animals; and that a state resembling animal anæsthesis is also produced especially in those plants which are endowed with excitable organs, and in many flowers that open and close at fixed times.

THE last two parts of vol. xviii. of the *Izvestia* of the East Siberian branch of the Russian Geographical Society contain a variety of valuable information. In a paper on the lower course of the Upper Angara, Dr. Kiriloff brings together some interesting facts about the fishing in Lake Baikal, which, notwithstanding complaints about the disappearance of the *Salmo omul*, still yields every year about 30,000 cwt. of fish. MM. Priklonsky and Slyeptsoff contribute notes on the religious beliefs of the Yakutes, who, although christened, have retained in full their Shamanist religion and practices. M. Karpinsky gives some notes on the gold-diggings of the Olekma system. Especially valuable papers are contributed by M. Savenkoff, on his archæological researches on the Yenisei, and by M. Eleneff on the caves on the banks of the Biryusa River. It would be impossible to enumerate in a short note all the interesting data mentioned in M. Savenkoff's preliminary report. His numerous collections contain, among other things, big bones of the mammoth and the rhinoceros, which bear unmistakable traces of having been broken by man for the sake of the marrow, and thus belong to the very rare relics of the Palæolithic period in Siberia. His collections also include bones with grooves for the insertion of a stone arrow-head, and many interesting implements, showing that stone implements were largely used during the Bronze Age, and partly during the Iron Age. The full report of M. Savenkoff, which will contain accurate drawings of the Yenisei inscriptions, will be most valuable. As to the exploration of caverns on the banks of the Biryusa and the Yenisei, M. Eleneff gives only a short description of his diggings, with detailed drawings and lists of the implements and various things found: Chinese money from the thirteenth or fourteenth century in the upper layers, various iron implements in the middle layers, and Neolithic stone implements in the lowest layers. The same parts of the *Izvestia* contain preliminary reports about an excursion to Lake Kosogol and the Munku-Sardyk, by MM. Prein and Yaczewski, during which excursion the glacier of this peak was thoroughly mapped and photographed, and large collections of Alpine flora were gathered.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 22, 1887.—"Heat Dilatation of Metals from Low Temperatures." By Thos. Andrews, F.R.S.E.

The experiments of this paper were made to approximately determine the coefficients of heat dilatation of modern steels from low temperatures. The metals employed were wrought iron, "soft" Bessemer steel, "hard" Bessemer steel, "soft" Siemens-Martin steel, "hard" Siemens-Martin steel, "soft" cast steel, "hard" cast steel, &c., of known composition, specific gravity, &c., given in detail in the paper. The terms "soft" and "hard" relate only to difference of percentage of combined carbon. The ranges of tempera-

ture chosen for the observations were from $-45°$ C. to 300° C. The experiments were made on rolled bars of the various steels and also on large hammered forgings 5 inches diameter. Details are given in the paper of the general method of experimentation, and also of the methods adopted for reducing the metals to the very low temperature employed. The results of an extensive series of experiments are recorded in tabular form in the paper. The coefficients of dilatation were found generally to decrease with the reduced temperature. The author also found such to be the case in his recent observations on the heat dilatation of pure ice from low temperatures. There seemed to be a slightly greater dilatation in the direction of the length of the forged metallic cylinders than when measured across the diameter. It was also noticed that the coefficients of dilatation were greater in the case of steels having a lower percentage of combined carbon than in those containing a higher percentage.

January 12.—"Invariants, Covariants, and Quotient Derivatives associated with Linear Differential Equations." By A. R. Forsyth, F.R.S.

The memoir deals with the covariantive forms associated with the general ordinary linear differential equation. The most general transformation to which such an equation can be subjected without changing its character is one whereby the dependent variable y is changed to u by a relation $y = uf(x)$, and at the same time the independent variable is changed, say, from x to z. When these transformations are effected there are n relations between the coefficients P and Q of the equation in its two forms, and it is shown that from these others can be deduced which are of the form

$$\psi(\mathrm{P}) = \left(\frac{dz}{dx}\right)^{\rho} \psi(\mathrm{Q}).$$

Such a function ψ is called an invariant of index ρ.

Irreducible invariants are proved to be divisible into two classes, fundamental and derived. Each of the former, which are $n-2$ in number, consists of two parts; one of these is linear in the quantities P and their derivatives, the other is not linear, but has in every term as a factor either P_2 or some derivative of P_2. It is shown that the differential equation can be reduced to a canonical form without any term in $\frac{d^{n-1}u}{dz^{n-1}}$ or $\frac{d^{n-2}u}{dz^{n-2}}$; and hence each of the prior class of invariants is linear in the coefficients of the canonical form and their derivatives. These fundamental invariants are called priminvariants. The derived invariants are obtained from the priminvariants by two processes, which are called the quadriderivative and the Jacobian; they are most conveniently arranged in classes according to their degrees in the coefficients of the equation. The number of quadrinvariants is $2n-5$; the number of invariants of every degree higher than the second is $n-2$.

The relation between the independent variables of a semi-canonical form and of the canonical form shows that the dependent variable may be considered as a covariant. It is proved that there are other $n-2$ associate dependent variables, each satisfying a linear equation and possessing for the canonical form the invariantive property.

From this aggregate of dependent variables, a set of irreducible identical covariants is derived by the two processes formerly used for the invariants; when the equation is taken in its canonical form, all these covariants up to a certain order involve the dependent variables alone. There is also a set of irreducible mixed covariants which are the Jacobians of each of the dependent variables in turn, and one of the invariants.

Illustrations of the results are given for the equations of the second, the third, and the fourth orders; and in this connection, functions, called quotient derivatives, are obtained. Some of their properties are given, one of the most important being that they are covariantive for homographic transformation of both the dependent and the independent variables.

Finally, the characteristic differential equations satisfied by all concomitants are obtained; and among other inferences it is proved that the aggregate of concomitants constituted by the invariants and covariants obtained in the earlier part of the memoir is complete, *i.e.* that any concomitant can be algebraically expressed in terms of the members of that aggregate.

"Preliminary Note on the Nephridia of Perichæta." By Frank E. Beddard, M.A.

The following observations are the result of a study of a species of Perichæta, which is probably identical with Perrier's *P. aspergillum.* I owe a number of excellently preserved examples to the kindness of Mr. Shipley, Fellow of Christ's College, Cambridge.

In transverse sections of the anterior segments the nephridia are seen to form numerous tufts of glandular tubules closely related to the body-wall and to the septa. This appearance, which is also seen in dissections, is very different from that of most earthworms, and has been commented upon by other observers.

The remarkable appearance of the nephridia led me to infer that I should find the external apertures in each segment to be numerous, as I showed to be the case in Acanthodrilus. I am now able to state that this is also the case in Perichæta (in all probability in other species besides *P. aspergillum*). The external pores lie between the setæ, but have no regularity in their arrangement; frequently there were three or four between two successive setæ, as often there seemed to be only one or two. The minute structure of the terminal section of nephridia is slightly different from that of Acanthodrilus. Another point, to which I wish to direct attention in this communication, is that *in Perichæta there is a connection between the nephridia of successive segments.*

Quite recently, Ed. Meyer and Cunningham have shown that in *Lanice conchilega* the nephridia of each side are connected by a continuous longitudinal duct. This discovery is in accord with the presumed origin of the Annelid from the Platyhelminth excretory system, and also with the development of Polygordius (Hatchek) and Lumbricus. In Perichæta the connection between the nephridial tufts of successive segments is not brought about by a continuous longitudinal duct, one on each side of the body, but by numerous tubules which perforate the intersegmental septa. Thus it appears that *the nephridial system of Perichæta consists of a network of tubules.* In this respect Perichæta agrees with the leech Pontobdella, but differs in the presence of numerous nephridiopores in each segment. These facts appear to lend further support to the view that it is possible to derive the Annelid from the Platyhelminth excretory system.

Lang has pointed out that the "secondary" pores by which the excretory organ of the Platyhelminths communicates with the exterior have probably given rise to the nephridial pores in the Annelida; by a subsequent arrangement of these in a metameric fashion, and by the breaking up of the nephridial network, the paired nephridia have originated. The longitudinal canal has disappeared, except in the cases that I have already mentioned. In some Platyhelminths the longitudinal canals are, partly at least, broken up into a network; and it is this condition which has persisted in Perichæta and Pontobdella; moreover, in some Platyhelminths, where the "secondary" pores have become metamerically arranged, there are more than one pair to each "segment." For this reason it is perhaps allowable to regard the condition of the nephridia in Perichæta as more archaic than Pontobdella. The disappearance of the connection between the nephridia of successive segments leads to the condition which exists in Acanthodrilus; the reduction of the external pores, already perceptible in the posterior segments of *A. multiporus,* culminates in the disappearance of all but two in each segment. The irregularity in the position of these, which is best marked in Plutellus, is the last trace of the presence of multiple nephridiopores in each segment.

Royal Meteorological Society, January 18.—Mr. W. Ellis, President, in the chair.—The paper read was on the non-instrumental meteorology of England, Wales, and Ireland, by Mr. G. M. Whipple. This is a discussion of the observations of wind, cloud, thunderstorms, hail, snow, &c., made at the stations of the Royal Meteorological Society during the eight years 1878–85, and published in the *Meteorological Record.* The S.W. wind is the most prevalent, and blows on the average seventy-four days in the year; the W. wind occurs almost as frequently, blowing sixty-five days. The least dominant winds are the S.E. and N., which occur on twenty-seven days, and the N.E. on thirty-two days. Thunderstorms are most frequent in the eastern and midland counties, and least frequent in the north of Wales.—After the reading of this paper, the annual general meeting was held. The report of the Council showed the Society to be in a satisfactory condition, the number of Fel'

being 522.—Mr. Ellis in his Presidential address reviewed briefly the work and position of the Society, remarking that such a Society, whilst unable to carry out expensive original or experimental work, could yet act with great advantage in inciting volunteer workers throughout the country to united action, of which one recent example was the ready response to the request of the Society for photographs of lightning, an excellent collection of which had been obtained, and which would shortly be exhibited; in addition to which arrangements were being made for the more systematic observation of thunderstorms. Referring to the question of sympathetic relation between sunspots and magnetism and meteorology, he thought that any complete treatment of the question in its meteorological aspect seemed to require that it should be dealt with in a much more comprehensive manner than before, for which purpose observations more completely covering the surface of the globe might be necessary, if indeed not necessary also for the solution of many other meteorological questions, the present meteorological stations being distributed over the earth in such isolated clusters. The attention given to synoptic charts was most important, but the general meteorological characteristics of places should also still continue to be studied. After remarking upon other matters, he laid before the meeting tables showing the monthly means of amount of cloud from observations made in three different series at the Royal Observatory, Greenwich, extending in all from 1818 to the present time. In concluding, Mr. Ellis said that at one time the science of meteorology seemed likely to form an exception to the general rule of advance, for more than any other it has required the united action of many workers, but the field of inquiry of late years opened out allows us already to talk of the new or modern meteorology, phrases typical of the advance achieved, although the knowledge gained seems only to remind us of how much has yet to be done.—The following gentlemen were elected the officers and Council for the ensuing year:—President: Dr. Wm. Marcet, F.R.S. Vice-Presidents: Francis Campbell Bayard, William Ellis, Charles Harding, Richard Inwards. Treasurer: Henry Perigal. Trustees: Hon. Francis Albert Rollo Russell, Stephen William Silver. Secretaries: George James Symons, F.R.S., Dr. John William Tripe. Foreign Secretary: Robert Henry Scott, F.R.S. Council: Hon. Ralph Abercromby, Robert Andrew Allison, M.P., Edmund Douglas Archibald, William Morris Beaufort, Henry Francis Blanford, F.R.S., Arthur Brewin, George Chatterton, William Henry Dines, Henry Storks Eaton, Baldwin Latham, Edward Mawley, Dr. Charles Theodore Williams.

Chemical Society, December 15, 1887.—Mr. William Crookes, President, in the chair.—The following papers were read:—An apparatus for comparison of colour-tints, by Alfred W. Stokes.—The alloys of copper and antimony and of copper and tin, by E. J. Ball.—The constitution of the so-called mixed azo-compounds, by Francis R. Japp, F.R.S., and Felix Klingemann.—The interpretation of absorption-spectra, by G. H. Bailey.—The reduction of potassium bichromate by oxalic acid, by C. H. Bothamley.—The reduction of chlorates by the zinc-copper couple, by C. H. Bothamley and G. R. Thompson.—Preliminary notice on the oxidation of oxalic acid by potassium dichromate, by Emil A. Werner.—Isomeric change in the naphthalene series; No. 1, by Henry E. Armstrong.—Isomeric change in the naphthalene series; No. 2, β-Ethoxynaphthalenesulphonic acids, by E. G. Amphlett and Henry E. Armstrong.—Isomeric change in the naphthalene series; No. 3, β-Chloronaphthalenesulphonic acids, by Henry E. Armstrong and W. P. Wynne.—Isomeric change in the naphthalene series; No. 4, α-Haloidnaphthalenesulphonic acids, by Henry E. Armstrong and S. Williamson.—The sulphonation of naphthalene, by Henry E. Armstrong and W. P. Wynne.

Entomological Society, January 18.—Fifty-fifth aniversary meeting.—Dr. D. Sharp, President, in the chair.—An abstract of the treasurer's accounts was read by Mr. H. T. Stainton, F.R.S., one of the auditors; and Mr. H. Goss, the Secretary, read the Report of the Council.—It was announced that the following gentlemen had been elected as Officers and Council for 1888:—President: Dr. David Sharp. Treasurer: Mr. Edward Saunders. Secretaries: Mr. Herbert Goss and the Rev. Canon Fowler. Librarian: Mr. F. Grut. As other Members of Council: Mr. Henry J. Elwes; Sir John Lubbock, Bart., M.P., F.R.S.; Mr. Robert McLachlan, F.R.S.; Dr. P. Brooke-Mason; Mr. Edward B. Poulton; Mr. Osbert Salvin, F.R.S.; Henry T. Stainton, F.R.S.; and Lord Walsingham, F.R.S.—The President delivered an address, and a vote of thanks to him was moved by Mr. McLachlan, seconded by Mr. F. Pascoe, and carried.—A vote of thanks to the Treasurer, Secretaries, and Librarian, was moved by Mr. Kirby, seconded by Mr. Waterhouse, and carried. Mr. E. Saunders, Mr. H. Goss, Canon Fowler, and Mr. F. Grut replied.

Mathematical Society, January 12.—Sir J. Cockle, F.R.S., President, in the chair.—Messrs. J. M. Dodds and G. G. Morrice were elected members, and Mr. E. W. Hobson admitted into the Society.—The following communications were made:—The theory of distributions, Capt. P. A. Macmahon, R.A.—On the analogues of the nine-points circle in space of three dimensions, S. Roberts, F.R.S.—On a theorem analogous to Gauss's in continued fractions with applications to elliptic functions, L. J. Rogers.—A theorem connecting the divisors of a certain series of numbers, Dr. Glaisher, F.R.S.—On reciprocal theorems in dynamics, Prof. H. Lamb, F.R.S.

Mineralogical Society, January 10.—Mr. L. Fletcher, President, in the chair.—The following papers were read:—On the development of lamellar structure in quartz crystals by mechanical means, by Prof. J. W. Judd, F.R.S.—On the polysynthetic structure of some porphyritic quartz crystals in a quartz-felsite, by Colonel C. A. McMahon.—Notes on hornblende as a rock-forming mineral, by Mr. A. Harker.—On the invitation of the President, Mr. Allan Dick, who was present as a visitor, made some remarks on the process of kaolinization, illustrated by models of crystals.

Paris.

Academy of Sciences, January 16.—M. Janssen, President, in the chair.—Remarks on M. Wolf's last note on the subject of synchronization, by M. A. Cornu. The author is glad to find himself in harmony with M. Wolf on the important points that no synchronizing system is possible without some controlling or regulating apparatus, and that such apparatus forms an essential feature of the systems of Jones and Vérité.—Remarks accompanying the presentation of the third volume of the "Annales de l'Observatoire de Rio Janeiro," by M. H. Faye. This volume, which was presented by the Emperor of Brazil, is entirely devoted to the three Brazilian expeditions sent to the Island of Saint Thomas, Pernambuco, and Punta Arenas (Patagonia) to observe the transit of Venus in the year 1882. From a comparative study of the recorded results, M. Cruls has calculated the solar parallax at 8″·808.—Fresh researches on the phenomena produced by a potent toxic agent, which is constantly emitted with the air exhaled from the lungs of man and other mammals, by MM. Brown-Séquard and d'Arsonval. The experiments here described and made on seven rabbits entirely confirm the conclusions already announced regarding the powerful character of this volatile organic poison, which appears to be almost certainly an alkaloid. Further researches have been undertaken in order to determine this point by direct proof.—On spontaneous tetanus, by M. Verneuil. A case reported by Dr. Buisson, of Auberchicourt, is referred to as confirming in a striking way the author's opinion that there is no such thing as spontaneous tetanus, and that all reported cases will be found, if carefully studied, to be caused by some virus introduced in some way into the system.—On the canalization of the Isthmus of Panama, by M. de Lesseps. In supplement to his recent remarks on this scheme the author announced that the proposal to establish provisionally a lock canal for one at a dead level has just been adopted by the Company. He further explained how the extensive works already executed can be adapted to the new design, so that the Canal might still be completed and opened for traffic by the year 1890. It would moreover be so constructed that the original plan of a level canal might be gradually carried out without any interruption to the navigation. Both would be of the same length of 74 kilometres, with a breadth of 22 metres at the bottom, and 44 on the surface. Four locks will be needed, each 18 metres wide at the entrance, and with a total length of 180 metres.—On the barometric curves recorded during the third scientific expedition of the *Hirondelle*, by Prince Albert of Monaco. These barometric readings seem to show that the motions of the ship are insufficient to explain the oscillations recorded during the course of a storm, and that these oscillations accompany certain meteorological disturbances without at all aiding to forecast the weather.—On the measurement of the absolute intensity

of weight, by M. G. Defforges. The apparatus constructed by MM. Brunner Brothers on the principles here laid down has already been applied with satisfactory results to the measurement of absolute gravity at Paris, Lyons, Dunkirk, Algiers, Laghwat, and Nice.—On elliptical polarization by transmission through metals, by M. Georges Meslin. The author here studies the modifications which polarized light undergoes in its passage through metal plates thin enough to be transparent. As in metallic reflection, the two polarized vibrations in the plane of incidence and in the perpendicular plane undergo in relation to each other a certain retardation, while the rectilinear polarization becomes elliptical.—On the application of the phenomenon of transversal magnetization to the study of the coefficient of magnetization of iron, by M. Paul Janet. This question is here studied by means of a method of mutual induction which presents several advantages over other processes, and which may be easily applied to the study of the influence of the medium in the phenomena of induction.—On the decreasing solubility of the sulphates, by M. A. Etard. The author has already shown that between 103° and 190° C. the sulphate of copper becomes less soluble according as the temperature increases. He now finds that most of these salts undergo a certain disturbance at some point of the line of complete solubility, beyond which point the solubility increases less rapidly and even remains almost stationary. Details are given for the sulphates of zinc, manganese, and potassium.—Symmetric disposition of the centres of the four chief continents, by M. Alexis de Tillo. By graphic processes the author finds that the co-ordinates of the orographic centres of the continents are as under: Asia (with Europe) 43° N., 85° E. of Greenwich; Africa, 4° N., 27° E.; North America, 45° N., 102° W.; South America, 14° S., 56° W. The geometric centre of the Old and New World lies in the region of the Azores and Canaries, and the meridian of Delisle (20° W. of Paris) may in some respects be regarded as the *natural* meridian of the globe.

BERLIN.

Physical Society, December 23, 1887.—Prof. du Bois Reymond, President, in the chair.—Prof. Schwalbe gave a detailed account of the research which Dr. Aubel and Prof. Spring have carried out on the rapidity of the interaction between acids and zinc which is mixed with lead.—Prof. Vogel made a statement of his observations of the solar eclipse of August 19. As is well known, the observations during the whole of the lengthy period of totality were unproductive of results at all stations except those in Siberia—which were not much utilized by observers—owing to unfavourable weather. The speaker appears to have been among the most fortunate at Jurjewetz, where he was stationed in company with the Belgian astronomer Niesten, and the Russian astronomers Kortazzi and Belopolski, for at this place the sun was momentarily visible through the clouds. As a matter of fact, several photographs were successfully obtained, on which, as shown by a specimen exhibited, a corona and several protuberances were visible. These photographs, however, scarcely suffice as a basis for any scientific research. Prof. Vogel had also received a photograph of the eclipse taken in clear weather by an amateur in the Ural Mountains; it showed a complete but small corona, and near it is the image of a star, probably Mercury. Unfortunately no details are given about this photograph. The photographer Karelin has secured some very interesting results at Jurjewetz. This observer, using a very sensitive apparatus, had obtained some very successful photographs of the lunar eclipse, which had taken place about a fortnight before the solar eclipse. The plates were only exposed for 1/60 of a second, and working upon this experience he obtained photographs during the solar eclipse by a similar exposure of 1/60 of a second. The results were quite satisfactory, and from this the important conclusion may be arrived at that exposures of the above very short duration may be used during future solar eclipses. Herr Karelin has further taken a photographic landscape during the eclipse, and from a comparison of the time necessary to obtain this with the time required by the speaker's son to obtain a similar picture during full moon, the speaker concluded that the brightness during the solar eclipse was fifty-six times as great as that of the full moon. Prof. Vogel had intended to photograph the spectrum of the corona, but was not successful in his attempt. He further exhibited a photograph of the spectrum of pure oxygen contained in a Geissler tube and made luminous by the sparks from a battery. The photograph was then photographically enlarged, so that it could readily be seen by a large audience at the same time, and in this form it showed the red and green line, together with a long series of bands and lines extending far into the ultra-violet region. Many of the lines described by Dr. Schuster as single could be seen to be double in this photograph. One of the chief things shown by the enlarged photograph is that the oxygen-spectrum of the positive pole, and of the negative pole, as well as the spark-spectrum of the oxygen itself are here combined into a single spectrum. The speaker intends to apply this method of magnifying the photographs to the spectra of other gases, and thus make the enlarged spectra accessible for teaching purposes in the form of diagrams.

January 6.—Prof. du Bois Reymond, President, in the chair.—Prof. Oettingen, of Dorpat, spoke on the explosion of a mixture of hydrogen and oxygen obtained by electrolysis. As is well known, Bunsen has advanced the following view, based on his experiments, on the explosion of electrolytic gas: by the explosive union of the oxygen and hydrogen, when the spark is passed, a temperature of 3000° C. is produced, the water formed being at once dissociated at this temperature; the temperature of the mixture of gases formed by the dissociation then falls, whereupon a new union between the two takes place, and so on; hence the explosion of electrolytic gas is to be regarded as made up of a series of partial explosions following each other in rapid succession. The speaker had intended several years ago to subject Bunsen's theory to an experimental investigation, and hoped to be able to analyze the phenomenon by the use of a rapidly revolving mirror. As a matter of fact, when the mirror was rotated at a suitable speed, the image observed was not that of a single narrow strip of light, but was rather of considerable width; it was not found possible to interpret this image, notwithstanding that the somewhat complicated experiments were repeated many times. An endeavour was next made, with the assistance of a photographer, to obtain a record of the image, which was equally unsuccessful. He then underwent a course of photographic study; and when he had acquired sufficient experience, he last year repeated his former experiments, with a positive result, using the new methods of sensitizing the plates for the less refractive parts of the spectrum, and the most sensitive possible dry plates. The speaker had further shown, by a spectroscopic examination of the light emittted during the explosion of electrolytic gas, that the light is due, not to the combustion of the gases, but of sodium, which is doubtless accounted for by the incandescence of small particles of glass torn off by the passage of the sparks. He hence introduced, in accordance with the method of Dewar and Liveing, portions of finely powdered salts of various metals, such as copper, zinc, lithium, and cadmium, &c., into the eudiometer in which the explosion of the electrolytic gas was to be made, and now obtained, not only excellent spectra of the respective metals, but also quite distinct photographs of the images in the rotating mirror. A plane mirror was used, placed at fixed distances from the eudiometer and camera, which projected the images of the successive events taking place during the explosion on to the flat sensitized plate. The speaker exhibited a series of the photographs thus obtained: these presented the following appearances, most clearly when the salt used was chloride of copper. In the first place, a bright point, corresponding to the place of passage of the spark, from which a short bright ray passed both upwards and downwards in the tube; then secondly, at a fixed distance from this and occupying the whole length of the eudiometer, a bright image intersected lengthways from end to end by zigzag lines and transversely by parallel sinuous waves. The speaker interpreted the above images by referring the intersecting zigzag lines to a series of waves of impulse caused by successive explosions; he considered on the other hand that the sinuous waves are due to the small particles of the metal which are set in motion by the impulse waves, and hopes to render this explanation still more probable by a new series of experiments on the explosion of carbon-disulphide. According to Prof. Oettingen, the experiments of Berthelot, and Vieille, and of Mallard and Lechatelier, have no bearing upon the explosion which he has studied, occurring as it does in a few thousandths of a second, but refer to the combustion which occurs subsequently to the explosion.—Dr. Kötter spoke on the problem of determining the pressure exerted by the earth, discussed the difficulties in the way of estimating the pressure which the earth exerts upon a wall built into it, and stated the limits within

which some theoretical calculations may be relied upon.—Prof. Schwalbe announced that he is engaged in drawing up a Greek nomenclature in connection with physics, and invited the members of the Society to communicate to him any expressions borrowed from Greek which are either rare or difficult to understand.

Meteorological Society, January 3.—The President, Prof. von. Bezold, opened the meeting with a short speech in memory of the late member of the Society, Prof. Kirchhoff, whose many-sided works had not been without importance to the science of meteorology.—The Secretary then made his report on the activity of the Society during the past year, and on the establishment of new meteorological stations in connection with the circle of such stations surrounding Berlin promoted by the Society.—At the election of officers which then followed Dr. Vettin was chosen as President, and Prof. Von Bezold as Vice-President.—Dr. Hellmann spoke on the meteorology of the Iberian Peninsula. During a prolonged stay in Spain in the years 1875–76, the speaker was unable to study the rainfall of the country owing to insufficient data. Since then, however, some 760 annual statements have been published from 70 stations, so that he was now in a position to work out the rainfall, and he presented the results of this in the form of a chart, which formed the basis of his communication. The local distribution of rainfall is very varying. In the district of the Ebro and the whole of the south-east part of the country as far as Carthagena and Old Castile, the rainfall is very slight, the annual fall being about 270 mm.; on the other hand, on the west coast, and in the district of the Pyrenees, the rainfall is considerable, presenting a fall of some 1600 mm. per annum. The maximum fall is found in Serra da Estrella, where it amounts to 3500 mm. The course of the lines of equal rainfall of 300, 400, 600, 800, 1000, and 1600 mm. per annum is extremely curious, and was carefully discussed by the speaker. Two sections through the peninsula, on which the rainfall was represented by ordinates, showed how steep the gradients are when passing from the west coast towards the interior. The speaker threw a good deal of interesting light on the close connection which exists between the agricultural and social conditions of the inhabitants and the rainfall. It appeared that very profound differences have developed themselves between the districts where the rainfall is great and small, and in the latter where the district is well supplied with water or not, these differences completely governing the character and mode of life of the inhabitants. All the stations in common showed a minimal rainfall in the summer, occurring in the months of July and August. In the most southerly stations this minimum falls to 4 mm. for the above two months, whereas in the north-west it rises to more than 100 mm. The curve of maximal rainfall shows three typical forms and three transitional forms. One set of stations shows a maximum in winter, another set has its maximum in the spring, and the third shows it in the autumn, and between these three a graduated transition is observed. The quotient $\frac{\text{maximum}}{\text{minimum}}$ increases rapidly on going south. The difference in the amount of rainfall per annum could only be calculated for thirty-two stations, since it must be based on the records of ten consecutive years at least. The ratio of the extreme to the mean annual rainfall in the north-west, as well as in Central Europe, was two, while in the interior of the country this ratio rose to five. The rainstorms are rarely continuous; they occur chiefly in the morning, and are followed by sunshine: three days of continuous rain, or even of clouds, scarcely ever occur in the whole of Spain. This statement was confirmed by the records of the autographic sunshine recorder. Snow rarely falls in the Iberian Peninsula; the maximum fall of twenty-two snowy days was observed at a station on the upper Douro. At the southern stations snow falls once in thirty years, and it never falls at all at many stations. It is impossible to give any account here of the large mass of further details which the speaker brought before the meeting; they will shortly be published by him in a very extended form.

STOCKHOLM.

Royal Academy of Sciences, January 11.—An account of a memoir by Prof. Ewart, of Edinburgh, on *rigor mortis* and its relation to the putrefaction of fish, by Prof. Smith.—A report of the work done by the Swedish Ornithological Society, by the same.—On the organs and modes of attachment of the marine Algæ, by Count H. CONTENTS.

THURSDAY, FEBRUARY 2, 1888.

THE COMPOSITION OF WATER.

DUMAS, in his well-known memoir on the gravimetric composition of water, which every student is taught, and rightly so, to regard as one of the classics of chemistry, states that of all analyses presented to a chemist that of water is the one which offers the greatest uncertainty. Critics of a certain type may possibly take exception to the literal accuracy of this remark. No one, however, will gainsay the statement that, in view of the momentous issues which depend upon our knowledge of the composition of water, this knowledge is not by any means so exact as the state of contemporary science demands. It is, of course, not merely the question of the quantitative composition of water, but the far more important matter of the relative values of the atomic weights of hydrogen and oxygen. Of all stoïchiometrical constants required by chemists nowadays, those of hydrogen and oxygen are infinitely the most important. Every chemist knows what is dependent on these ratios, and he knows too that the difficulties which their direct determination involves are well-nigh insuperable.

All the discussions within recent years on the validity of Prout's law have tended to show that so far as experimental work is concerned, the question may now be said to hang upon these particular values. It is not too much to say that, if any chemist could succeed in showing by irrefragable experimental evidence that the atomic weight of oxygen was exactly sixteen times that of hydrogen, he would in the present state of scientific opinion at once succeed in inducing his brethren to accept Prout's law and all its far-reaching consequences as articles of their chemical creed.

It may be worth while to examine very briefly the nature of the ground upon which the present accepted values for the relative atomic weights of hydrogen and oxygen are based. It will be generally conceded that the evidence upon which chemists have almost exclusively relied is that afforded by Dumas' gravimetric analysis of water, and by Regnault's determination of the specific gravities of oxygen and hydrogen.

Dumas' work was published in 1843. His method was identical in principle with that employed by Dulong and Berzelius for the same purpose, and consisted, as is well known, in heating copper oxide with an unknown weight of hydrogen, and determining (1) the loss of weight suffered by the oxide, and (2) the weight of the water formed. The decrease in weight of the copper oxide was assumed to represent the weight of the oxygen evolved, and the difference between this weight and that of the water formed was held to be the amount of hydrogen which had combined with that of the oxygen.

In all, nineteen experiments were completed, in which quantities of water varying from about fifteen to eighty-six grammes were formed. Treating the results in the manner adopted by Meyer and Seubert—that is, in accordance with the equation

$$x = \frac{b_1 + b_2 + b_3 + \ . \ . \ . + b_n}{a_1 + a_2 + a_3 + \ . \ . \ . + a_n} = \frac{[b]}{[a]},$$

in which a = weight of oxygen used, and b = weight of water formed—it follows that $[a]$ = 840·16 grammes, and $[b]$ = 945·44 grammes, whence the ratios H : O = 1 : 15·96.

When, however, we come to examine more nearly the details of the method of determination, we find that these ratios are certainly affected by errors of which the magnitude cannot be even approximately known. In the first place, the sulphuric acid solution employed to generate the hydrogen must have contained dissolved air, the effect of which would be to lower the ratio of the oxygen. This fact was not indeed unnoticed by Dumas, but its effect could not be estimated with any certainty. Moreover, it seems almost impossible to prepare hydrogen from zinc and sulphuric acid without the formation of more or less sulphur dioxide, the last traces of which can only be removed by prolonged exposure to potash solution. Copper is one of the few metals that have the power of forming a hydride, and although this hydride, like the palladium hydride, is more or less readily decomposed by heat, the affinity of hydrogen for copper may be still traceable even at moderately high temperatures. Melsens, working in Dumas' laboratory, found that the reduced copper did actually retain hydrogen, and in amount varying with the temperature to which it had been heated. The weight of the condensed water must have been increased, as Berzelius pointed out, by the air which it eventually dissolved. Now the effect of all these errors would be to lower the value for the atomic weight of oxygen. Of course there may have been errors working in the opposite direction of which we know nothing, but it is reasonably certain that the net result of the constant errors, so far as these can be ascertained, is to give too small a value for oxygen. Above all, there are the fortuitous errors, such as those caused by differences in the power of surface-condensation of the vessels employed; errors of weighing and of reduction to a standard atmosphere, &c.; which, although theoretically allowed for and eliminated by a sufficiently frequent repetition of the experiments, may, on the whole, tend to operate in a given direction. Lastly, there is a source of error of the same order in a circumstance which, as there is a certain touch of pathos in them, may be stated in Dumas' own words:—

"Il faut même ajouter que la durée nécessaire de ces opérations, en m'obligeant à prolonger le travail fort avant dans la nuit, en plaçant les pesées vers deux ou trois heures du matin dans la plupart des cas, constitue une cause d'erreur réelle. Je n'oserais pas assurer que de telles pesées méritent autant de confiance que si elles avaient été exécutées dans des circonstances plus favorables et par une observateur moins accablé de la fatigue inévitable après quinze ou vingt heures d'attention soutenue."

There is, above and beyond all, a fundamental flaw in the principle of the method, of which Dumas himself was fully conscious. After having declared that of all analyses presented to a chemist water is the one which offers the greatest uncertainty, he goes on to state to what this uncertainty is due:—

"En effet, 1 partie [d'hydrogène se combine avec 8 parties d'oxygène pour former de l'eau, et rien ne serait

plus exact que l'analyse de l'eau, si l'on pouvait peser l'hydrogène et peser l'eau qui proviendrait de sa combustion. Mais l'expérience n'est pas possible sous cette forme. Nous sommes obligés de peser l'eau formée, et l'oxygène qui a servi à la produire, pour en déduire, par différence, le poids de l'hydrogène qui en fait partie. Ainsi, une erreur de 1/900 sur le poids de l'eau, ou de 1/800 sur le poids de l'oxygène, affecte d'une quantité égale à 1/90 ou à 1/80 le poids de l'hydrogène. Que ces erreurs étant dans le même sens viennent à s'ajouter, et l'on aura des erreurs qui iront à 1/40."

Let us now turn our attention to the evidence afforded by Regnault's determinations of the densities of oxygen and hydrogen. Prof. Le Conte has detected some slight numerical errors in Regnault's reductions (*Phil. Mag.* [4] 27–29), and when the necessary corrections are made it follows that the density of oxygen is 1·105612, and that of hydrogen 0·069269; whence, on the assumption of Avogadro's law, we have the ratio O : H = 15·9611 : 1. This result is in such striking agreement with Dumas' value that it is generally held to afford the strongest corroboration of it. The number given for oxygen is probably among the most accurate of Regnault's determinations of gaseous densities; the subsequent results of Von Jolly, which are alone comparable in character with those of Regnault, when reduced to the geographical position of Regnault's laboratory have not materially altered the value. The number given for hydrogen is certainly not entitled to the same degree of confidence. Indeed, it has been stated that Regnault was himself of this opinion, on account of the great difficulty of procuring hydrogen free from air. It is hardly necessary to point out that even an extremely minute admixture of air would tend to lower the relative value of the atomic weight of oxygen. Moreover, the hydrogen in the course of its preparation must have been saturated with moisture; and although, of course, all precautions at that time known were taken to dry the gas, it is quite certain that it could not have been absolutely free from traces of water. The experiments of Dixon have shown how extremely difficult it is to dry a gas perfectly, and it is now recognized that the ordinary methods of desiccation still leave appreciable traces of moisture in it. The effect of this moisture in the case of hydrogen would be to increase its density, whereas in the case of the oxygen it would tend to decrease it. On the other hand, oxygen and hydrogen when measured under the standard conditions of temperature and pressure are not, strictly speaking, under exactly comparable conditions, and the assumption of the validity of Avogadro's law is not mathematically correct.

Within recent years the question of the composition of water has been again attacked, and with a fuller knowledge of the various sources of error which the progress of science has shown to be present in the older methods. Julius Thomsen found that 1 litre of dry hydrogen, measured under standard conditions of temperature and pressure, when burnt with oxygen gave, as the mean of eight concordant experiments, 0·8041 grammes of water. Accordingly, 2 litres of hydrogen, on combining with oxygen, would give 1·6082 grammes of water. Assuming the validity of Gay-Lussac's law, and using Regnault's values for the weights of the gases at standard temperature and pressure, the calculated weight becomes—

2 litres hydrogen	= 0·1791	grammes
1 litre oxygen	= 1·4298	,,
water	= 1·6089	,,

The difference is 0·7 milligramme. But the question may be immediately asked, "Is Gay-Lussac's law actually valid?" The work of Regnault and Amagat on the relation of volumes of gases to heat and pressure indicates that, as ordinarily stated, it cannot be absolutely valid. Dr. A. Scott has recently put the question to the test of experiment, and, from a long series of trials in which large volumes of gases were caused to combine, he finds that the most probable ratio is 1·994 : 1 (Proc. Roy. Soc., 1887, 398). Taking Regnault's data as before, we have—

1·994 litres hydrogen	= 0·1876	gramme
1 litre oxygen	= 1·4298	,,
water	= 1·6084	,,

which differs only by 0·2 milligramme from Thomsen's result.

Now, from Regnault's densities of oxygen and hydrogen, as recalculated by Prof. Le Conte, it follows that the weights of equal volumes of the gases are as 1 : 15·9611, which, on the basis of Dr. Scott's ratio for the combining volumes, gives—

$$O = 16·009.$$

Prof. J. P. Cooke and Mr. T. W. Richards, of Harvard College, have recently presented us with a further contribution to the subject (Proc. Amer. Acad. of Arts and Sciences, xxiii. 149), which merits very special attention, not only on account of the intrinsic excellence of the experimental work of which it is an account, but also because it is here attempted to obviate certain of the sources of error which have already been pointed out as inherent in Dumas' method. The method adopted by the American chemists was to pass a known weight of hydrogen over heated copper oxide and to weigh the amount of water formed. It will be seen that the essential feature in this method is that the weight of the hydrogen is known whilst that of the oxygen is obtained by difference; in contradistinction to the method of Dumas, where the weight of the oxygen was known and that of the hydrogen found by difference. The preparation of this hydrogen and the determination of its weight were, however, problems which required the highest manipulative skill. Obviously, everything depends upon the purity of the hydrogen. A glass globe of about 5 litres capacity and weighing about 570 grammes was so provided with stopcocks that it could be evacutated by the air-pump. The vacuous globe was weighed against a similar globe, in the manner already adopted by Regnault, filled with hydrogen, and its weight again determined. The weight of hydrogen taken was about 0·42 gramme. The hydrogen was then driven over the heated copper oxide by a current of dry air, and the water formed collected partly in a weighed tube, and partly by means of sulphuric acid and phosphoric oxide. The hydrogen was obtained by three different methods: (1) by the action of sulphuric acid

upon zinc; (2) by means of caustic potash and aluminium; and (3) by electrolysis. In all, sixteen experiments are given. The results are stated in the following table:—

Series.	No. of Experiments.	Sum of the weights of hydrogen. grammes.	Sum of the weights of water. grammes.	Atomic weight of oxygen. max.	min.	Calc. from sums.
I.	5	2·0876	18·7406	15·977	15·937	15·954
II.	5	2·0803	18·6740	15·962	15·942	15·953
III.	6	2·5350	22·7541	15·967	15·937	15·952

The final mean is O = 1 0·0017.

This very bald account does but scanty justice to the beauty and simplicity of the methods adopted by Prof. Cooke and Mr. Richards, and to the manipulative skill and patience with which they carried them out. With respect to the bearing of their result on Prout's hypothesis, the question seems to them to narrow itself to this point: Is the hydrogen they have made use of the typical hydrogen element? They are inclined to believe that the theoretical question in regard to Prout's law has been settled so far as analytical work can solve the problem. On this point, however, we are at issue with them. That statement implies a finality about our present quantitative methods which we have no right to assume. It implies, too, that the methods employed by the authors have yielded as close an approximation to the typical element as we are ever likely to obtain. Their method in principle no doubt removes one fundamental objection to Dumas' plan of work, considered as an experimental process, but it by no means removes all the sources of error, and anybody who will patiently sift out these sources and seek to appreciate their net effect must admit that the ultimate tendency is to apparently lower the relative value of the atomic weight of oxygen.

If we have regard to this fact, and if we consider too what we may call the volumetric evidence, as given above, it seems premature to assume that the ultimate question has actually been narrowed down to the point to which Prof. Cooke and Mr. Richards are disposed to conclude that they have brought it. T. E. THORPE.

PHYSICAL GEOGRAPHY OF THE SEA.

Handbuch der Ozeanographie. Von Dr. Georg von Boguslawski und Prof. Dr. Otto Krümmel. Two Vols. (Stuttgart: Engelhorn, 1884–87.)

THESE volumes belong to a series of geographical hand-books—each written by an acknowledged master of the subject—brought out on a uniform plan, under the editorship of Prof. Dr. F. Ratzel, by the well-known Stuttgart publishing firm of Engelhorn.

Dr. Ratzel's own volume on Anthropogeography, Dr. Hann's on Climatology, and Dr. Heim's on Glaciers have already appeared; and now, under the somewhat novel name of "Oceanography," the physical geography of the sea has been exhaustively treated. The editor has divided the subject into two parts, and given each to a specialist. In Volume I., Prof. Dr. G. von Boguslawski, of the Hydrographical Department of the German Admiralty, treats of the distribution, physical condition, and chemical composition of sea-water; while in Volume II., Dr. Otto Krümmel, Professor of Geography in the University of Kiel, discourses on the motions of the ocean. Each part is complete in itself, but the index to both is given only in the second volume.

It is somewhat difficult to give an idea of the multifarious contents of this exhaustive treatise. In Volume I., Dr. Boguslawski begins with an account of the shape and area of the different oceans, and then naturally describes successively the physical character of their various coast-lines, and the depths of the sea all over the world. But we must remark on the poverty of illustration and the absence of maps which characterize this and so many other first-rate German books. Here we have actually no map, however rough, to show graphically the depth of the oceans. The unfortunate reader who wants to get his information as easily and quickly as possible has first to read through about 100 pages of closely-printed type, and then to try and picture to himself the relief of the floor of the sea.

After discussing ocean depths, the author devotes a short chapter to the chemical composition of salt water; and then a somewhat longer space to the density or specific gravity of the sea. Colour and transparency are next discussed, and the last 200 pages are occupied with what is called maritime meteorology.

Of this space only thirty-four pages are devoted to wind and storms, and very rightly, as these subjects would require a special volume for their proper treatment. The remainder is occupied with a minute account of the temperature of the ocean, both on the surface and at various depths; and with a notice of the distribution of ice in high latitudes. Here too, the value of the admirable text is greatly diminished by the absence of maps.

So far no mathematics have been required, but it is impossible to treat of the motions of the sea without algebraical formulæ. Dr. Krümmel, however, uses great judgment in only giving the formulæ of motion, which only involve simple algebra, and not the investigation of the formulæ, that would require much higher analysis.

In the second volume he begins with the consideration of waves. The theory of wave-motion, both in deep and shallow water, he gives first, mostly following Airy; while experimental illustrations, and observations on the actual length, height, and speed of waves follow next. Breakers and rollers are then discussed, together with their influence on the abrasion of coast-lines. Earthquake and volcanic waves are illustrated by a self-recorded tidal trace from South Georgia, which will be new to English readers; and the section ends with a capital account of stationary waves, *sèches*, and of the curious tidal phenomena in the Straits of Euripus, which so puzzled the ancient Greeks.

The author then turns to tides, dealing mostly with the theories of Laplace, Whewell, Ferrel, Airy, Thomson, &c., but very wisely ending with a chapter on "unsolved problems." The difficult subject of the vertical circulation of the ocean is next discussed, and an admirable account given of the cold *aufreibwasser*—up-rubbed water—of tropical weather coasts. This uneuphonious term is applied to the cold water that is found

close to many tropical shores off which the wind blows steadily. For instance, near Cape Guardafui, when the south-west monsoon blows off shore, cold water is found near the land, but when the north-east monsoon blows on shore nothing but warm water can be discovered. The theory is that an off-shore wind blows, or rubs, the sun-heated surface water to leeward, and that the proper level of the sea is maintained by cold water welling up from below. Mr. J. Murray, of the *Challenger*, has discovered a similar effect in the long, narrow, deep waters of Loch Ness. With a south-west wind the coldest water is at the south-west end of the lake, but when the wind changes to north-east the lowest temperature is found at the north-east extremity.

The remainder of the work is taken up by a description of the currents of the ocean. The theory, of course, is fully given, and we may note that the author uses Ferrel's formula for the deflection of a moving particle to the right, through the influence of the earth's rotation, which has been accepted in every country except England. The long detail of the currents in different oceans of course contains little novelty, but is illustrated by an excellent map in blue and red of the direction and velocity of these well-known cold and hot streams.

Both of these volumes are to a certain extent uncritical compilations, for the results of various experiments and observations are merely recorded, without any comment on the varying quality of the work. We have already commented on the absence of maps; and the instruments used in oceanic research might well have been much more copiously illustrated. Still this work is a most valuable addition to the literature of the subject, and we wish that it could be translated into English.

There is no text-book of the subject in England, beyond School-Board primers, except the work of Maury; and this, in spite of a fascinating style, is too fanciful, and too much out of date, to be of any use.

Though the volumes now under review can never be popular in the ordinary sense of the word, still they would be invaluable to scientific men and others, who though not specialists wish to study in a compact and available form the present state of knowledge of one of the most interesting branches of modern research.

RALPH ABERCROMBY.

BULLETIN OF THE UNITED STATES FISH COMMISSION.

Bulletin of the United States Fish Commission. Vol. VI., for 1886. (Washington: Government Printing Office, 1887.)

THE immense number of short articles in this volume are as usual classified in a topical synopsis of the contents. The largest class is that of articles concerning the fisheries, the next in size contains those concerning aquiculture, the next those concerning natural history, and there are two other classes headed U.S. Fish Commission—General, and Miscellaneous. Of the biological articles Mr. John A. Ryder contributes only three, and the reader regrets there are not more from his hand. One is on the early development of the toad-fish, *Batrachus tau*, whose eggs are described as adherent, being fixed to the under surface of submerged boulders. The young toad-fish have this unique peculiarity, that when the egg-membrane bursts they are not set free but the lower surface of the yolk-sac remains firmly fixed to the adherent portion of the membrane, and this adhesion continues until the yolk-sac has become almost entirely intra-abdominal. The second of Mr. Ryder's papers is on the cleavage of the blasto-disk in the ovum of *Raja erinacea*; and the third on the intra-ovarian gestation of the viviparous *Sebastes marinus*: this last is based upon the examination of a gravid specimen obtained by the *Albatross*.

The few articles on the reproduction and generative organs of eels are of little value, as the information contained in them is not up to date. One, for instance, is a translation of a paper by Prof. Pavesi, published in 1880, and therefore of course treating as probabilities propositions concerning the testes which were proved in 1881 by Otto Hermes.

Among the aquicultural articles there are a great many on the shad-hatching work of the Commission, most of them detailing statistics of the operations of 1886. In one of these Marshall McDonald announces that for the entire period of the Commission's work up to and including 1882, 200,000,000 of young shad were produced, while for 1886 alone the total was 90,000,000, and this last number was fifteen times as great as the number of adult shad captured for market in one season. In another report by the same writer we find that the cost of production of shad-fry was $127·66, or about £25, per million. The exact effect of the artificial production of shad-fry on the supply of the adult fish is not estimated, but in one place we find that the catch in the Potomac was much larger in 1886 than in 1885; and in another that in Connecticut pollutions and sewage are diminishing the number of shad in the rivers.

Evidence is given that shad are now fairly abundant on the whole coast of California, apparently from plantings in the River Sacramento, but no regular run of shad seems to have been produced in that river; and we find statistics of plantings in 1886, in the Columbia and Colorado, from which a better result is expected. But of course the Bulletin is not the place to look for a connected and logical discussion of the operations carried out and their results. The publication contains occasional notes and statistics which are interesting to those who are familiar with the matters to which they belong, and which place on record facts which form materials for a connected study.

Of the very large amount of information comprised under the heading Fisheries, we cannot say more here than that it includes details and statistics not only of American fisheries but of those of all parts of the world.

OUR BOOK SHELF.

Flour Manufacture: a Treatise on Milling Science and Practice. By Friedrich Kick; translated by H. H. P. Powles. (London: Crosby Lockwood and Son, 1888.)

THE art of flour-milling, which of late years has undergone changes in its method of the most marked character, has at no time been productive of anything like a copious technology; and, in the attempt to supply this deficiency, it was natural that Mr. Powles should turn his regard towards Austria, where the manufacture of flour had engaged the attention of scientific experts long before the

necessity for systematic inquiry into its processes became obvious in this country. The publication of Dr. F Kick's supplement to his treatise "Die Mehlfabrication," which tabulated the improvements in machinery for preparing and grinding cereals introduced up to the year 1883, placed at the disposal of the translator a manual complete in its investigations into the nature of grain from the miller's technical standpoint, and into the best means of reducing it to flour. It is true that the book does not concern itself with the construction of the mill building nor with the motive power to be employed; but, from this point onward, the leading principles which should guide the milling engineer are carefully and accurately related, and their application justified when necessary by mathematical demonstration; the *rationale* at the same time being within the comprehension of the practical miller. Of this method the chapters on "balancing millstones" (p. 113), and on "disintegrators" (supplement, p. 25), afford admirable examples. The various operations of grain preparation, grinding, and of bolting, sifting, and dressing the meal, with descriptions and plates of the best known machines employed, are fully detailed, whilst the controversy between the advocates of "high" milling and "low" milling is discreetly adjusted by the author in the incidental remark that "which of these methods is to be used can only be settled by the local demand, if, as is generally the case, the mill works for the home market."

It is, however, to those portions of the work which relate to roller-mills that the reader at the present time will probably turn in the first instance. He will find here, not only information as to the various kinds in use and as to the manner in which they have been found to perform their work, but an intelligible account of the operations involved in the reduction of cereals by rollers, and good reason shown why the time honoured millstones have become almost entirely discarded in the manufacture of wheaten flour.

The book is very fully illustrated by woodcuts throughout the text, and by some thirty supplementary sheets of diagrams; whilst a preliminary chapter contributed by Dr. August Vogel, of Vienna, on the histology of farinaceous grains, adds completeness to the work.

We congratulate the translator on his introducing to the English reader a volume of the utmost value to millers and engineers, and of great interest to many other persons more or less concerned with this important industry.

Elements of Chemistry: a Text-book for Beginners. By Ira Remsen. (London: Macmillan and Co., 1887.)

OPINIONS no doubt differ much as to what is simple enough for a beginner. A good deal depends on the age of the beginner. We hold, in opposition to the author in his preface, that the present production is not well adapted for very young pupils.

There is a good deal of promise in the book which might be better fulfilled, and there is an attempt to cover far too large a field, with the result—not intended by the author—that it reads more like a book on general chemical information than an elementary introduction to chemistry.

Metals and non-metals are dealt with under "family" groups, and most of their common, and many uncommon, compounds described, generally with formulæ, and this in cases and with equations which cannot be termed simple; for instance, technical processes like soda-making, or bleaching powder, or potassium chlorate, or nitro-benzene, &c. Otherwise the order and arrangement of matter and the questions attached to each section are most excellent, and the book would be most useful even for general reading, exercise, and information on the chemistry of common things to the great mass of partially informed, ordinarily well educated, people of any age. To the senior boys of public schools, who have already had a little instruction in science, this book would be really useful, as taking them in a different manner over ground already partially covered, widening their general knowledge, and cultivating the main thing, "*thinking.*"

A Primary Geometry, with Simple and Practical Examples in Plane and Projection Drawing, and suited to all Beginners. By S. E. Warren, C.E. (New York: Wiley and Sons; London: Trübner, 1887.)

THIS work bears as motto, "Geometry should be begun as early and as simply in behalf of industrial life as arithmetic is in behalf of business life"; and its object is, accordingly, to contribute to a general earlier beginning of the study of geometry. "The truths of *form*, as needed in *drawing*, have been made prominent, while not neglecting elementary ones of *measure*."

The text treats of straight lines, triangles, regular figures, areas, lines and planes in space, the elementary bodies, and projections of elementary solids, the subject being considered in a common-sense fashion without much use of purely geometrical proofs. Having perused a very large portion of his book without detecting any flaw, we consider the author competent for the task he has undertaken, but we do not take kindly to such presentments of geometry. We believe, however, the book to be well adapted to junior pupils as an introduction to the study, and also to artisans and others who are likely to be able to grasp the illustrations given better than they would purely geometrical proofs for which their antecedents have not prepared them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

The Duke of Argyll's Charges against Men of Science.

I REGRET to find that the Duke of Argyll has once more evaded the point at issue. The question is one not of *formulas* but of *facts*. If the statements upon which his Grace bases the severe strictures of his "Great Lesson" were *true*, I for one should take no exception to any "metaphorical or rhetorical expression" by which he chose to enforce his lesson.

Three months have elapsed since the Duke's attention was directed to the discussions which during the last seven years have taken place upon the subject of Mr. Murray's theory of coral reefs—and especially to that one in which the Director-General of our Geological Survey, and the most eminent of American geologists, Prof. J. D. Dana, bore the leading parts; the Duke has been referred to the scientific journals in which this and the other discussions have been carried on; and the fact has been pointed out to him that all the principal text-books of geology, foreign as well as British, which have been published since the theory was announced, have given it a prominent position in their pages. In the face of these facts, is the Duke of Argyll still prepared to maintain that, with respect to the theory in question, there has been "a grudging silence as far as public discussion is concerned"; that there has been "a silence of any effective criticism"; and that "no serious reply has ever been attempted"? If his Grace admits that he was mistaken in making these assertions, is he prepared to withdraw them and also the comments which he has based upon them?

Instead of doing anything of the kind up to the present, the Duke of Argyll has fathered two stories about the wrong-doings of geologists—both of which stories have as little foundation in fact as his statements in "the Great Lesson."

The first of these stories is related in very circumstantial terms, but without any authority being given for it. It is said that a Fellow of the Geological Society offered a certain paper, which the authorities of the Society refused; and it is asserted that the reason of their refusal was that the paper "was not orthodox," and "they probably smelt heresy." Now the Duke of Argyll is well aware that every Fellow of the Geological Society has the right to present papers for reading, and that the responsibility for accepting or refusing papers rests in the first instance with the President; but he, in the case of exercising his veto, is bound to report the fact, and the reasons for his action, at the next meeting of the Council. The records of the Society show that no such paper was ever offered to it; that the President never exercised his right of veto; and that the Council never discussed the grounds of the supposed refusal. The Duke of Argyll has been informed of these facts, but he has not yet retracted the very serious charge which he has made affecting the honour and good faith of the President and the other twenty-two members of the Council of the Geological Society.

In the case of the second story circulated by the Duke of Argyll, the authority is given. The complaint is made that since 1862 "advanced geologists" have "ignored" views which "tend to dethrone" their own "pet theories." Anyone who chooses to refer to the *Philosophical Magazine* for 1862 will see that the "pet theories" in question are those relating to the antiquity of man; that the "advanced geologists" implicated in the charge must have been the late Sir Charles Lyell, Prof. Prestwich, and those who have followed up their researches and arguments; and that the "views" which they "ignored" were the suggestions which I described in my last letter!

JOHN W. JUDD.

The Total Eclipse of the Moon of 1888 January 28, as observed at Birr Castle Observatory, Parsonstown.

THE total eclipse of the moon on Saturday last was, like its predecessor in 1884 (see NATURE, vol. xxx. p. 589, and Trans. Royal Dublin Society for October 1885), favoured by a very clear sky during the whole time of its progress, so that very extensive observations of the changes of the moon's heat in consequence of the passing over of the earth shadow could be made. The apparatus used was essentially the same as that used before; yet the two old thermopiles had been replaced by two new ones especially made for this occasion by the Earl of Rosse.

The observations began at 7h. 19m. M.T. Greenwich, and were, as much as possible, uninterruptedly continued till 15h. 45m.

During this time 638 distinct readings of the galvanometer were obtained, which, when fully reduced, will enable a very satisfactory heat-curve to be drawn. A few preliminary results, reduced to zenith, I communicate at once.

Galvanometer.	
739·4	... 1h. 10m. before first contact with penumbra.
663·4	... 24m. ,, ,, ,,
624·1	... First contact with penumbra.
252·1	... ,, shadow.
34·9	... 22m. before beginning of total phase.
30·2	... 22m. after ,, ,,
231·9	... Last contact with shadow.
545·6	... ,, penumbra.
540·8	... 1h. 34m. after last contact with penumbra.

From these figures it will be seen—

(1) That the heat radiated by the moon begins to decrease a considerable time before the first contact with the penumbra.

(2) That 22m. before the beginning of totality the heat is only 4·7 per cent. of the value obtained 1h. 10m. before the first contact with the penumbra. Unfortunately an unforeseen stoppage of the driving-clock prevented the observations from being carried on closer up to and during the total phase.

(3) That in spite of the rapid fall on approach to totality, the heat, after the last contact with the penumbra, does not at once increase to anything like the value observed at corresponding times before the first contact.

It is worth remarking that points 2 and 3 are confirmatory of the results arrived at in 1884. OTTO BOEDICKER.

Birr Castle Observatory, Parsonstown, January 30.

"Elementary Chemistry," and "Practical Chemistry."

I CRAVE leave from the Editor for space in which to reply, on my own behalf and on that of my fellow-authors Messrs. Slater and Carnegie, to the charges brought by "H. E. A." in NATURE of January 19 (p. 265) against our method of teaching chemistry. At the outset I thank "H. E. A." for the patience which, as he publicly announces, he has shown in waiting for the publication of these books, and I condole with him in his disappointment. Like him, I too am waiting patiently; I trust my disappointment will be less bitter.

One of the important points in our plan of chemical teaching is the connection of the work in the laboratory with the student's reading and lecture-work. To emphasize this connection, and to make our course run fairly smoothly, we have published two books, one to be used in the laboratory, the other to be used in the lecture-room and in reading in connection with the whole work of the student. "H. E. A." acknowledges the advantages of this division, but throughout his review he ignores the statement distinctly made by us, that one book is complementary to the other and that both must be used together. He confines his remarks almost wholly to one of our books, viz. the "Practical Chemistry"; and yet he condemns our system of teaching. On this ground alone I claim that his review is misleading and unfair. I go further, and assert that "H. E. A." has condemned our system without acquainting himself with its essential features. He says that "in the earlier part of the 'Practical Chemistry' Messrs. Muir and Carnegie do not sufficiently bear in mind their own intention, and that much of the matter would find a more fitting place in the companion volume." No one reading this would suppose that almost every experiment used in Chaps. I. to VIII. of the "Practical Chemistry" is also used in Chaps. I. to IX. of the "Elementary Chemistry." Yet this is the case. In one book the experiments are described, along with others, in such terms as allow attention to be concentrated on their results and on the reasoning on these results; in the other book the experiments are described in detail in order that the student may repeat them in the laboratory. In another part of his review "H. E. A." says that most of the subjects dealt with in the third part of the "Elementary Chemistry" "ought never to have been introduced into an 'Elementary Chemistry.'" He has here made a slip: it is the third part of the "Practical Chemistry" which includes subjects not touched on in the other book. This correction involves a point of some importance. Although the preface to our "Practical Chemistry" states that the book forms part of a course of elementary chemistry, yet the student who uses both books will see that the course of work laid down in the practical book carries him much beyond the limits of treatment adopted in the other volume. There are numerous direct and indirect indications of this in the book itself, which those for whom the work is intended will not fail to notice. One cannot put the whole of one's book into the preface. I admit that it would have been better had we indicated in the preface to the "Practical Chemistry" that many experiments in Parts II. and III. are difficult to perform, and require skill and training; but I assert that the nature of the experiments themselves, the references to the original papers to be read before conducting these experiments, and the suggestions as to other work to be done preparatory to Parts II. and III. respectively, suffice to indicate to the student, although not necessarily to the reviewer, the character of the work described in the later chapters of the "Practical Chemistry."

Chapter I. of Part III. of the "Practical Chemistry" involves a repetition of some of Stas's determinations of the atomic weight of silver. "H. E. A." says that this chapter should have been included in Part I., and he adds, "the remaining chapters ought never to have been introduced into an 'Elementary Chemistry,'" kindly informing his readers that these chapters are included "because of the senior author's well-known tendency to worship physical constants." I venture to remind "H. E. A." that no election has taken place to the office of supreme pontiff of chemistry. Were that official in existence, I feel inclined to think he would admit that accurate determinations of atomic weights—and "H. E. A." allows these in the most elementary part of the course—are determinations of constants which have physical as well as chemical meanings.

"H. E. A." says that in the "Practical Chemistry" there is an "entire absence of anything approaching to a *systematic* arrangement." The boldness and baldness of the assertions made by the reviewer encourage me to meet this statement with

a direct denial. There *is* a systematic arrangement in the whole book, or rather in the whole scheme embodied in both books. Because "H. E. A." fails to discover that plan which finds favour with him, it does not follow that systematic arrangement is absent. To say that the arrangement is not that which one would like to see adopted is fair criticism; but to imply that there is no alternative between one's own system and chaos is to expose one's own ignorance. And what is the feature of that system of practical chemistry in which alone the reviewer thinks the student can find salvation? He says, "in a properly chosen series of experiments everything should be proved; no assumption should be necessary." In another part of the review he tells us that "air and the phenomena of combustion should be first studied: the composition of air should be determined, and oxygen should be *discovered* by the student . . . The composition of water should next be qualitatively ascertained." I should be deeply indebted to "H. E. A." if he would kindly describe experiments on these subjects, suited to beginners in chemistry, in which no assumptions are made, and which convey sound teaching. He must not get over the difficulty by cleverly hiding the assumptions made, and so appearing to make none; everything must be proved, and proved by experiments which the beginner can satisfactorily conduct. I hold, and I am convinced that the history of science bears me out, that all scientific reasoning starts with certain assumptions, and that in every particular train of reasoning assumptions are made. If the beginner can be taught to recognize the assumptions which are involved in his reasoning on experimental data, he will do well. In the "Practical Chemistry" we have tried to emphasize the assumptions which the beginner must make. In our opinion the fatal thing is to cover over and hide away the assumptions; by doing this, the student acquires a habit of confounding hypotheses with facts, and so unconsciously he slides into loose methods of reasoning. I fancy I can detect the effects of such a method in the whole review: has not "H. E. A." tacitly, probably unconsciously, assumed that chemical truth abides with him and with him only?

We thank "H. E. A." for indicating some points in the descriptions of certain experiments which might be improved, and also for reminding us that the drawings of apparatus are not as good as they might be. These things can and will be improved. The mistake in the description of the diffusion-experiment, on p. 30 of the "Elementary Chemistry," to which "H. E. A." alludes, has been already pointed out to us, and a slip has been inserted in all copies except the first few hundred correcting this mistake. We cannot congratulate the reviewer, nor do we think he will be inclined on second thoughts to congratulate himself, on the trifling quibbles in which he has indulged regarding one of our experiments on the electrolysis of water.

Cambridge, January 23. M. M. PATTISON MUIR.

"Physical Science and the Woolwich Examinations."

I AM afraid that the moderation of your article on the regulations for admission to the military colleges may give some readers the impression that science is merely being discouraged more or less seriously in their examinations. The fact is, however, that it is being ousted with absolute certainty, for hardly anyone can afford to take up an optional subject which is at a disadvantage of 1000 marks. Severity of competition has within the last few years quite doubled the number of marks qualifying for admission to Sandhurst, and it will soon be impossible, even if it is not so at present, for a candidate to gain a place if he takes up any subject other than Latin, French, German, or mathematics.

This making all the men fit square holes whether they are round or not can hardly be for the advantage of the service, and one's curiosity is aroused as to the reason for such retrogressive changes—whether it is due, as has been asserted, to the action of head masters who do not desire to accumulate or encourage new-fashioned lore; or whether the military authorities really opine that to an officer who may have to deal with telegraphy, to choose a camping-ground, or perhaps direct a search for water, Latin is half as important again as electricity or physical geology.

Is it really too much to expect that they might insist first on a thorough knowledge of those parts of an ordinary education which are specially necessary or helpful to an officer, and then treat the unessential subjects on an equality as far as possible, and let a boy do in his preparation as he will when a man—adequately fulfil the duties of his position, and then follow his own bent? W. A.

January 30.

"The Art of Computation for the Purposes of Science."

HAVING read with much interest Mr. Sydney Lupton's second article on this subject, I think it right to draw his attention, and that of your readers, to Table III. of my book of five-figure and other logarithms published by Messrs. C. and E. Layton in 1870.

This table was framed by me for the purpose of enabling computers who occasionally require to use logarithms to ten places to get same with as little trouble as possible, and without shifting to any other book. In fact, I believe results can be got from my table almost as quickly as from the voluminous and beautiful volume of George Vega.

For instance, referring to Mr. Lupton's example, I find from my table and the instructions that $\log 1{\cdot}0542482375 = \log 1{\cdot}05 + \log 1{\cdot}0040459405$—this by simple division; then—

$$\begin{aligned} &\text{By part A } \log 1{\cdot}05 &&= 0{\cdot}0211892991 \\ &\text{By part B } \log 1{\cdot}0040459405 &&= 0{\cdot}0017535845 \\ \hline &\log 1{\cdot}0542482375 &&= 0{\cdot}0229428836 \end{aligned}$$

correct by Mr. Lupton's solution from Vega.

My whole table is contained in eight octavo pages, and I believe is in as narrow a compass as is consistent with utility.

I may add that in the preliminary part of my book will be found a method of finding the logarithms of all numbers by nothing more than simple multiplication.

The late Prof. Augustus De Morgan, when I showed him this Table No. III., I well remember, replied: "It is very good indeed, but you will get no one to look at it," showing how rarely logarithms are ever required for any practical use beyond five, or at the most seven, figures. E. ERSKINE SCOTT.

6 Bond Court, Walbrook, London, E.C.,
January 18.

THE articles of Mr. Sydney Lupton on the above subject, which have appeared in recent numbers of your paper, do not profess to be complete; still, as their declared object is to assist those who are not mathematicians to work sums by the aid of tables, it seems to me that the best methods should not be passed over in silence, while others that are practically obsolete are discussed at length.

I beg of you therefore to allow me to call attention to the labours of the late Peter Gray, F.R.A.S., in the direction of supplying facilities for computing logarithms and antilogarithms. He contributed papers on the subject to various magazines; notably a series (with a table for formation of logarithms and antilogarithms to twelve places) to the Journal of the Institute of Actuaries in 1865. His most important work on this subject was, however, published as an independent volume in 1876. It is entitled "Tables for the Formation of Logarithms and Antilogarithms to Twenty-four or any less number of places"; and it contains, besides the tables, an explanatory introduction and an exhaustive historical preface. The published price is only 7*s.* 6*d.*, and it is therefore not beyond the reach of those who require such tools.

Weddle's method, the last mentioned by Mr. Lupton, consists in multiplying the given number down to unity, by means of a series of factors of the form $1 - (\cdot 1)_n \times r$, where r may take any integral value from 1 to 9. The logarithms of the factors are then obtained from a previously prepared table, and the complement of the sum of these logarithms is the logarithm of the given number. Weddle also used his method conversely, to calculate antilogarithms.

Hearn, of the Royal Military College, Sandhurst, improved upon Weddle's method, by substituting factors of the form $1 + (\cdot 1)^n \times r$ for the computation of antilogarithms, r, as before, ranging in value from 1 to 9; but he retained the factors $1 - (\cdot 1)^n \times r$ for computing logarithms.

Gray's improvements on Hearn were twofold. In the first place, he gave r the range from 1 to 999, taking for factors $1 + (\cdot 001)^n \times r$, and he thereby brought within narrow compass the arithmetical work involved. In the second place, by a simple arrangement of the calculations, he showed how to use factors of the form $1 + (\cdot 001)^n \times r$, instead of $1 - (\cdot 001)^n \times r$,

for computing logarithms as well as antilogarithms; and thus, not only made the operations more convenient, but also caused one set of preparatory tables to be sufficient.

The principal table in Gray's book above-named consists of the logarithms to twenty-four places of all the possible factors $1 + (\cdot 001)^n \times r$, up to that limit. An auxiliary table contains, also to twenty-four places, the logarithms and their complements of the natural numbers 1 to 9, these being frequently required to "prepare" the given number. A smaller table to twelve figures only appeared, as already mentioned, in the Journal of the Institute of Actuaries, and was subsequently published separately by Messrs. C. and E. Layton; but as the twenty-four-figure table can be worked quite easily to any extent up to that limit, there is no particular advantage in the smaller one.

By means of Gray's tables the work of forming logarithms and antilogarithms is reduced to a minimum, and the process is so simple that any arithmetician can perform it, the more especially as many numerical examples are given in the introduction.

London, January 23. GEORGE KING.

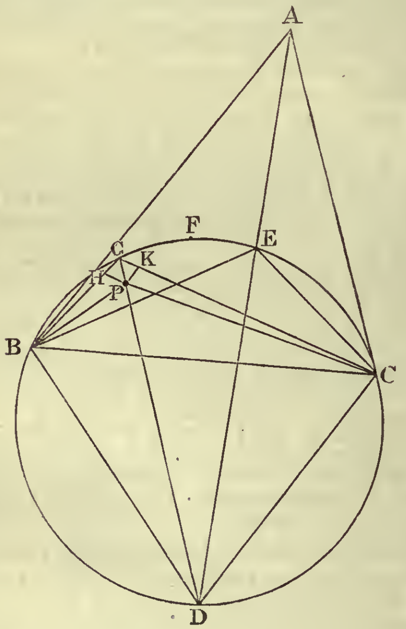
Note on a Problem in Maxima and Minima.

To find a point such that the sum of the straight lines joining it with the angular points of a given triangle shall be a minimum.

This problem was proposed by Fermat to Torricelli, who solved it, and sent it to Vincent Viviani, who also solved it, but called it a problem "quod, ut vera fateor, non nisi iteratis oppugnationibus tunc nobis vincere datum fuit."

The solution is given in Gregory's "Examples of the Differential and Integral Calculus," and in Todhunter's "Differential Calculus," pp. 240–42.

Yet it can be solved in the most elementary manner.



Let ABC be the triangle. Describe an equilateral triangle on BC on the side remote from A. Describe a circle round the triangle BCD. Join AD. Then E is the point required. Join BE, CE.

(1) It follows, from Euc. vi. D, that

$$BE + EC = ED,$$
$$\therefore BE + EC + AE = AD,$$

and evidently $\angle BEC = BEA = AEC = 120^\circ$.

(2) Let F be a point on the circumference BC.

$$BF + FC = FD \quad \text{(Euc. vi. D)},$$
$$\therefore BF + FC + FA = FD + FA > AD.$$

(3) Let P be a point not on the circumference. Join DP, and produce it to the circumference at G. Let fall the perpendiculars PH and PK, on GB and GC respectively.

$$\text{By Euc. i. 26, } GH = GK = \tfrac{1}{2}GP.$$
$$\text{Since } \angle GPH = 30^\circ = GPK,$$
$$\therefore BH + KC = PD,$$
$$\therefore BP + PC > PD,$$
$$\therefore BP + PC + PA > PD + PA > AD.$$

(4) It also follows from the above that if $\angle A = 120^\circ$, then the point required is $A \equiv E$.

If $\angle A > 120^\circ$, the point A will be within the circle, and A itself will be the point required. R. CHARTRES.

Note on the Dimensions and Meaning of J, usually called the Mechanical Equivalent of Heat.

THE title "mechanical equivalent of heat" tends to make one consider that J means the ratio of a quantity of mechanical energy to an equivalent quantity of heat; but since heat *is* mechanical energy (in a molecular form) it follows that J on this supposition is equal to *unity*, and therefore unnecessary.

Another way in which J is sometimes regarded is as the ratio between the ordinary *units* of heat and work; that is to say, in England, it is the ratio of the British thermal unit to a foot-pound, viz. the number 772. This definition makes it a simple number, the number of work units in a heat unit, a number which depends on the units of heat and work employed, and is different in France and England.

Now although J generally has one or other of these significations—that is, must be either unity or some pure number—yet people speak of the *dimensions* of J as being, not zero, but $\dfrac{\text{Work}}{\text{Mass} \times \text{Temperature}}$.

It is evident that there must be some confusion here, a confusion arising from the fact that most people when *talking* of quantities *mean* only so many times the units of those quantities, and so are not always sufficiently careful about the definitions of the various quantities which they introduce.

Now if we confine our attention to quantities themselves, independently of any systems of measurement, we shall be led to a perfectly consistent mode of regarding J, a way moreover in which it will have the required dimensions $\dfrac{\text{Work}}{\text{Mass} \times \text{Temperature}}$.

A British thermal unit is the heat required to raise a pound of water at freezing-point through 1° F., and Joule discovered that the mechanical equivalent of that amount of heat was about 772 foot-pounds.

Hence if we wish to consider the work necessary to raise any other mass of water at freezing-point through any small range of temperature, we have only to notice that the quantity $\dfrac{\text{Work}}{\text{Mass} \times \text{Range of Temperature}}$ is constant, and equal to $\dfrac{772 \text{ foot-pounds}}{1 \text{ pound} \times 1^\circ \text{ F.}}$.

This quantity is very fitly denoted by J, and might, if thought convenient, be called *a Joule*.

But this quantity is the *specific heat of water*, according to the definition that specific heat is the heat required to raise a mass through a small range of temperature *divided by* the mass and the range. So that we have arrived at these conclusions: a quantity of heat is the same thing, whether expressed in British thermal units, or in foot-pounds, or in terms of any other standard; and the specific heat of water at 0° C. is denoted by the letter J.

Indeed it may be said that the result of Joule's experiments is the determination of the specific heat of water in absolute measure. Again, if c is the ratio of the specific heat of any substance to that of water, the full expression of its specific heat is cJ; that is, its specific heat is some multiple or fraction of a *Joule*.

The first law of thermo-dynamics will then be expressed as—

$$dQ - p \,.\, dV = cJm \,.\, d\theta + m \,.\, dI,$$

where $dQ - pdV$ is the total energy supplied, $cJmd\theta$ is the amount of new energy evidenced by increase of temperature, and mdI is the increment of the latent energy of the body.

The Temporary Thermo-Current in Iron.

IN the *Philosophical Magazine* for January, Mr. Herbert Tomlinson has proposed an explanation of the remarkable fact that in an iron wire, heated red hot by a burner, an electric current is produced when the flame is shifted along the wire (see Wiedemann's "Galvanismus," ii. 453).

As his explanation is inadequate, perhaps I may be excused again drawing attention to this subject. Briefly his explanation is as follows:—That, as the portion of the wire in the flame rises in temperature, it, thermo-electrically speaking, becomes in fact like a different metal, and that then, on shifting the flame, the junction with the unaltered wire on the side moved towards becomes hotter than before, while the one on the other side falls in temperature, thus presenting the ordinary case of a thermo-couple with junctions at different temperatures. Now this explanation entirely overlooks the fact that, by the first assumption, just as fast as the temperature on one side rises, the wire there changes into the "second state," and correspondingly changes back on the other side as the temperature falls there; so that, as far as this explanation goes, there ought to be no current whatever, for thus both junctions must always be at the same temperature.

When I first noticed this current, which from considerations to follow I have ventured to call the "temporary thermo-current," it appeared to me to be due to the difference in the temperature-slope (or gradient) along the wire in front from that behind the flame, as it heats more rapidly in front than it cools behind, and to the electromotive force being a function of the slope, *i.e.* of $\frac{d\theta}{dx}$. But this hypothesis did not stand the test of experiment, as I have shown in a paper published in the Proceedings of the Royal Dublin Society, July 1886. So that as there *is* a current, we must suppose the "second state" to be not only a function of the temperature, but also of the time, *i.e.* that the wire changes into (or from) the "second state" more slowly than it is possible for it to change in temperature. So that the electromotive force at any point depends on the rate of change of the temperature slope, or equals $\phi\left(\frac{d}{dt}\frac{d\theta}{dx}\right)$. In support of this it will be found that if the flame be steadily moved along very slowly no current is produced—at all events less than would be otherwise expected; and, secondly, that the maximum current is got by moving the flame the fastest consistent with the condition of keeping the wire red hot.

It is with the view of emphasizing this dependence on the time that the term "temporary thermo-current" seems appropriate. FRED. T. TROUTON.

Physical Laboratory, Trinity College, Dublin.

Causes influencing the Bathymetrical Range of Deep-Sea Fishes.

YOU refer (p. 219) to the fact that Dr. Günther has adopted the 100-fathom line as the boundary at which with the extinction of sunlight the bathybial fauna commences. This selection of 100 fathoms as the limiting horizon is of much interest in connection with the theory that the shallow-water marine fauna is greatly influenced by wave-currents. In a letter you published in 1885 (NATURE, vol. xxxii. p. 390) I indicated 100 fathoms as the depth to which wave-action of some sort must extend, as evidenced by the character of the deposits at the mouth of the English Channel. Dr. Günther now shows that the deep-sea fishes do not rise above that horizon. But, although the 100-fathom horizon agrees very well with the apparent limit of wave-action, it does not seem to agree with the most recent experiments on the penetration of sunlight in water.

So recently as November last you recorded the fact that during the past year Prof. Forel found that the greatest "depth-limit of absolute darkness" from March to July in the Lake of Geneva was 100 metres (NATURE, vol. xxxvii. p. 88). If experiments in a fresh-water lake may be taken as a guide to light-penetration in the ocean, 50 fathoms will be nearer the limit than 100. In this case the bathymetrical range of the bathybial fauna cannot be much influenced, if at all, by the presence or absence of sunlight. This view is moreover fortified by the fact that, though the deep-sea forms do not usually ascend above the 100-fathom line, the shallow-water forms go far below it; and there is no reason why they should not do so; for, although a form unfitted to withstand wave-currents cannot face them, there is nothing to prevent a flat-fish, fully equipped in this respect, from passing at will from the disturbed to the tranquil horizon, and *vice versâ*. A. R. HUNT.

Torquay, January 10.

Wind Force at Sea.

IN reference to a letter on the above subject in NATURE (p. 274), I beg to acquaint your readers that Capt. Barker's wish that anemometers should be used more on board ship has been endeavoured to be met by an instrument designed by myself on the sail principle. It has now been in use on some ships at sea for long voyages for five years, and daily observations have been obtained and sent home of the data observed, of pressure, direction, and velocity of the winds met with.

Regarding the further inquiry of ascertaining the rainfall at sea, this has now been carried on for about ten years by means of a rain-gauge designed by myself on the pivot principle, and it has been used by many vessels in all the great seas.

The daily observations have been sent home and are now on hand, and about five years of the returns have already been announced, and a further compilation of the data may be prepared when the materials become sufficient.

It may be added that the late Capt. Symington, of the s.s. *Hankow*, amongst his meteorological observations took the rainfall by rain-gauge on his ship for twenty years or more. The marine anemometer and rain-gauge above mentioned were exhibited at the Liverpool Exhibition in 1886, and at the Meteorological Exhibition of last year. W. G. BLACK.

Edinburgh, January 21.

Untimely Insect Development.

SOME of your readers may be interested in a case of untimely insect development, caused no doubt by the phenomenal mildness of the weather in this part of the country during the last few days. Last evening a perfect imago of the common tortoise-shell butterfly (*Vanessa urtica*) was found inside my house on the wall of my nursery. It is fully developed in every way, and the only thing in its appearance at all abnormal is that the antennæ are bent back and lie between the wings, which are in the erect position usual in repose. The insect has evidently only just emerged from the pupa, and is in a torpid condition, only just flapping its wings when touched. The nursery is a warm room looking to the south, and has a fire in it all day.

St. Albans, January 10. JOHN MORISON.

Weasels killing Frogs.

SEEING a note in NATURE (December 29, 1887, p. 208), about weasels killing frogs, I thought that the following fact would be a further confirmation.

I was walking near the village of Clifton Hampden in August last, when I saw a weasel, carrying a good-sized frog in its mouth, come cautiously out of the rank grass by the road-side; directly the weasel perceived me, it dropped its prey on the road and retreated to the cover of the grass. The frog was dead. I kept silence, and the weasel left its hiding-place, and advanced a few steps, but again retreated. Soon, after several advances and retreats, it rushed out, seized the frog with its teeth, and running across the road disappeared in the long grass on the other side.

January 20. M. S. PEMBREY.

"British and Irish Salmonidæ."

THE author of "British and Irish Salmonidæ" calls in question the justice of three criticisms in my review of that book. In reply to his first objection, I have to point out that my quotation of the sentence referred to was, as Mr. Day has himself noted, made to draw attention to its grammatical errors, and therefore the omission of a few words which affected the sense but not the construction was of no consequence at all. I omitted the words intentionally, to shorten the quotation, and gave no opinion on the statement contained in the sentence: the statement which is implied rather than expressed is perfectly correct.

With regard to the second point, the statement in the text of the book which I questioned is as follows:—"The main principle is to employ thin layers of well-packed and pressed moss in trays with perforated bottoms, *the eggs being separated from the moss by muslin, mosquito-netting, swans' down, calico, or butter-cloth*, and that each tray contains two or three layers." In all the methods of packing salmonoid eggs in which moss is employed, the descriptions I have read state that the eggs are placed in direct contact with the moss, and Mr. Day does not justify the statement above quoted by referring to another statement in his notes, that for shorter journeys eggs are thrown off the frames on to swans' down. I doubted, and still doubt, if there is any method practised in which layers of moss are used, and are separated from the eggs by muslin or similar material.

With regard to the third point, it is true that on p. 249 of his book, in the chapter on *S. fontinalis*, Mr. Day refers to Brown Goode's "Game Fishes of the United States," and to the statement in that work that *S. namaycush* has, as its nearest relative, *S. fontinalis*. But I think a more direct reference to a speciegraphical description of *S. namaycush* might have been expected in a footnote referring to errors in the descriptions of this fish by certain writers. My remark about the omission of such reference was not made under the impression that S. *namaycush* was not a char, for I am aware that it is described as such in recent American reports on pisciculture, and have no doubt that such description is correct. But reference to speciegraphical determinations are rare in such reports, and I think readers of Mr. Day's book would have been glad of the references which he now supplies in his letter. YOUR REVIEWER.

MODERN VIEWS OF ELECTRICITY.[1]

PART III. (*continued*).

VI.

LET us now pass in review the various facts and experiences which have led us to a dual view of electricity; a kind of two-fluid theory, but in a very modified form.

First, there are the old experiments which vaguely suggest the separate existence of negative electricity, such as:—

(1) The wind from a point whether positive or negative; so that a candle gets blown always away from it, whether the point be on the prime conductor and the candle held in hand, or whether the point be held in the hand and presented to the candle or prime conductor; so, also, that a point whirligig turns the same way, whether supported on the prime conductor, or whether attached to the earth and placed near it.

(2) Phenomena connected with the spark discharge, such as Wheatstone's old experiment on what he called the velocity of electricity, with the three pair of knobs; and the double burr produced in cardboard when pierced with a spark, suggesting that something has pierced it both ways at once.

Then there are the more recently observed facts; as, for instance:—

(3) The fact that an electrostatic strain scarcely affects the volume of a dielectric; thereby at once suggesting something of the nature of a shearing or distorting stress, which alters shape but not size; a displacement of positive outwards and simultaneous negative inwards.

(4) The facts of electrolysis, and the double procession of atoms past each other in opposite directions.

(5) The phenomena of self-induction, and the behaviour of a thick wire to an alternating current. The delay also in magnetizing iron, and especially the possibility of permanent magnetism; combined with

(6) The absence of momentum in an electric current, or moment of momentum in an electro-magnet, as tested by all mechanical means yet tried.

I admit at once that many of these are mere superficial suggestions which may hardly bear examination and criticism. Only (3), (4), (5), and (6) can be at all seriously appealed to; but (5) and (6), in conjunction, seem to me to afford a sort of provisional and hypothetical proof, which (3) greatly strengthens.

At this point we must for the present again leave the question.

[1] Continued from p. 110.

Representation of a Magnetic Field.

The disturbance called magnetism, which we have shown to be something of the nature of a spin—a rotation about an axis—is conspicuously not limited to the steel or iron of the magnet: it spreads out through all adjacent space, and constitutes what is called the magnetic field. A map of the field is afforded by the use of iron filings, which cling end to end and point out the direction of the force at every point.

These lines of force so mapped are to be regarded as the axes of molecular whirls. They are continuous with similar lines in the substance of the steel, and every line really forms a closed curve, of which a portion is in the steel and a portion in the air. In a wire helix, such as Figs. 16 or 29, the lines are wholly in the air, but in one part of their course they thread the helix, and in another part they spread out more or less between its faces.

But according to Ampère's theory of molecular currents there is no *essential* difference between such a helix and a steel magnet; directly the currents in the molecules of the magnet are considered, everything resolves itself into chains of molecular currents, threading themselves along a common closed curve or axis. Each atom, whether in the steel or in the air, is the seat of a whirl of electricity, more or less faced round so as on the average to have its plane at right angles to the lines of force. The simplest plan of avoiding having to consider those only partially faced round, is to imagine the whole number divided into a set which face accurately in the right direction, and a set which look any way at perfect random, and to neglect this latter set.

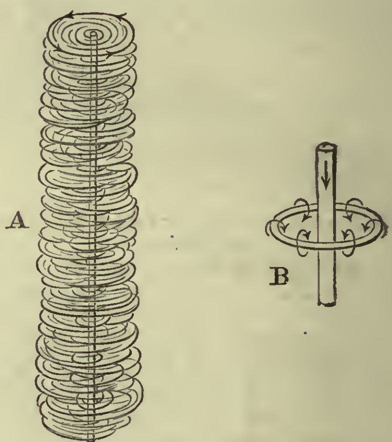

FIG. 30.—A, an element of a magnetic line of force with the electric whirl round it; B, a bit of an electric circuit with one of its magnetic lines of force shown round it, and the electric whirl round this; each magnetic line of force round a current being an electric vortex ring.

Well now try and picture a chain of whirls like beads spinning on a wire threading them all, and think of the effect of a material fluid thus rotating. Obviously it would tend to whirl itself fatter, and to shorten its length. An assemblage of such parallel straight whirls would thus squeeze each other laterally, or cause a lateral pressure, and would tend to drag their free ends together, causing a longitudinal tension.

Such whirls cannot in truth have free ends except at the boundary of a medium—as at the free surface of a liquid. Magnetic whirls are in reality all closed curves;

but inasmuch as part of them may be in a mobile fluid like air, and part of them in a solid like iron or steel, it is convenient to distinguish between their two portions; and one may think of the air whirls alone as reaching from one piece of iron to another and by their shortening tendency or centrifugal force pulling the two pieces together.

The arrangement shown in Fig. 31 illustrates the kind

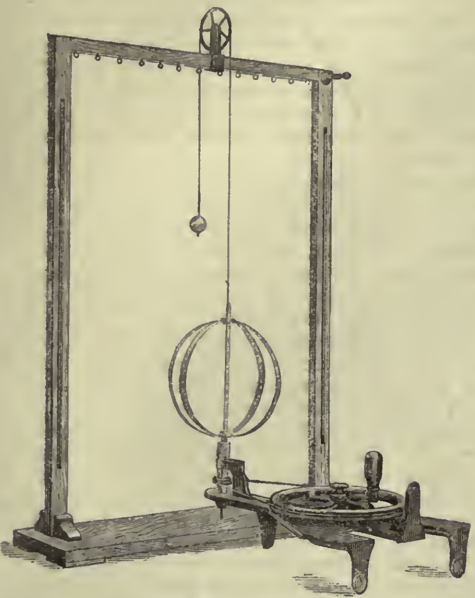

Fig. 31.—A "shape of the earth" model which, when whirled, exerts a tension along its axis, pulling up the weight attached to it, and a pressure at right angles, by reason of its bulging out.

of force exerted by a spinning elastic framework along and perpendicular to its axis of rotation.

One can easily see this effect of a whirl in a tea-cup or inverted bell-jar full of liquid. Stir it vigorously, and leave it. It presses against the walls harder than before, so that if they were elastic they would bulge out with the lateral pressure; and it sucks down the top or free end of its axis of rotation, producing quite a depression or

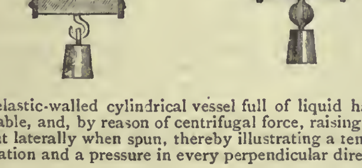

Fig. 32.—An elastic-walled cylindrical vessel full of liquid hanging from a whirling table, and, by reason of centrifugal force, raising a weight and bulging out laterally when spun, thereby illustrating a tension along the axis of rotation and a pressure in every perpendicular direction.

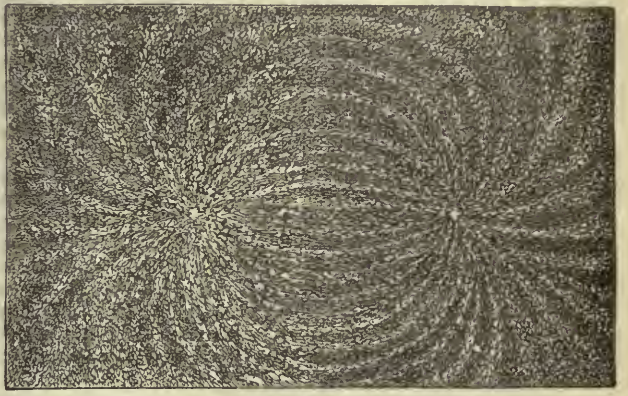
hollow against the force of gravity. Or, as a more striking illustration, make the following apparatus.

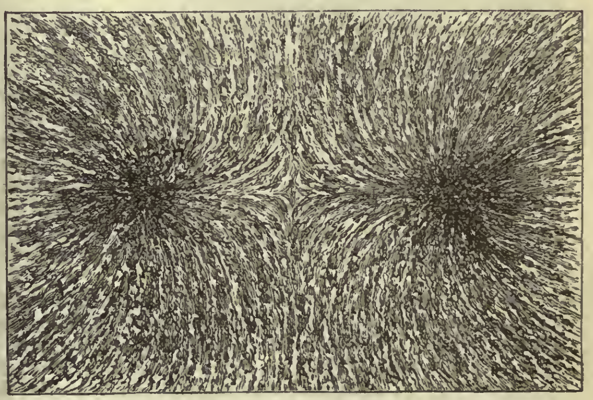
Two circular boards joined by a short wide elastic tube or drum: a weight hung to the lower board, the top board hung from a horizontal whirling table, the drum filled with water, and the whole spun round. The weight is raised by the longitudinal tension; the sides bulge out with the lateral pressure.

There is no need for the whole vessel to rotate. If the liquid inside rotates, the same effect is produced.

Imagine now a medium composed of a multitude of such cells with rotating liquid inside: let the cells be either very long, or else be joined end to end so as to make a chain—a series of chains side by side—and you have a picture of a magnetic medium traversed by a field of force. End-boundaries of the field will be dragged together, thus representing magnetic attraction; while, sideways, the lines of force (axes of whirl) squeeze each



Attraction.



Repulsion.

Fig. 33.—Attraction and repulsion. The tension along the lines of force or axes of rotation drags the one pair of poles together; and the pressure in directions perpendicular to the axis of rotation due to the centrifugal force of the whirls drives the other pair apart.

other apart, thus illustrating repulsion. This is Clerk-Maxwell's view of an electro-magnetic medium, and of the mode in which magnetic stress, and magnetic attractions and repulsions between bodies, arise.

Wherever lines of force reach across from one body to another, those bodies are dragged together as if pulled by so many elastics (Fig. 33); but wherever lines of force from one body present their *sides* to those proceeding from another body, then those bodies are driven apart.

Oliver J. Lodge.

(*To be continued.*)

LANGUAGE-REASON.

The inclosed letter on "Reason-Language" was written to an American friend, and has been published in an American paper in Chicago. I thought it might possibly interest the readers of Nature.

Oxford, January 22. F. Max Müller.

"You tell me that my book on the 'Science of Thought' is thoroughly revolutionary, and that I have all recognized authorities in philosophy against me. I doubt it. My book is, if you like, evolutionary, but not revolutionary; I mean it is the natural outcome of that philosophical and historical study of language which began with Leibniz, and which during our century has so widely spread and ramified as to overshadow nearly all sciences, not excepting what I call the science of thought.

"If you mean by revolutionary a violent breaking with the past, I hold on the contrary that a full appreciation of the true nature of language and a recognition of its inseparableness from thought will prove the best means of recovering that unbroken thread which binds our modern schools of thought most closely together with those of the Middle Ages and of ancient Greece. It alone will help us to reconcile systems of philosophy hitherto supposed to be entirely antagonistic. If I am right—and I must confess that with regard to the fundamental principle of the identity of reason and language I share the common weakness of all philosophers, that I cannot doubt its truth—then what we call the history of philosophy will assume a totally new aspect. It will reveal itself before our eyes as the natural growth of language, though at the same time as a constant struggle of old against new language—in fact, as a dialectic process in the true sense of the word.

"The very tenet that language is identical with thought —what is it but a correction of language, a repentance, a return of language upon itself?

"We have two words, and therefore it requires with us a strong effort to perceive that behind these two words there is but one essence. To a Greek this effort would be comparatively easy, because his word *logos* continued to mean the undivided essence of language and thought. In our modern languages we shall find it difficult to coin a word that could take the place of *logos*. Neither *discours* in French, nor *Rede* in German, which meant originally the same as *ratio*, will help us. We shall have to be satisfied with such compounds as thought-word or word-thought. At least, I can think of no better expedient.

"You strongly object to my saying that there is no such thing as reason. But let us see whether we came honestly by that word. Because we reason—that is, because we reckon, because we add and subtract—therefore we say that we have reason; and thus it has happened that reason was raised into something which we have or possess, into a faculty, or power, or something, whatever it may be, that deserves to be written with a capital R. And yet we have only to look into the workshop of language in order to see that there is nothing substantial corresponding to this substantive, and that neither the heart nor the brain, neither the breath nor the spirit, of man discloses its original whereabouts. It may sound violent and revolutionary to you when I say that there is no such thing as reason; and yet no philosopher, not even Kant, has ever in his definition of reason told us what it is really made of. But remember, I am far from saying that reason is a mere word. That expression, 'a mere word,' seems to me the most objectionable expression in the whole of our philosophical dictionary.

"Reason is something—namely, language—not simply as we now hear it and use it, but as it has been slowly elaborated by man through all the ages of his existence on earth. Reason is the growth of centuries, it is the work of man, and at the same time an instrument brought to higher and higher perfection by the leading thinkers and speakers of the world. No reason without language—no language without reason. Try to reckon without numbers, whether spoken, written, or otherwise marked; and if you succeed in that I shall admit that it is possible to reason or reckon without words, and that there is in us such a thing or such a power or faculty as reason, apart from words.

"You say I shall never live to see it admitted that man cannot reason without words. This does not discourage me. Through the whole of my life I have cared for truth, not for success. And truth is not our own. We may seek truth, serve truth, love truth; but truth takes care of herself, and she inspires her true lovers with the same feeling of perfect trust. Those who cannot believe in themselves, unless they are believed in by others, have never known what truth is. Those who have found truth know best how little it is their work, and how small the merit which they can claim for themselves. They were blind before, and now they can see. That is all.

"But even if I thought that truth depended on majorities, I believe I might boldly say that the majority of philosophers of all ages and countries is really on my side (see 'Science of Thought,' pp. 31 *et seq.*), though few only have asserted the identity of reason and language without some timorous reserve, still fewer have seen all the consequences that flow from it.

"Some people seem to resent it almost as a personal insult that what we call our divine reason should be no more than human language, and that the whole of this human language should have been derived from no more than 800 roots, which can be reduced to about 120 concepts. But if I had wished to startle my readers I could easily have shown that out of these 800 roots one-half could really have been dispensed with, and has been dispensed with in modern languages (see 'Science of Thought,' p. 417), while among the 120 concepts not a few are clearly secondary, and owe their place in my list (*ib.* p. 619) merely to the fact that in Sanskrit they cannot be reduced to any more primitive concept. To dance, for, instance, cannot be called a primitive concept; perhaps not even to hunger, to thirst, to cook, to roast, &c. Only it so happens that in Sanskrit, to which my statistical remarks were restricted, we cannot go behind such roots as NÆT, KSHUDH, TÆSH, PAK, &c. It is in that limited sense only that such roots and such concepts can be called primitive. The number of really primitive concepts would be so alarmingly small that for the present it seemed wiser to say nothing about it. But so far from being ashamed of our modest beginnings, we ought really to glory rather in having raised our small patrimony to the immense wealth now hoarded in our dictionaries.

"When we once know what our small original patrimony consisted in, the question how we came in possession of it may seem of less importance. Yet it is well to remember that the theory of the origin of roots and concepts, as propounded by Noiré, differs, not in degree, but *toto cœlo* from the old attempts to derive roots from interjections and imitations of natural sounds. That a certain number of words in every language has been derived from interjections and imitations no one has ever denied. But such words are not conceptual words, and they become possible only after language had become possible—that is, after man had realized his power of forming concepts. No one who has not himself grappled with that problem can appreciate the complete change that has come over it by the recognition of the fact that roots are the phonetic expressions of the consciousness of our own acts. Nothing but this, our consciousness of our own repeated acts, could possibly have given us our first concepts. Nothing else answers the necessary requirements of a concept, that it should be the consciousness of something manifold, yet necessarily realized as one. After the genesis of the first concept, everything else becomes intelligible. The results of our acts become the first objects of our conceptual thought; and with

conceptual thought, language, which is nothing if not conceptual, begins. Roots are afterwards localized, and made the signs of our objects by means of local exponents, whether suffixes, prefixes, or infixes. What has been scraped and shaped again and again becomes as it were 'shape-her',' *i.e.* a shaft; what has been dug and hollowed out by repeated blows becomes 'dig-her',' *i.e.* a hole. And from the concept of a hole dug, or of an empty cave, there is an uninterrupted progress to the most abstract concepts, such as empty space, or even nothing. No doubt, when we hear the sound of cuckoo, we may by one jump arrive at the word cuckoo. This may be called a word, but it is not a conceptual word, and we deal with conceptual words only. Before we can get at a single conceptual word, we have to pass through at least five stages:—

"(1) Consciousness of our own repeated acts.
"(2) *Clamor concomitans* of these acts.
"(3) Consciousness of that *clamor* as concomitant of the act.
"(4) Repetition of that *clamor* to recall the act.
"(5) *Clamor* (root) defined by prefixes, suffixes, &c., to recall the act as localized in its results, its instruments, its agents, &c.

"You can see from my preface to the 'Science of Thought' that I was quite prepared for fierce attacks, whether they came from theologians, from philosophers, or from a certain class of scholars. So far from being discouraged, I am really delighted by the opposition which my book has roused, though you would be surprised to hear what strong support also I have received from quarters where I least expected it. I have never felt called upon to write a book to which everybody should say *Amen*. When I write a book, I expect the world to say *tamen*, as I have always said *tamen* to the world in writing my books. I have been called very audacious for daring to interfere with philosophy, as if the study of language, to which I have devoted the whole of my life, could be separated from a study of philosophy. I have listened very patiently for many years to the old story that grammar is one thing and logic another; that the former deals with such laws of thought as are observed, the latter with such as ought to be observed. No, no. True philosophy teaches us another lesson—namely, that in the long run nothing is except what ought to be, and that in the evolution of the mind, as well as in that of Nature, natural selection is rational selection; or, in reality, the triumph of reason, the triumph of what is reasonable and right; or, as people now say, of what is fittest. We must learn to recognize in language the true evolution of reason. In that evolution nothing is real or remains real except what is right; nay, in it even the apparently irrational and anomalous has its reason and justification. Towards the end of the last century, what used to be called *Grammaire Générale* formed a very favourite subject for academic discussions; it has now been replaced by what may be called *Grammaire Historique*. In the same manner, *Formal Logic*, or the study of the general laws of thought, will have to make room for *Historical Logic*, or a study of the historical growth of thought. Delbrück's essays on comparative syntax show what can be done in this direction. For practical purposes, for teaching the art of reasoning, formal logic will always retain its separate existence; but the best study of the real laws of thought will be hereafter the study of the real laws of language. If it was really so audacious to make the identity of language and reason the foundation of a new system of philosophy, may I make the modest request that some philosopher by profession should give us a definition of what language is without reason, or reason without language? "F. M. M."

FERDINAND VANDEVEER HAYDEN.

WE reprint from the American journal *Science* (January 6) the following article on Dr. Hayden, whose death we lately announced:—Prof. Ferdinand Vandeveer Hayden, M.D., Ph.D., LL.D., who died in Philadelphia on the morning of December 22, was born in Westfield, Mass., September 7, 1829. Early in life he went to Ohio. In 1850 he was graduated from Oberlin College, and soon afterward read medicine at Albany, N.Y., receiving his degree from the Albany Medical College in 1853. He did not begin the practice of medicine, but in the spring of the year of his graduation was sent by Prof. James Hall of Albany, with Mr. F. B. Meek, to visit the Bad Lands of White River, to make collections of the Cretaceous and Tertiary fossils of that region. This was the beginning of his explorations of the West, which continued with little interruption for more than thirty years.

In the spring of 1854, Dr. Hayden returned to the Upper Missouri region, and spent two years in exploring it, mainly at his own expense, although he was aided a portion of the time by gentlemen connected with the American Fur Company. During these two years he traversed the Missouri River to Fort Benton, and the Yellowstone to the mouth of the Big Horn River, and explored considerable portions of the Bad Lands of White River and other districts not immediately bordering upon the Missouri. The large collections of fossils he made were given partly to the Academy of Sciences in St. Louis, and partly to the Academy of Natural Sciences of Philadelphia.

As one of the members of the Geological Survey has recently said, these collections and researches mark the commencement of the epoch of true geologic investigation of the Great West. The collections attracted the attention of the officers of the Smithsonian Institution; and in February 1856, Dr. Hayden was employed by Lieut. G. K. Warren, of the United States Topographical Engineers, to make a report upon the region he had explored; so that the results of his labours during the three previous years were utilized by the Government. This report was made in March of the same year, and in May following he was appointed geologist on the staff of Lieut. Warren, who was then engaged in making a reconnaissance of the North-West. He continued in this position until 1859, when he was appointed naturalist and surgeon to the Expedition for the exploration of the Yellowstone and Missouri Rivers, by Capt. William F. Raynolds of the Corps of Engineers of the United States Army, with whom he remained until 1862. The results of his work while with Liutenant Warren were published in a preliminary report of the War Department, and in several articles in the Proceedings of the Academy of Natural Sciences of Philadelphia for the Years 1857 and 1858, and more fully in a memoir on the geology and natural history of the Upper Missouri, published in the Transactions of the American Philosophical Society, Philadelphia, 1862. This paper also included chapters on the mammals, birds, reptiles, fishes, and recent mollusca of the region in which his geological investigations were carried on. During this period also he found time to make notes upon the languages and customs of the Indian tribes with which he came in contact. These notes were embodied in "Contributions to the Ethnography and Philology of the Indian Tribes of the Missouri River," published in the Transactions of the American Philosophical Society, Philadelphia, 1862; in a "Sketch of the Mandan Indians, with some Observations illustrating the Grammatical Structure of their Language," published in the *American Journal of Science* in 1862; and in "Brief Notes on the Pawnee, Winnebago, and Omaha Languages," published

in the Proceedings of the American Philosophical Society, Philadelphia, 1869.

In May 1862, Dr. Hayden was appointed acting-assistant surgeon of volunteers by the Surgeon-General of the United States Army, and was sent to Satterlee Hospital in Philadelphia. He was confirmed by the United States Senate as assistant-surgeon and full surgeon of volunteers on the same day (February 16, 1863), and sent to Beaufort, S.C., as chief medical officer, where he remained for one year, when he was ordered to Washington as assistant medical inspector of the Department of Washington. On February 19, 1864, he was sent to Winchester, Va., as chief medical officer of the army in the Shenandoah valley. Here he remained until May 1865, when he resigned, and was brevetted lieutenant-colonel for meritorious services during the war. During the remainder of the year 1865 he was employed in work at the Smithsonian Institution. It was during this year that he was elected Professor of Geology and Mineralogy in the University of Pennsylvania,—a position he held until 1872, when the increased executive duties in connection with the Geological Survey of the Territories induced him to resign it.

In the summer of 1866 he undertook another expedition to the Bad Lands of Dakota, under the auspices of the Academy of Natural Sciences of Philadelphia, for the purpose of clearing up some doubtful points in the geology of that region, and returned with large and valuable collections of vertebrate fossils, which were described in a memoir published by the Academy of Natural Sciences of Philadelphia in 1869. From 1867 to 1879 the history of Dr. Hayden is the history of the United States Geological and Geographical Survey of the Territories, of which he was geologist-in-charge, and to the success of which he devoted all his energies during the twelve years of its existence. In this time more than fifty volumes, together with numerous maps, were issued under his supervision. One of the results of his surveys, and the one in which he probably took the greatest interest, was the setting aside by Congress of the Yellowstone National Park. The idea of reserving this region as a park or pleasure-ground for the people originated with Dr. Hayden, and the law setting it apart was prepared under his direction. The work of the Geological Survey of the Territories had its consummation in the Atlas of Colorado, which increased greatly our knowledge of one of the most interesting portions of the Great West. In 1879, after the disbanding of the Survey of the Territories, Dr. Hayden received an appointment as geologist on the newly organized United States Geological Survey. For about three years he was occupied in the completing of the business of the Geological and Geographical Survey of the Territories, and the preparation of the final results of that survey. His health had already begun to fail, but early in 1883 he asked to be relieved from the supervision of the printing of the reports, and during the three following seasons he undertook field work in Montana. By the latter part of the year 1886 his health had become so poor that he was confined most of the time to his bed. He then resigned his position as geologist, closing an honourable connection with the Government that included twenty-eight years of actual service as naturalist, surgeon, and geologist. To the general interest in science excited by the enthusiastic labours of Dr. Hayden in his geologic explorations, is due in a great degree the existence and continuance of the present United States Geological Survey.

In 1876 the degree of LL.D. was conferred upon him by the University of Rochester, and in June 1886 the same degree was conferred upon him by the University of Pennsylvania. Dr. Hayden was a member of the National Academy of Sciences and of many other Societies scattered throughout the country. He was also honorary and corresponding member of a large number of foreign Societies.

As to Dr. Hayden's personal character, those who were personally associated with him know best how genial he was, and how sincere and enthusiastic his desire to forward the cause of science. Although impulsive at times, he was generous to a fault. His subordinates all knew that each one stood upon his own merits, and that due credit would be awarded to his successful efforts. The same spirit actuated him in respect to those not immediately connected with him. His views are expressed as follows in one of his earliest reports, when speaking of those who had preceded him: "Any man who regards the permanency or endurance of his own reputation will not ignore any of these frontier men who made their early explorations under circumstances of great danger and hardship."

His ideas were broad and liberal. He aimed to make a thorough astronomical, topographical, geological, and botanical survey of the Great West, with a view to the development of its mining and agricultural resources. The greater part of his work for the Government and for science was a labour of love.

To the foregoing notice some token of recognition and regret on the part of brother geologists on this side of the Atlantic may perhaps be fittingly appended by one who knew Dr. Hayden personally, was familiar with his writings, and had wandered in his footsteps among the solitudes of the Far West. The first impression which the late geologist made on those who came to know him was one of gentleness, almost of timidity. They could hardly help asking themselves, "Can this be the man who has so successfully won over the blustering Congressmen to grant him year after year such large appropriations for his western surveys; who has organized such wonderful expeditions; who has gone through such hardships, and in an incredibly short space of time has made such excellent reconnaissances and published such voluminous Reports and admirable maps?" It was some time before one could see the real underlying secret of his success. This was undoubtedly a quiet enthusiasm for science, supported by an undemonstrative but indomitable courage, and a determination to gain the proposed end, cost what it might in bodily and mental endurance. No one who has not been in some measure admitted behind the scenes of political wire-pulling in the States, can realize what had to be undertaken by the man of science who would obtain and retain an annual subsidy from Congress for scientific investigation in the days when Hayden carried on his explorations. There were other rival claimants for Parliamentary aid who were doing similar work, under other Government Departments. There was likewise the wide outside circle of scientific men who had no State employment, and some of whom thought themselves at least as deserving of it as those who fortunately had gained it. Then there were the Gallios of Congress, who cared nothing about science of any kind, those who grudged money spent out of their own States, those who required to see on their drawing-room table a well got up Annual Report with pictures and maps before they could be made to believe that the money was well bestowed. And the weeks and months of early summer, so precious for field work, had to be passed in the lobbies of the Capitol, making sure that there would be no failure in the granting of the appropriation. The most wearisome and profitless part of his year was this "lobbying" at Washington. But Hayden had no choice in the matter. He must either go through with that part of his work or abandon his western surveys altogether. This alternative has not always been borne in mind by those who have judged of him.

There can be no doubt that among the names of those who have pioneered into the marvellous geology of Western North America, that of F. V. Hayden will

always hold a high and honoured place. This place will be his due, not only because of his own personal achievements in original exploration. His earlier work exhibits much of that instinctive capacity for grasping geological structure which is the main requisite for a field geologist. He had a keen "eye for a country." But he likewise possessed the art of choosing the best men for his assistants, and the tact of attaching them to himself and his corps. In this way he accomplished much excellent work, keeping himself latterly rather in the background so far as actual personal geological investigations were concerned, and contenting himself with the laborious task of organization and supervision, while he encouraged and pushed forward his coadjutors.

The abolition of his Survey and the appointment of one of his rivals to the post of Director of the reconstituted Geological Survey of the United States, was a blow from which he does not seem ever to have recovered. He was treated, however, with great generosity by the new Director, and had a share of the large annual appropriation to enable him to complete his Reports. He was urged to condense these voluminous works, and to present a concise and readable account of what he and his fellow-workers had done for the geology of the far West. But he had no literary proclivities, and in the end gladly surrendered the task of writing for the more congenial employment of renewing his personal acquaintance with the geology of the Western Territories. Perhaps among those, and there must be many, who personally knew and esteemed him, there may be one competent and willing to compile or complete the summary which he never completed, and thus to erect to his memory a more fitting and lasting monument than one of brass or marble. A. G.

NOTES.

We regret to announce the death of Dr. Asa Gray, the most eminent of American botanists. He died at Cambridge, Massachusetts, on Monday, aged seventy-seven. Next week we shall give some account of his services to science.

Mr. George Godwin, F.R.S., well known as the editor of the *Builder*, died on January 27. He was seventy-three years of age. Among his writings were several works in which, with great earnestness, he pressed upon the attention of the public the evil consequences springing from the neglect of sanitary laws.

Mr. George Robert Waterhouse, late Keeper of the Department of Geology in the British Museum, died at his residence, Curton Lodge, Putney, on January 21, in his seventy-eighth year.

We have also to record the death of the well-known botanist, Dr. J. T. I. Boswell, who was for many years Curator to the Botanical Society in London, and a Lecturer at the Charing Cross and Middlesex Schools of Medicine.

The Medals and Funds to be given at the annual meeting of the Geological Society on February 17 have been awarded as follows:—Wollaston Medal to H. B. Medlicott, F.R.S.; Murchison Medal to Prof. J. S. Newberry, M.D., of New York; Lyell Medal to Prof. H. Alleyne Nicholson, M.D., D.Sc.; Wollaston Fund to John Horne, F.R.S.E.; Murchison Fund to E. Wilson of the Bristol Museum; Lyell Fund to Arthur H. Foord, and T. Roberts, B.A.

The Academy of Sciences at Turin has awarded the great Bressa prize of 12,000 francs (£480) to M. Pasteur.

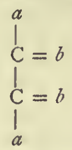
The eighteenth International Congress of Orientalists will meet in Stockholm on September 2 next, and be opened by King Oscar in person, attended by the whole of the Royal family. The Congress will sit till September 6, when the members will visit Christiania as guests of the King, in whose name they will be entertained in the Norwegian capital for two days. They will then proceed to Gothenburg, where the Congress will be dissolved. In honour of the Congress a bibliography is to be issued, containing the portraits in heliography of all living Orientalists, and a *résumé* of the works published by each. The work is to be most sumptuously got up. The editor is Count Carlo Landberg.

The following arrangements have been made for the Penny Science Lectures at the Royal Victoria Hall: February 7, by Dr. Percy Frankland, "Germs in the Air, and what they do for us"; February 14, by E. Wethered, "Earthquakes and Volcanoes"; February 21, by F. R. Cheshire, "Insects as Florists and Fruit-makers"; February 21, by E. Hodder, "Incidents in the Life of Lord Shaftesbury."

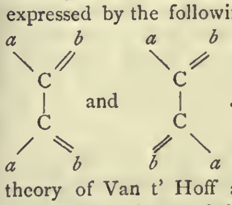
Information has been received of the arrival of H.M. surveying-ship *Egeria*, Capt. P. Aldrich, at King George's Sound, after a very successful deep-sea sounding cruise across the Indian Ocean. Between latitudes 10° and 35° S.,—a belt 1500 miles wide,—not a single sounding has heretofore been obtained in this ocean, and it is therefore satisfactory to learn that forty-three soundings, all of them accompanied with several sets of temperature observations, have been now obtained. The *Egeria's* track was from Sunda Strait to Mauritius, thence south to latitude 38°·5, and thence to Western Australia.

Memorials are being sent from various public bodies in Hampshire to the Lord President of the Council, requesting that the proposed Forestry School for England may be established in that county. It is pointed out that the extensive Crown lands of Hampshire are peculiarly well fitted for scientific and practical forestry.

A paper of exceptional interest was read by Prof. Victor Meyer at the meeting of the Chemical Society of Göttingen held on January 24 In it were embodied some remarkable speculations upon the shape of the ultimate atoms of carbon. These ideas are the outcome of his recent work upon the oxims of benzil and certain other complicated organic compounds, and may be briefly summed up as follows. Certain compounds of the type



(where *a* represents a monad and *b* a dyad radicle) exist in two isomeric modifications which can only be expressed by the following different geometrical arrangement:



. This necessitates an expansion of the theory of Van t' Hoff and Wislicenus, according to which, by rotation of one of the carbon atoms in the first case, the latter would be the only stable form; there are cases in which this rotation is free to occur, and cases like the present where it is prevented. From a consideration of the geometrical isomers of the benzyl cyanides, Prof. Meyer further shows that the valencies of carbon may be displaced out of their normal positions at the corners of a regular tetrahedron by the unequal attractions of unlike radicles. Finally, as the only means of accounting for all these varied phenomena, Prof. Meyer expresses his conviction that the atoms of carbon are spheres, each surrounded by an ether-shell, which forms the seat of the four valencies. On account of their probable electrical connection he terms these valencies "electrules," and considers that the electrules of the same atom are in isochronous oscillation, and

therefore, in accordance with the law, repel each other but are attracted by the dissimilar oscillations of other atoms. In consequence of this repulsion they must take up the regular tetrahedral position, from which, however, under the circumstances mentioned above, they may be slightly displaced. In course of the discussion which ensued, Prof. Riecke followed up the subject with a preliminary notice of his own researches upon the shape of odd-valent atoms, and showed that, in case of nitrogen, phosphorus, and other pentad elements, the ether-shell is probably not spherical, but an ellipsoid; three valencies being situate upon the great circle at the angles of an equilateral triangle, whilst the other two are located at the poles. If this indeed be the case, the tri- and penta-valency of the nitrogen group will be completely and very simply explained.

In a paper contributed to the Royal Society of Edinburgh, and to be published in a forthcoming volume of the Society's *Transactions*, Mr. A. Crichton Mitchell gives the results of an experimental inquiry, made at the Edinburgh University Physical Laboratory, into the thermal conductivity of iron, copper, and German silver. The method employed was that of Forbes. The experiments were, for the most part, a repetition of those made by Prof. Tait about ten years ago; the main difference being that the bars used were nickel-plated in order to prevent oxidation, and thus render the estimation of the amount of surface loss of heat a matter of greater certainty than hitherto. The results arrived at confirm, in the main, those of the previous work, on the same bars, already mentioned, and are of some importance in deciding the question as to whether thermal conductivity increases or decreases with increase of temperature. The principal conclusion in the paper is, that in iron, thermal conductivity increases with increased temperature, and that therefore iron can no longer be looked upon as an exception to the rule followed by the other metals, viz. that their conductivity increases with temperature.

The first rack-railway in France was opened lately at Langres (in Haute-Marne), which is perched on a hill 1460 feet high, and is the principal seat of the French manufacture of fine cutlery. The two railway-stations which have hitherto served it are several kilometres from the town, and much inconvenience has been felt. The new line is made on the type of the Righi railway, and rises to the heart of the town. A company has recently been formed to construct a funicular railway at Hong Kong, for ascent of the hill overlooking the town, and much frequented by the inhabitants. This line will rise to a height of 500 metres, and will be 1600 metres in length. The formation of the ground is exclusively granite, affording a fine solid base. There will be three viaducts, the largest 30 metres in length. Two compound engines of forty horse-power each will be installed at the upper station.

One of the most important questions in optics is whether the velocity of propagation, and therewith the wave-length of light, depend on its intensity or not. A determination of wave-length from prismatic decomposition is not capable of great accuracy. Dr. Ebert, of Erlangen, in studying the subject, preferred a more accurate method based on interference phenomena. Using eight variously coloured light sources (lithium, hydrogen, sodium, &c.), varied in intensity between the values 1 and 250, he established the constancy of the wave-length and velocity of propagation to nearly a millionth within those limits of intensity. Considering, with these results, that the great brightness of the sun does not destroy the coincidences of the Fraunhofer lines with lines of our terrestrial light sources, even with the greatest dispersions, Dr. Ebert thinks his affirmation (of independence of intensity) is generally valid within ordinarily occurring limits of brightness.

Mr. M. W. Harrington has contributed to the *American Meteorological Journal* for December the results of an interesting inquiry as to whether the rainfall is increasing on the plains. The subject is one of importance, as an annual increase of the rainfall would increase the agricultural capacity of a large territory. In order to come to a definite conclusion he has used two long series of observations representing the average conditions at the epochs of 1850 and 1880. The author compares the lines of equal rainfall for the two periods, and shows that, if there had been an increase, any one line should have travelled westwards in the interval between the two epochs. The result of the inquiry shows an apparent advance along the zone included between the parallels of 35° and 45°, and a regression above and below these latitudes, in other words that there has been apparently a consistent increase of rainfall toward the plains.

M. A. Lancaster, Meteorologist at the Royal Observatory of Brussels, and Inspector of Meteorological Stations in Belgium, has published a paper on the climate of that country in 1887, based on the observations at Brussels, and three other stations at the west, north, and east limits of the kingdom, the stations selected being typical of all other points of observation. The weather for each month is discussed at considerable length, and the results are compared with the normal values. The observations show that the mean barometer is highest in December and lowest in October; the absolute maximum temperature during the year at Brussels was 91°·0, and the minimum 15°·4. The prevalent winds are from west-south-west to south-south-west. The rainfall during the year amounted to 24·42 inches, being considerably below the average, viz. 28·78 inches. The rainfall diminishes with the distance from the sea, excepting in the neighbourhood of the forests; the amount increases notably in the Ardennes.

Dr. Fines has published, in the fifteenth *Bulletin Météorologique* of the Department of the Pyrénées-Orientales, the results of experiments carried on at the Perpignan Observatory:—(1) To test the theory of M. Kammermann, of Geneva, for the prediction of spring frosts by comparison of the readings of the wet-bulb and minimum thermometers (explained in the *Archives des Sciences physiques et naturelles*, vol. xiv. p. 425); the result being that the data, so far as Perpignan is concerned, do not bear out the character of accuracy attributed to them elsewhere. (2) To compare the results of wind-velocity given at each instant by a Bourdon's anemometer (presented to the Academy of Sciences, July 30, 1882) with the records of Robinson's velocity anemometer. The result of this inquiry shows a mean increase in the maximum velocities of over 21 per cent. by the use of Bourdon's instrument as compared with the means of the greatest velocities obtained by Robinson's anemometer.

We have received from the Imperial Observatory at Tokio the monthly summaries and means of the observations of the meteorological service in Japan for the year 1886, accompanied by charts showing the tracks of central areas of high and low barometer and by synoptic weather charts for each month. The stations are supplied with good instruments (in some cases with self-recording apparatus), and thee obsrvations which have now been regularly taken for about eleven years under the present organization compare favourably with those of European systems. The climate is generally of the oceanic type—the highest mean temperature at Tokio occurring in August. The winds are governed by the monsoon seasons; during the first three months of the year the prevalent directions at Tokio are north and north-west. From April to June the winds shift round to the south, through east. In July and August southerly winds predominate, but in September a sudden change to the north occurs, and continues generally until December. Warn-

ings of wind and weather are issued to various stations; the general percentage of success for both elements during the year 1886 was 80. Rainfall maps for each month and for the year are also given.

WE have received the *Annuaire* for the year 1888, published by the Bureau des Longitudes with Messrs. Gauthier-Villars, Paris. It contains, besides the tables usually expected in works of this class, much useful information as to the monetary systems of the various nations of the world, mineralogy, meteorology, and other subjects. We may especially note an excellent account, by Admiral Mouchez, of the International Astronomical Congress which met in Paris in April 1887, to prepare the way for the execution of a photographic chart of the heavens.

THE Syndics of the Cambridge University Press have undertaken the publication of a collected edition of the mathematical papers of Prof. Cayley. These papers, originally contributed to the Royal and other Societies and to various mathematical journals, will be arranged for publication by Prof. Cayley himself, who will add notes containing references to the writings of other mathematicians on allied subjects. It is expected that the edition will extend to ten quarto volumes; it is intended to publish two volumes each year until the completion of the work.

"MY TELESCOPE; a Simple Introduction to the Glories of the Heavens," is the title of a little half-crown work on astronomy by "A Quekett Club Man," whose kindred volumes on "The Microscope" have been so successful. It will be issued in a few days by Messrs. Roper and Drowley.

A NEW geological map of the Government of Kutais, by MM. Simonovitch and Sorokin, has been published at Tiflis by the Mining Department.

AT a recent meeting of the Asiatic Society of Japan (reported in the *Japan Weekly Mail* of November 19), Mr. Batchelor read a paper on the *Kamui*, or gods of the Ainos of Yezo. He enumerated under thirteen heads these deities as they appear to be arranged in the Aino mind. These are: (1) the chief of all the deities, the possessor of heaven and the maker of worlds and places; (2) the progenitor of the Aino race, and presider over the affairs of men, who is the only human being worshipped by the people; (3) the sun and moon (the stars are not worshipped); (4) the fire-god, worshipped because of its general usefulness in cooking, healing, purifying, &c.,—sometimes spoken of as the "messenger" or mediator between gods and men; (5) the goddesses who preside over springs, lakes, rivers, and waterfalls,—they are worshipped as benefactors of mankind, particularly in alluring fish to ascend and descend the rivers; (6) the sea-gods, two in number, one being good and one evil,—the latter is the originator of all storms, and the direct cause of shipwrecks and death from drowning at sea; (7) bears, the most powerful animals known to the Ainos, as well as the most useful, supplying them at once with food and clothing; (8) the autumn salmon, the largest fish ascending the rivers,—it is not worshipped, but the term *Kamui* or deity is applied to it; (9) many birds, some of good, others of ill, omen, though not worshipped, are called deities. The same term is applied to beautiful localities, to high mountains, to regions full of bears or rivers full of fish, to large trees, to cool breezes on a warm day, to men of official rank, to devils, evil spirits, and reptiles. When applied to anything good, the term *Kamui* expresses the quality of usefulness, beneficence, divinity; when applied to anything evil, it implies dread, hatefulness, and such like. Applied to animals, it represents the greatest, fiercest, or most useful; to men, it is a mere title of respect. Subsequently, in the course of the discussion, Mr. Batchelor said that the facts of the Aino religion were very simply stated. They had one chief god, and all the others were officers or messengers of this supreme being; there was no lightning- or thunder-god. These were the facts, but he could not explain them. The Ainos, he said, regarded the sun as a body in which a deity resides, "distinguishing, so to speak, between a body and a soul."

THE fossil head of a mammoth has just been unearthed in the Montmartre cemetery in Paris. The distance between the tusks is nearly 2 feet. Further excavations are being made in the hope that the remainder of the skeleton may be discovered.

ABOUT 20 cwt. of bones of prehistoric animals have been found in the bear cave near Rübeland, in the Harz Mountains. Only a part of the cave has yet been explored.

THE University of Upsala has recently been presented with the fossil skeleton of a whale, found in a layer of marl at a depth of 10 feet in the province of Halland, in the south of Sweden. The skeleton, which is almost perfect, is that of a whale which has been called *Eubalæna svedenborgii*, from some portions of a whale skeleton found last century in the province of West Gothia, and now also in the Museum at Upsala. The skeleton is the only one complete ever found. It is that of a young whale.

ON January 8, about 4 p.m., a magnificent meteor was seen at Porsgrund, in the south-east of Norway. It moved rapidly in an easterly direction towards the constellation Taurus. It was square in appearance, but the corners were rounded, the colours being intense green and violet, increasing in strength as the meteor disappeared behind a hill. The size was about that of the full moon. No sound was heard, nor did it leave a train. The passage occupied about two seconds.

THE fog which lately prevailed over our islands and the North Sea extended far into the heart of Norway.

ON December 27, about 11.30 p.m., a severe shock of earthquake was felt at Solum, in the province of Bratsberg, in the south-east of Norway. The shock was so severe that beds seemed lifted from the floor, and the occupants fled in terror into the open. The shock lasted several seconds, and was accompanied by several deep detonations. Large cracks were afterwards seen in the earth. The motion was from east to west.

A SEVERE earthquake occurred at Algiers on January 8. It was noticed throughout the whole province. In one village a house fell in, and the church and the school-house were damaged.

FROM the Consular Report on the Trade of France for 1886–87, it is apparent that the desire for technical education is not at present widespread throughout that country. M. Lockroy, thinking that one of the great causes of the depression in trade, from which France, like England, has been suffering for some years, was the almost total absence of technical education in France, and that the usual remedies were of little or no avail unless aided by a sounder education of tradesmen and merchants, founded a new department in the Ministry of Commerce to supervise the carrying out of his plans. By his help and that of other supporters of his scheme, technical schools have so increased and multiplied, that there are at present ninety of these institutions in Paris and the provinces subsidized by the State. Very few of them are self-supporting, and the number of students in attendance is lamentably small. Students now, it is said, are not anxious to attend, but it is thought that if technical schools received the power of conferring degrees equivalent to the lower degrees in a University, the students would come more readily. It is also urged that these schools should be freed from Governmental control, and be

handed over to the mercantile bodies that in France correspond to our Chambers of Commerce, who understand local needs and local industries better than any department of State. Most of these institutions are behind the age, and the collections at the Conservatoire des Arts et Métiers, Paris, are not so full as those in other countries, and the building itself is in a half-ruinous condition. If the other establishments are inferior to this, as the Report seems to imply, perhaps it is not so difficult to account for the paucity of students and their lack of interest as the Ministry of Commerce seems to think it is.

THE additions to the Zoological Society's Gardens during the past week include two Poë Honey-eaters (*Prosthemadera novæ-zealandiæ*) from New Zealand, presented by Capt. Brabazon J. Barlow, s.s. *Tamui*; a Brazilian Hangnest (*Icterus jamaicai*) from Brazil, presented by Mr. Geo. D. Morce; a White-bellied Sea Eagle (*Haliaetus leucocephalus*) from Newfoundland, presented by Mr. Geo. M. Johnson; three Egyptian Cobras (*Naia haje*), three Cerastes Vipers (*Vipera cerastes*), two Hissing Sand Snakes (*Psammophis sibilans*), a Clifford's Snake (*Zamenis cliffordi*), an Egyptian Eryx (*Eryx jaculus*), a Blunt-nosed Snake (*Dipsas obtusa*) from Egypt, presented by Capt. W. G. Burrows; twenty-one Horrid Rattlesnakes (*Crotalus horridus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

AMERICAN OBSERVATORIES.—The January number of the *Sidereal Messenger* states that the University of California has allotted $19,000 for the current expenses of the Lick Observatory during the present year. The Observatory has received an accession to its staff in Mr. Charles B. Hill, formerly of Chabot Observatory. The equipment of the Observatory has also been furthered by the arrival of the 36-inch photographic corrector and the micrometer for the great telescope. The micrometer is by Fauth and Co.

A new Observatory has been opened in connection with the Syracuse University, New York. This Observatory, erected in memory of Mr. C. D. Holden, a former graduate of the University, was dedicated on November 18, 1887, Prof. Newcomb pronouncing the inaugural address. The new institution possesses a transit instrument by Troughton and Simms, of 3 inches aperture, a chronometer by Dent and Co., a chronograph by Fauth and Co., and an 8-inch equatorial by the Alvan Clarks. Prof. John R. French is the Director.

At the Washburn Observatory, Prof. Brown, the new Director, who was formerly at the Naval Observatory, Washington, is engaged at Prof. Auwers' request in the determination of the fundamental star-places of the Zusatz-sterne in Auwers' system.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 FEBRUARY 5-11.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 5

Sun rises, 7h. 35m.; souths, 12h. 14m. 13·6s.; sets, 16h. 53m.: right asc. on meridian, 21h. 14·6m.; decl. 16° 0′ S. Sidereal Time at Sunset, 1h. 54m.

Moon (between Last Quarter and New) rises, 1h. 20m.; souths, 6h. 24m.; sets, 11h. 19m.: right asc. on meridian, 15h. 23·5m.; decl. 13° 16′ S.

GEOGRAPHICAL NOTES.

AT Monday's meeting of the Royal Geographical Society, Admiral Mayne gave an account of recent explorations in British North Borneo. The paper of most original interest was, however, that of Mr. Maurice Portman, on the exploration and surveys of the Little Andaman. As an official on the Andaman Islands, Mr. Portman made it his business to conciliate the natives of the Little Andaman, who were regarded as quite intractable, and had been severely punished several times for murdering shipwrecked sailors. After a great deal of trouble and much risk, Mr. Portman succeeded in making friends with the natives, with the result that he and those who accompanied him could visit the island with impunity. He has thus been able to collect much welcome information both concerning the island and its highly interesting inhabitants. He completely surveyed the island, and has thus been able to make important corrections on our maps. At the north end the island consists of mangrove swamp and low belts of sandy soil, on which the aborigines have their huts. On the west and south-west the land rises into low hills of a coarse sandstone, running more or less north and south. The timber appears to be much the same as that of the South Andaman, though Mr. Portman saw no padouk and very few bamboos. The rocks are chiefly lime and sandstone, with a good deal of actual coral rock on the east and south coasts. In one place, south of Daogulé Bay, Mr. Portman noticed an outcrop of igneous rock. He found no minerals of importance. This island is about 27 miles long by 15 miles broad, and is encircled by a fringing coral reef. The products of the sea are the same as at the Great Andaman; but the Tubiporine family of coral, particularly *Tubipora musica*, occur in profusion. Dugong and turtle are very plentiful. On the South Sentinel Island, about 12 miles west of the Little Andaman, the turtle appear to have their breeding-station. This island, which is composed entirely of coral rock, is infested by large iguanas, and the *Birgus latro*, or cocoa-nut-stealing crab

(which certainly does not live on cocoa nuts there, as there are none). In rough weather landing is almost impossible on the coast of the Little Andaman, and even in fine weather there are heavy ground-swells and tide-rips. On the north coast large isolated reefs and ledges exist, which make navigation dangerous. With regard to the aborgines of the island, Mr. Portman is of opinion that the whole of the Little Andaman Island is peopled by one race, calling themselves Öngés. These people are subdivided into tribes, who adhere more or less to their own villages, and who quarrel and fight with each other considerably. They appear healthy; their principal diseases being chest complaints, colds, fever, and itch. In physique they compare favourably with the inhabitants of the Great Andaman. Their manners and customs differ somewhat from those of the Great Andaman people, the principal differences being the following:—Instead of small lean-to's, they build large circular huts, some measuring as much as 35 feet in height, and 60 feet in diameter. In these huts the various families sleep on charpoys of wood and cane matting, raised from 6 to 18 inches off the ground, and about 2 feet 6 inches square. Their habits are more cleanly, particularly as regards their huts, and the manner of preparing their food, which is invariably cooked. They cook, dry, and store in baskets, a small fish like a sprat, and this, with the boiled seed of the mangrove, seems to be their principal food, which they supplement with what they can. Their canoes, utensils, ornaments, and bows, are different from those of other Andamanese, and the women wear a tassel of yellow fibre in place of the leaf. They do not smear their bodies over with red ochre, or tattoo themselves, nor do the women keep their heads clean shaved. They are by no means expert in the use of a canoe in rough water, and do not harpoon turtle or dugong, though very fond of the former. They have no religion of any kind, and Mr. Portman learnt nothing of their traditions or superstitions, from which they seem even more free than their neighbours.

Mr. C. M. Woodford has recently returned from a two years' visit to the Solomon Islands, with extensive collections of mammals, birds, reptiles, Lepidoptera, &c. Nearly six months were spent on Guadalcanar, an island the interior of which has never been previously explored. Ascents were made of several rivers, the furthest point reached being about fifteen miles from the coast; but the hostility of the bushmen prevented the ascent of Mount Lammas.

OUR ELECTRICAL COLUMN.

Mr. Willard Case, of Auburn, N.Y., U.S.A., whose extremely interesting paper on a thermic voltaic cell was read before the Royal Society on May 6, 1886, is systematically pursuing his studies to obtain electric energy direct from carbon without passing through the intermediate stage of heat. A paper read on January 10, 1888, in New York, narrates his latest experiments. Jablochkoff tried to do it by immersing plates of carbon and iron in fused nitre. Mr. Case has been using chlorate of potassium and chlorine peroxide (perchloric acid), and with the latter has obtained an E.M.F. with certain forms of carbon varying from 0·3 to 1·24 volt.

In 1869, Dr. Gore proposed a thermo-magnetic generator of electricity (Proc. R.S. 1868–69, p. 261), in which an increasing or decreasing magnetic field was produced by heating and cooling an iron wire placed as a core to a coil of wire. Mr. Edison has recently endeavoured to make this principle practical, but M. Menges, of the Hague, has been more successful. The difficulties to overcome are waste of heat, energy, and consumption of time, in heating and cooling. The results obtained at present are, however, poor, though encouraging.

M. Tereschin, following Quincke's examples and directions, has found with water, methyl and ethylic alcohol, bisulphide of carbon, ether, oil of turpentine, and rape oil, a considerable transport of mass in capillary tubes in the direction of the positive current (*Beiblätter* No. 10, 1887); and Prof. Horace Lamb, in the *Phil. Mag.* for January, prints the admirable paper on the subject which was read before Section A of the British Association at Manchester last September, in which he criticizes the work of Wiedemann and Helmholtz, and explains the phenomenon on the assumption of Quincke, that there is a contact potential difference between the fluid and its solid boundaries, and his own conclusion that there is a sliding coefficient for a fluid in contact with a solid. This transport of mass, due to currents, and the electromotive forces produced by the passage of liquids through capillary tubes, and porous diaphragms are facts undeveloped and unapplied at present.

Considerable attention is being devoted to the heating and fusing of wires by currents. Short lengths of fine wire are used in nearly all electric light equipments as safety valves or cut outs; but the law determining the behaviour of these fuses was little known. Mr. Preece has written two papers for the Royal Society. Profs. Ayrton and Perry introduced the subject in a recent paper read at the Society of Electrical Engineers, and Mr. Cockburn has brought the whole subject before that Society, where it has been well threshed out. For fine wires, viz. those under ·010 in., the fusing current varies with the diameter; but for wires over ·010 in., is given by the equation—

$$C = ad^3/_2.$$

The constant a has been determined for all metals. The behaviour of tin, which is very commonly used, is peculiar. When it approaches the temperature of fusion, its surface oxidizes and coats the wire with a thin skin, which acquires a higher temperature and allows a greater current to flow before fusing. Mr. Cockburn breaks through this skin with a weight—a pellet of lead; while Mr. Preece prevents the skin forming by covering the wire with shell-lac, which acts as a flux and prevents oxidation.

Major King, U.S.A., has recently made a mammoth electro-magnet out of two Rodman guns, weighing about 60 tons. It was excited by a powerful dynamo, and the armature resisted a pull of nearly 10 tons. The field was felt and watches were stopped at very great distances.

Von Bernardo's system of welding by directing an arc itself along the crack, fissure, or edge of the metal to be welded is attracting great attention on the Continent. Prof. Rühlmann, of Chemnitz, has read a very interesting paper before the Electrotechnical Society of Berlin. A carbon rod is the positive and the metal to be fused the negative pole of the arc. The arc acts like a blow-pipe flame. It is eminently adapted to repair cracks and leaks in boilers, heaters, and condensers, to repair tools and generally to cover the ground of soldering and welding.

A novel mode of forming electrolytically deposited copper tubes is attracting considerable attention. The copper is slowly deposited in a thin coating on an iron mandril kept constantly rotating in the bath. As the copper forms it is pressed by an agate burnisher, which compresses the molecular structure into a hard and solid mass of great tensile strength. Such copper has reached a breaking strain of 40 tons on the square inch. The process is due to Mr. W. Elmore.

A curious experiment is mentioned by the *Electrician* (January 27). A disk of soft iron has a spindle put through it so that it can be spun like a top. When at rest or moving slowly the disk is attracted by the poles of a magnet; but when it turns with sufficient velocity it is repelled by the magnet. The reaction of the induced currents in the mass of the metal is greater than the magnetic attraction.

H. F. Weber has cast doubts on the dull red rays being the first luminous rays to appear. He says that the carbon filaments, platinum, gold, and iron give a "gray glow," which is evident at temperatures much below that of dull red, viz. 525° C. Gold gives this gray effect at 417°, iron at 377°, and platinum at 390°.

THE PROPOSED TEACHING UNIVERSITY FOR LONDON.

The following is the text of the petition which has been drawn up by the Association for Promoting a Teaching University for London:—

To the Queen's Most Excellent Majesty in Council.

The Humble Petition of the Association for Promoting a Teaching University for London

Showeth—

1. That the Association for Promoting a Teaching University for London was formed in 1884, and has enrolled up to the present time about 250 members, each of whom was specially invited to join on the ground of eminence, or of experience in matters affecting University teaching in London, or of being

actively engaged in educational or administrative work in one of the institutions in which such teaching is given.

2. That your petitioners have been engaged for the last three years in examining the state and requirements of University education in London, and in conferring with the persons responsible for the teaching and administration of the institutions in which such education is carried on. They have thus been led to the conclusion that there exists in the metropolis and its suburban districts a general and growing demand for the development of University education. They are convinced that this demand cannot be met while higher education in London remains in its present unorganized state, and while the various institutions giving University instruction are deprived of the means of common discussion and concerted action. For the teaching given in these institutions their respective governing bodies are alone responsible, and each of these bodies for the most part acts in educational matters on the advice of its own teachers; but there is no common centre, such as a University would supply, where these governing bodies and their teachers could meet for purposes of conference, and wherein measures for the better organization of teaching could be discussed and settled. It is matter of experience to those who have taken part in the administration of such institutions that they suffer from the want of public recognition and support—a want due, not to defects in their work, but mainly to the anomaly of their position as institutions performing some of the functions without having the *status* of a University.

3. That the severance from the work of teaching of the work of examination for degrees, and the assignment of such examination to the existing University for London as its sole function, has had an injurious effect upon University education in London. The restraint exercised over efficient institutions through examinations held by a body which is neither responsible for their teaching nor in communication with their teachers acts as a fetter upon education, and gives undue consequence to examinations and their results. Examinations so arranged are less efficient than they might be made as a test of real merit, and tend to encourage dissipation of intellectual energy. In the Faculty of Medicine, although a systematic course of study in a recognized school is now required by the existing University of London, the want of due relations between the examining institution on the one hand and the teaching bodies and professional authorities on the other has led to unsatisfactory results.

4. That the evils above mentioned cannot be fully remedied but by the establishment in London of a Teaching University—that is to say, a University which (1) provides for the student in all the subjects included in its Faculties the best attainable teaching with the necessary aids and appliances; (2) requires a regular course of attendance on such teaching as a preliminary to graduation; and (3) secures to the teacher a direct and adequate representation in its councils, and a due share in its administration.

5. That such a University may be formed without trenching upon the province of the existing University of London, the functions of which are entirely different, and without superseding any institution now giving genuine University instruction in the metropolis. A Teaching University for London would incorporate or associate such institutions without injury to their individual life, as the Victoria University has incorporated Colleges in the North of England.

6. That the metropolis, regarded as the seat of a Teaching University, possesses for students in every Faculty, but especially in the Faculties of Laws and Medicine, advantages which cannot be equalled in any other place in the United Kingdom. Such a University, once established, would supply the motive power for various amendments in the University education of London, which are generally admitted to be needful, such as the greater concentration of the teaching of particular subjects in the earlier scientific stages of medical education; the foundation of additional chairs, attached either to particular institutions or to the University, for the further prosecution of special studies; the promotion of new Faculties; the encouragement of general education as a preliminary to the training for all professions; and, finally, such a presentation to the public of the needs of higher education in London as might secure from the corporate or private munificence of the metropolis the endowments necessary to enable it to keep pace with the growth of population and with the progress of learning.

7. That your petitioners, wishing to promote the foundation of a Teaching University in London, have held conferences with representative London teachers of University rank in the Faculties of Arts, Science, and Medicine, and have submitted to them the following statement of the objects to be aimed at in the foundation of such a University:—

(1) The organization of University teaching in and for London, in the form of a Teaching University, with Faculties of Arts, Science, Laws, and Medicine.

(2) The association of University examinations with University teaching, and the direction of both by the same authorities.

(3) The conferring of a substantive voice in the government of the University upon those engaged in the work of University teaching and examination.

(4) Existing institutions in London of University rank not to be abolished or ignored, but to be taken as the basis or component parts of the University, and either partially or completely incorporated, with the minimum of internal change.

(5) An alliance to be established between the University and the professional societies or corporations, the Council of Legal Education as representing the Inns of Court, the Royal College of Physicians of London, and the Royal College of Surgeons of England.

8. That these conferences have resulted in three reports, each embodying a substantial approval of the objects above stated and of the proposals of your petitioners for the purpose of effecting them.

9. That your petitioners have also held conferences with committees of the Senate and Convocation of the existing University of London, and that, simultaneously with the action taken by your petitioners, and, as they believe, in consequence thereof, the questions at issue have, it is understood, been under the consideration of the Senate and Convocation. Their deliberations have resulted in a report, which has been communicated to your petitioners, and recommends various changes in the constitution of the Senate as the governing body of the University, the establishment of Faculties and Boards of Studies, and the introduction on the governing body of representatives of such Faculties.

10. That such proposals differ from the proposals of your petitioners in the following, among other, respects:—

(1) In not requiring, as a preliminary to graduation in the Faculties of Arts and Science, a regular course of instruction in some recognized teaching institution. Such a course of instruction, however, continues to be required by the existing University as a preliminary to graduation in the Faculty of Medicine.

(2) In admitting Colleges not situated within the London district, the effect of this provision being that the suggested Faculties and Boards of Studies could meet but seldom, and thus would not afford to the teaching institutions of the metropolis adequate means of common discussion and concerted action.

(3) In the absence of any sufficient conditions for securing that the associated Colleges shall be doing effective University work.

(4) In not providing for the direct representation upon the governing body of the associated institutions, or of University teachers.

(5) In granting an unduly large representation to the graduates of the University.

11. That it appears to be difficult, if not impossible, for the University of London, consistently with its relations towards institutions situated elsewhere, and towards private students, to accept modifications which would enable it to fulfil the objects above mentioned.

12. That your petitioners have also held conferences with committees of the Councils of University College, London, and King's College, London, respectively, and have submitted to them the above statement of the objects of the Association. The subject having been subsequently brought by the committees before their respective Councils, these Councils adopted resolutions expressing their approval of the objects above stated, and have since determined to petition Your Majesty to the same general effect as is set forth in this petition.

13. That an alliance between the Teaching University above described and the chief professional societies and corporations of the metropolis, such as the Inns of Court, the Royal College of Physicians of London, and the Royal College of Surgeons of England, would be desirable as securing professional interests in

the arrangements for graduation, and in simplifying and re-arranging examinations in the Faculties of Laws and Medicine. Your petitioners have accordingly opened communications with the above-named bodies regarding this subject. They understand, however, that the Royal College of Physicians and the Royal College of Surgeons are disposed to seek conjointly for independent powers of granting degrees in a Faculty of Medicine. Your petitioners deprecate any severance of the machinery for granting degrees in London from academic influences. Many serious defects of University education in London are due to such a severance.

14. That, with a view to avoid multiplication of bodies conferring a diploma or a licence to practise, it is expedient that the possession of the conjoint diploma of the two Royal Colleges above named should be a preliminary condition for obtaining a medical degree in the University, the conferring of such diploma remaining, as at present, the function of the said Royal Colleges.

15. That the objects above set forth would, in the opinion of your petitioners, be most readily accomplished by the issue of a charter to a body of persons suitably constituted to be the governing body of a new University in and for London; such body to consist of the following persons:—

(1) The Chancellor of the University; the first Chancellor to be appointed by Your Majesty, and named in the charter.

(2) Members to be named by Your Majesty in the charter. Vacancies to be filled by the Lord President.

(3) Members chosen by the governing bodies of University College, London; King's College, London; and such other Colleges as may be associated with the University.

(4) Members chosen by the governing bodies of the professional societies and corporations hereinbefore referred to, if associated with the University.

(5) Members chosen by the professors or teaching staff of associated institutions doing University work, and assembled in the Faculties, whether of Arts, Science, Laws, or Medicine, to which they respectively belong, such members to be in number not less than one-third of the whole governing body.

16. That power should be given to the governing body of the new University to accept the application for association with the University of any teaching institution in the metropolis, the conditions of such association to be—(*a*) that the institution is giving instruction of a University character; (*b*) that it has established a complete curriculum, and possesses a sufficient teaching staff in at least one of the recognized Faculties; (*c*) and that it has furnished proofs of its means and appliances for teaching being established on a satisfactory basis.

Your petitioners therefore humbly pray Your Majesty to be pleased to grant a charter to a body of persons appointed as is described in this petition, or to such other person as Your Majesty may be pleased to select, constituting a University in and for London upon the principles and for the purposes hereinbefore stated, and having power to grant its own degrees in the Faculties of Arts, Science, Laws, and Medicine, and that Your Majesty will be pleased to make such orders in the premises as to Your Majesty, in your Royal wisdom and justice, may seem meet.

And your petitioners will ever pray, &c.

Executive Committee of the Association for Promoting a Teaching University for London:—W. Grylls Adams, M.A., F.R.S., J. W. Cunningham, Sec. King's College, J. Curnow, M.D., F.R.C.P., Sir Dyce Duckworth, M.D., F.R.C.P., G. Carey Foster, B.A., F.R.S., M. Berkeley Hill, M.B., F.R.C.S., W. H. H. Hudson, M.A., LL.M., J. Marshall, LL.D., F.R.S. (Chairman), Norman Moore, M.D., F.R.C.P., H. Morley, LL.D., W. M. Ord, M.D., F.R.C.P., F. Pollock, M.A., R. S. Poole, LL.D., W. J. Russell, Ph.D., F.R.S., T. E. Scrutton, M.A., LL.B., Rev. Henry Wace, D.D., G. C. W. Warr, M.A., A. W. Williamson, LL.D., F.R.S., Gerald F. Yeo, M.D., F.R.C.S., Sir George Young, LL.D.; Secretary, F. C. Montague, M.A., 12 New Court, Carey Street, W.C.

THE TOTAL ECLIPSE OF THE MOON, JANUARY 28.

THE weather on the night of January 28 proved decidedly unfavourable for those astronomers in London and the neighbourhood who had prepared to observe the occultations of small stars by the eclipsed moon. The sky, which had been beautifully clear in the morning, but which had become partially clouded towards evening, had cleared again a little before the commencement of the eclipse, thus raising hopes which were destined to be disappointed, for the clouds returned, and, with the exception of two or three short breaks, the moon was enveloped in cloud more or less dense during the entire duration of the total phase. Very full preparations for the observation of the occultations had been made at the Royal Observatory, Greenwich, but only the observers at the four largest telescopes were able to see even one of the predicted phenomena. At the Cambridge Observatory a similar disheartening experience was recorded, and at Mr. Crossley's Observatory, Halifax, it was quite cloudy, but in the west and south of England, and in Ireland at Dublin and Belfast, the conditions for observing were very favourable. On the Continent, at Vienna no observations could be made, the moon being enveloped in thick haze; at Paris and Berlin the sky had been overcast, and there had been a fall of snow before the eclipse, but the latter half of the eclipse was well observed at the former station, and some good results were obtained at the latter during a clear interval about a quarter of an hour after the commencement of totality. At Moscow the eclipse was seen in a very clear sky, and at Madrid it was partially clear.

The following table gives the number of observations obtained at those Observatories from which accounts have been received up to the present time:—

Observatory.	Aperture of telescope, inches	No. of Stars observed. Dis.	Reap.
Royal Observatory, Greenwich	24	3	7
,, ,, ,,	$12\frac{3}{4}$	1	4
,, ,, ,,	6	3	1
,, ,, ,,	$6\frac{1}{2}$	0	3
Col. Tupman's—Harrow	18	3	2
Mr. Penrose's—Wimbledon	6	3	2
Mr. Brodie's—Fernhill, I. of W.	$8\frac{1}{2}$	9	5
Mr. Stothert's—Bath	6	11	13
Cambridge Observatory	12	0	2
Miss Petrie—Bradford	6	1	1
Mr. Backhouse's—Sunderland	—	1	0
Glasgow Observatory	9	6	7
Mr. Heath—Edinburgh	$3\frac{1}{4}$	3	1
Dunsink Observatory	—	17	18

		No. of Stars observed.
Stonyhurst Observatory	8	1
,, ,,	$5\frac{1}{2}$	12
,, ,,	4	4

The 8-inch refractor at Stonyhurst was devoted to spectroscopic observations during the greater part of the eclipse. It had been in the programme to make similar observations at Greenwich had the night proved favourable, and also to take a series of photographs showing the progress of the eclipse. Three photographs were secured, but the clouds prevented all spectroscopic work. Dr. Copeland also at Dun Echt had intended to make spectroscopic observations, but was almost completely thwarted by snow-squalls.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 19.—"On the Secondary Carpals, Metacarpals, and Digital Rays in the Wings of existing Carinate Birds." By W. K. Parker, F.R.S.

In a paper "On the Morphology of Birds," already sent in to the Royal Society, but not yet published, I have described certain additional parts in the wings of Gallinaceous birds.

One of these lies on the radial side of the first metacarpal; the other two are on the ulnar side of the second and third metacarpals.

These parts, which at first caused me considerable surprise, being wholly unexpected by me, are only part of what I have since found in other families.

During the past year I have worked out the development of the skeleton in the Duck tribe ("Anatidæ"), in the Auk tribe ("Alcidæ"), and in the Gull tribe ("Laridæ"), and to some degree in some other families. The subject appears to me to be of great interest, and I have, through various English and American friends, obtained many scores of embryos and young birds, &c., that I may be able to trace these parts in every main group of the class. Normally, both the existing Carinatæ and Ratitæ,

and such extinct forms as have been worked out—*Archæopteryx*, *Hesperornis*, *Ichthyornis*—show that the primary form of the bird's wing is simply *tri-digitate.* In this I agree with Baur, who has helped me greatly in this matter, both by his valuable papers and also by personal discussion with me.

The normal "manus" of a Carinate bird contains two permanently distinct carpals: three carpals that lose their independence by anchylosis with the metacarpals, and three digital rays extending from the three fused metacarpals.

In some birds, *e.g.* the Passerinæ, the *pollex* of the first digit has only one phalanx attached to its short metacarpal, the second only two, and the third only one, phalanx. In others, Plovers, Gulls, Cormorants, &c., an additional or *ungual* phalanx is found on the first and second digit; and in some birds, *e.g. Numenius*, during their embryonic state, a small semi-distinct nucleus is seen on the end of the aborted phalanx of the third digit.

In my as yet unpublished paper I have mentioned a sub-distinct tract of very solid fibro-cartilage, which evidently corresponds with what has been called "præ-pollex" by Kehrer and others.[1]

I am satisfied, now, that this very notable part is the remnant of the skeleton of the *spur*, so remarkably developed in the Palamedidæ, certain Geese, Plovers, and Jacanas.

This part therefore need not interfere with the consideration of the *true secondary digital* parts.

Among the last communications received by me from Dr. Baur, I find in print what I had already learned from him orally.

In some "General Notes" published in the *American Naturalist*, September 1887, p. 839, I find the following paragraph:—"The oldest Ichthyopterygia had few phalanges and not more than five digits; the radius and ulna were longer than broad, and separated by a space. Later, through the adaptation to the water, more phalanges were developed, more digits appeared, mostly by division of the former, or by new formation on the ulnar side. I have never found a new digit developed on the radial side."

These are most important facts, some of which—namely, the bifurcation of the digital rays—I had received some light upon before, both from Dr. Gadow and from Prof. D'Arcy W. Thompson.[2]

I find that the *carpus*, *metacarpus*, and digital rays are all apt to increase in number beyond what is normal.

Long ago I found, in one of the Palamedidæ, *e.g. Chauna chavaria, two ulnar carpals*, apparently an "ulnare" proper, and "centrale." More recently, in the embryo of a more normal Chenomorph—the Falkland Island Goose (*Chloëphaga poliocephala*)—I found the ulnare nearly divided into two segments.

On the other side of the carpus in an embryo Kestrel (*Falco tinnunculus*) and in a young Sparrow-hawk (*Accipiter nisus*), I found a "radiale" in two pieces, the outer of which in the latter was degenerating into the large "*os prominens*" which is found in the tendon of the "tensor patagii" muscle of rapacious birds.

In the embryos of Gulls, Auks, Guillemots, &c., the large "distal carpal" of the index or second digit sends forward a long wedge of cartilage towards an additional metacarpal nucleus. Evidently this is the rudiment of another carpal seeking to be attached to its own intercalary metacarpal.

Further on, on the large second digit, the flat dilated part of the proximal phalanx, on its ulnar side, also, is developed from a distinct tract of true cartilage, but soon loses its independence; it forms the plate on which some of the *primary quills* are fixed.

Still further on, on the ulnar side, near the small well-developed ungual phalanx of the embryo, but later, after hatching, a small oval cartilage appears, and *is ossified independently.*

A similar tract of cartilage is formed on the pollex or first digit, also, but is somewhat smaller than that on the second; it is on the ulnar side and near the ungual phalanx.

In the feeble third digit I only find a rudimentary secondary metacarpal, on the ulnar side; this is very constant throughout the *Carinatæ;* and sometimes, as I have already mentioned, there is a small rudiment of a second phalanx on that digit which, in the Lizard, has *four* phalanges.[3]

[1] "Beiträge zur Kentniss des Carpus und Tarsus der Amphibien, Reptilien, und Saüger," *Berichte der Naturforschenden Gesellschaft zu Freiburg i. B.*, vol. i, 1886 (Heft 4 und Taf. 4).

[2] See his paper on the hind limbs of Ichthyosaurus, &c., *Journ. Anat. Physiol.*, vol. xx. pp. 1–4 (reprint).

[3] The figures of these parts, and also of the rest of the developing skeleton in these birds—Ducks, Auks, Guillemots, &c.—are ready for publication.

In seeking for evidence of the manner in which these high and noble hot-blooded feathered forms arose from among the Archaic Reptilia, I think that something has been gained in what I have stated above.

The skull brings evidence of the same sort during its development, and it is to ancient long-beaked forms, and not to modern short-faced types of Reptilia, that we must look for any near relationship of the Reptiles in the Birds.

In the Guillemot (*Uria troile*) I have satisfied myself that there has been a considerable amount of *secular* shortening of the beak (rostrum and fore-part of mandibles), and if we look at Dr. Marsh's figures of *Hesperornis* and *Ichthyornis* we shall see what long bills these toothed birds possessed.

But there is no part of a developing bird's skeleton that is not rich with suggestive facts of this kind, as I propose to show in due time.

January 26.—"On the Emigration of Amœboid Corpuscles in the Star-fish (*Asterias rubens*)." By Herbert E. Durham, B.A., lately Vintner Exhibitioner, King's College, Cambridge. Communicated by Dr. P. H. Carpenter, F.R.S., F.L.S.

When small particles (*e.g.* Indian ink) are introduced into the body cavity of a specimen of *Asterias rubens*, they are soon ingested by the amœboid corpuscles of the cœlomic fluid; the latter are carried in various directions by the currents set up by the cilia of the cœlomic epithelium. In the dermal branchiæ these granule-laden corpuscles were observed to adhere to the wall of the branchia, and migrate by amœboid movement to the exterior. [Where such migration is proceeding very actively, a perforation filled by a plug of the corpuscles is formed.] Arrived at the exterior, the corpuscles retain an irregular shape for a while, then they become spherical, swell up, and disintegrate.

Besides corpuscles thus laden with foreign granules, corpuscles containing refringent sphærules (sphæruliferous corpuscles, "Plasma-Wanderzellen") were observed in the extruded material: emigration of such corpuscles was also noted to take place in specimens kept in captivity in glass vessels. Hamann's observation that "Plasma-Wanderzellen" occur in the branchiæ of Echinids helps to confirm the view that this a normal process: further observations are necessary to elucidate its significance. [Dr. Hartog's statements as regards the outward current in the water-tube (stone-canal), were confirmed by the presence of corpuscles in the pore-canals of the madreporite.]

With regard to the other point, it seems clear that minute foreign bodies introduced into the system of a star-fish can be, and are, got rid of by scavenging corpuscles.

"Note on the Madreporite of *Cribrella ocellata.*" By the same.

The dogma laid down by Ludwig is that the cavity of the water-vascular system is isolated from other cavities. In a series of sections carried through the madreporite, &c., of *Cribrella ocellata*, it was seen that a few pore-canals of the madreporic plate open directly into the "Schlauchförmiger Kanal"; the ampulla into which the water-tube (stone-canal) dilates being also connected by an opening with the "Schlauchförmiger Kanal": this latter space being enterocœlic in origin, it is interesting to compare the arrangement in Crinoids.

Zoological Society, January 17.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of December 1887, and called attention to a small Fox from Afghanistan, presented by Lieut.-Col. Sir O. B. C. St. John, which should probably be referred to the species shortly noticed by Blyth as *Vulpes griffithi.* It was, however, somewhat doubtful whether the species was really distinct from *Vulpes leucopus*, Blyth, the small Desert Fox of Western India.—Mr. Francis Day exhibited and made remarks on some hybrid fishes from Howietoun, and on a British specimen of the Spined Loche.—Mr. Oldfield Thomas read a report on a collection of Mammals obtained by Emin Pasha in Central Africa, and presented by him to the Natural History Museum. The collection contained 115 specimens belonging to 39 species. The great mass of the collection had been obtained in a district called Monbuttu, just within the Congo Basin. A new Flying Squirrel, of small size, was named *Anomalurus pusillus*, and a new Tree-Hyrax, *Dendrohyrax emini*, after its discoverer.—Capt. G. E. Shelley. read a paper on a collection of birds made by Emin Pasha in Equatorial Africa. The series had been formed partly in the Upper Nile district and partly in the Monbuttu country in the

Congo Basin, and contained examples of four species new to science, proposed to be called *Indicator emini*, *Spermospiza ruficapilla*, *Ploceus castanops*, and *Glareola emini*.—Dr. A. Günther, F.R.S., read a report on a collection of Reptiles and Batrachians from Monbuttu, sent by Emin Pasha. The author enumerated seventeen specimens, of which nine were almost generally distributed over the African region; of the remainder, seven were known from various parts of West Africa. One Tree-Snake was described as new, and called, after its discoverer, *Ahætulla emini*.—Mr. Edgar A. Smith, read an account of the Shells collected by Dr. Emin Pasha on the Albert Nyanza, Central Africa. Of the five species of which examples were obtained, three were referred to new species. It was stated that fifteen species of shells were now known from Lake Albert, of which seven were peculiar to it.—Mr. Arthur G. Butler gave an account of the Lepidoptera received from Dr. Emin Pasha. The collection contained examples of 155 species, of which thirteen Butterflies, and two Moths were new to science.—A communication was read from Mr. Charles O. Waterhouse, containing an account of the Coleoptera from Eastern Equatorial Africa received from Emin Pasha. One of the species was new to science, and six of them had previously been received at the British Museum from West Africa only.

Geological Society, January 11.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On the law that governs the action of flowing streams, by R. D. Oldham.—Supplementary notes on the stratigraphy of the Bagshot Beds of the London Basin, by the Rev. A. Irving. This paper contained the results of field-work during the year 1887. Additional notes on the stratigraphy of the Bracknell and Ascot Hills were given, justifying the reading of the country as shown in Figs. 1 and 2 of the author's last paper (Q.J.G.S., August 1887), the examination of this line of country having been extended as far as Englefield Green. Sections of the beds of the Middle Group as they crop out at Cæsar's Camp, Swinley Park, Ascot, and Sunningdale, were described and correlated with the 76 feet of beds which constitute that group in the Well-section at Wellington College. The stratigraphy of the hills known as Finchampstead Ridges has been worked out from numerous sections on their flanks; and the strata of the Bearwood Hills were correlated directly with them. All along the northern margin a general attenuation of (*a*) the Lower (fluviatile) Sands, and of (*b*) the Middle (green earthy) Sands was shown to occur, and in some places on the northern margin they are found to have entirely thinned away, admitting of distinct overlap at more than one horizon. The second part of the paper dealt with the Highclere district, where the author believes he has established the full succession of the three stages of the Bagshot formation, a section being given across the valley south of Highclere Station, showing the succession of the whole Eocene series (with the *Ostrea bellovacina* bed for its base) as it is developed there. Some important conclusions were drawn as to the Tertiary physiography of the South of England; and the revised tabulation of the Tertiaries put forward by Prof. Prestwich at the Society's last meeting was referred to as supporting some of the main points for which the author has contended. The reading of this paper was followed by a discussion in which the President, Mr. Monckton, Mr. Herries, and Mr. Drew took part.—The red-rock series of the Devon coast section, by the Rev. A. Irving.

Chemical Society, January 19.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Morindon, by T. E. Thorpe, F.R.S., and W. J. Smith. Morindin, the active colouring-matter of A'l, the root-bark of *Morinda citrifolia*, yields 48·4 per cent. of morindon on hydrolysis. This latter substance is a methylanthracene-derivative of the composition $C_{15}H_{10}O_5$, and differs from all of the eight known compounds of the same formula.—Manganese trioxide, by T. E. Thorpe, F.R.S., and F. J. Hambly. The authors have repeated Franke's experiments (*Journ. für prakt. Chem.*, 1887) on the so-called volatile oxides of manganese, and have been unable to obtain any evidence of the existence of the blue gaseous manganese tetroxide. They find, however, that manganese trioxide exists, and can be formed by the action of a solution of potassium permanganate in sulphuric acid on dry sodium carbonate.—Note on Chatard's process for the estimation of small quantities of manganese, by the same.—Contributions to the theory of the vitriol-chamber process, by G. Lunge. The theory has been recently advanced by Raschig (*Liebig's Annalen*, 241, 161) that the vitriol-chamber process consists in the formation in the first instance from nitrous acid and sulphurous acid of dihydroxylaminesulphonic acid, which, being acted on by nitrous acid, yields sulphuric acid and nitric oxide, the latter being reconverted into nitrous acid. This theory is regarded by the author as untenable on all points, since it completely ignores the existence of nitrosyl sulphate (chamber-crystals), whilst nitric oxide, oxygen in excess, and water do not yield nitrous acid, but nitric acid. In the author's view it is not NO, but N_2O_3 which acts as a carrier of the oxygen in the vitriol-chamber, and the principal reactions are: $2SO_2 + N_2O_3 + O_2 + H_2O = 2SO_2(OH)(ONO)$; $2SO_2(OH)(ONO) + H_2O = 2SO_2(OH)_2 + N_2O_3$. Much NO is present in the front chambers along with N_2O_3; it is formed by a secondary reaction from nitrosyl sulphate, $2SO_2(OH)(ONO) + SO_2 + 2H_2O = 3SOH_2SO_4 + 2NO$, and is principally absorbed by the direct reaction, $4SO_2 + 4NO + 3O_2 + 2H_2O = 4SO_2(OH)(ONO)$; none of it can pass into NO_2 (which does not occur at all in normally working chambers), but some of it may pass into HNO_3, which is at once acted on by SO_2;—$SO + HNO_3 = SO_2(OH)(ONO)$. Thus the normal vitriol-chamber process is not as hitherto understood an alteration of reductions and oxidations, but it is a *condensation* of nitrous acid, or of NO with SO_2 and O_2 to nitrosyl sulphate, and a splitting up of the latter into N_2O_3 and sulphuric acid.

EDINBURGH.

Royal Society, January 6.—Sir W. Thomson, President, in the chair.—Mr. J. T. Bottomley described and exhibited a practical constant-volume air thermometer. This instrument has been designed by Mr. Bottomley so as to be more sensitive, more accurate, and, at the same time, of much greater range than air thermometers hitherto in use. Mr. Bottomley also exhibited some glass globes with internal cavities produced by cooling.—Prof. Tait communicated a paper by Dr. G. Plarr on the roots of $\epsilon^2 = -1$; and a paper by Prof. Burnside on a simplified proof of Maxwell's theorem.—Prof. Tait also read a paper on the Thomson effect in iron.—Dr. Thomas Muir read a paper on vanishing aggregates of determinants. He has obtained the general theorem of which a particular case was discovered lately by Kronecker, and attracted much attention in Germany.—Prof. Crum Brown communicated a paper by Dr. Griffiths on the Malpighian tubes and the "hepatic cells" of the *araneina* and the diverticula of the *asteridea*.

PARIS.

Academy of Sciences, January 23.—M. Janssen, President, in the chair.—Remarks in reference to M. J. Bertrand's recent note on the law of probability of error, by M. F. Tisserand. A solution is given of the problem, "To determine the function $\psi(x_1 - x_2, x_1 - x_3, \ldots . x_1 - x_n)$, where $x_1, x_2, \ldots . x_n$ indicate n arbitrary quantities independent one of the other, in such a way that this function is symmetrical in relation to $x_1, x_2, \ldots . x_n$."—The paper is followed by a communication from M. F. Tisserand on the law of probability as applied to target-firing.—On some notions, principles, and formulas, which come into play in several questions connected with algebraic curves and surfaces, by M. de Jonquières. A rapid summary is given of these principles, &c., some of which have been established by the author himself, some by other mathematicians.—Note on the second volume of the "Annales de l'Observatoire de Bordeaux," by M. M. Lœwy. This volume is largely occupied with the important observations undertaken for the purpose of revising the positions of the stars in Argelander-Oeltzen's catalogue. It contains the precise coordinates of about 3500 stars belonging to the southernmost region of the northern hemisphere.—Contributions to the history of the problematical organisms of old marine basins, by M Stanislas Meunier. The paper deals with the so-called Bilobites, regarded by some palæontologists as mere physical tracings, by others as real organic remains. Several arguments are advanced in favour of the latter opinion, which is regarded as fairly well established, although not yet rigorously demonstrated.—On the rapidity with which the report of fire-arms is propagated, by M. Journée. All the facts here described tend to show that a projectile possessing a greater velocity than that of the report produces, during its passage through the air, a continuous sound analogous to the explosion of gunpowder.—On the mean distances of the planets from the sun, by M. Roger. It is shown that, apart from certain deviations within a defined

limit, these distances form a geometric progression modified by a periodic irregularity. In a future communication the connection will be pointed out between this law and the theoretic views advanced by the author on the formation of the planetary system.—Summary of the solar observations made at Rome during the last quarter of the year 1887, by M. P. Tacchini. The diminution of spots already noted in September was continued during the two ensuing months, so that the mean was even less than in the previous quarter. The protuberances also were less frequent.—On the phases of Jupiter, by Dom E. Siffert. Most of these observations, which were taken at the Observatory of Grignon, are tabulated for the period from March to December, 1885.—On the application of the Cremonian quadratic substitutions to the integration of the differential equation of the first order, by M. Léon Autonne. In this paper the author develops, for the integration of the differential equation of the first order, the method based on the employment of the Cremonian quadratic substitutions, and applies this method to some special cases of a simple and comprehensive character.—Electric solution of algebraic equations, by M. Félix Lucas. It is shown how, by means of electricity, the solution of equations of any degree p, whose real or imaginary coefficients are given numerically, may be reduced to that of equations of degrees lower than p.—Action of vanadic acid on the alkaline fluorides, by M. A. Ditte. The present paper deals with the fluorides of sodium and ammonium, whose composition is shown to be analogous to that of the fluoride of potassium.—Action of hydrochloric acid on cupric chloride, by M. Engel. The results are tabulated of a series of experiments with the hydrochlorate of cupric chloride. In this substance the chloride of copper appears to be in the anhydrous state, all the water being ultimately combined with the hydrochloric acid.—On the alcoholic fermentation of galactose, by M. Em. Bourquelot. From these experiments, undertaken to determine the true character of the action of the yeast of beer on galactose, the author concludes that pure galactose does not ferment in the presence of the yeast at 15° to 16° C., but that it undergoes alcoholic fermentation when glucose, lævulose, or maltose are added.—On two new genera of Epicarides, by MM. A. Giard and J. Bonnier. The specimens here described live in the fresh waters of the Dutch East Indies, and are regarded as the types of two new genera, Probopyrus and Palegyge, whence are respectively derived the genera Bopyrus and Gyge. They are here named *Probopyrus ascendens*, Semper, and *Palegyge borrei*, G. and B.

BERLIN.

Physiological Society, January 13.—Prof. du Bois Reymond, President, in the chair.—Prof. Fritsch described the detent-joint of a Sheat-fish (Siluridæ). In this fish, as found in the Nile, the adjusting and fixing of the dorsal and pectoral fins is provided for by the various shape and arrangement of the surfaces of the joints, which take the form of hooks and detents. The speaker explained the above arrangements by means of drawings and preparations, by means of which it was easily seen that when once the dorsal spine is fixed it will withstand a very considerable force. These spines constitute a protective mechanism against other predatory fishes, and accounts for the numerical development of these fishes in the Nile. The speaker stated his inability to accept Sörensen's view that the detent-joints of these fishes are organs for the production of sound.—Dr. Joseph had studied the minute structure of the axis-cylinder in the nerves of the electric organ of *Torpedo marmorata* treating them with osmic acid and various staining reagents. By making a careful series of transverse sections he has become convinced that not only the medullary sheath, but also the axis cylinder, possesses a fan-like structure, and that the longitudinal fibrils run in the meshes of the radiating fibres, and are the true conducting tissue of the nerve. The diameter of the axis is six or seven times as great as that of the sheath.—Dr. Weyl had subjected silk to a thoroughly chemical examination, and obtained values for its percentage composition, after purification by treatment with caustic soda, which corresponded with those given twenty-five years ago by Cramer; according to these, silk may be taken as belonging to the proteid class of bodies. Raw silk, and to a greater degree that which has been purified by soda, is soluble in fuming hydrochloric acid; if this solution is poured into alcohol, a white cloudiness is produced, which speedily increases in intensity, and on cooling gives rise to a solid white gelatinous mass. The percentage composition of this new substance obtained from silk, and called by the speaker seroin, is, as regards its carbon and hydrogen, the same as that of silk, but it contains less nitrogen. It possessed in all cases the same composition, so that it is undoubtedly a distinctly characterized chemical substance, and is neither pure silk nor some closely related proteid formed by a splitting-off of ammonia. When treated with dilute acids, seroin yields the same products of decomposition as does fibroin—namely, large quantities of leucin and tyrosin, by which it is characterized as being a proteid. Dr. Weyl hoped shortly to resume this investigation in the direction of a general consideration of the proteid group.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Voltaic Electricity: T. P. Treglohan (Longmans).—Practical Physics for Schools and the Junior Students of Colleges, vol. i. Electricity and Magnetism: Stewart and Gee (Macmillan).—Behind the Tides: C. B. Radcliffe (Macmillan).—Pflanzen-Teratologie: M. T. Masters; German by U. Dammer (Leipzig).—Practical Amateur Photography: C. C. Vevers.

CONTENTS.

THURSDAY, FEBRUARY 9, 1888.

MESSRS. GOSCHEN AND HUXLEY ON ENGLISH CULTURE.

WITHIN the last few days two noteworthy utterances on the subject of our national prospects have been made by men whose opinions deserve and command attention. Prof. Huxley has told us, in the *Nineteenth Century*, that though the restraints imposed by civilization have altered the methods by which the struggle for existence is carried on, they have not made it less real or less bitter.

"In a real, though incomplete, degree we have attained the condition of peace which is the main object of social organization; and it may, for argument's sake, be assumed that we desire nothing but that which is in itself innocent and praiseworthy—namely, the enjoyment of the fruits of honest industry. And lo! in spite of ourselves, we are in reality engaged in an internecine struggle for existence with our presumably no less peaceful and well-meaning neighbours. We seek peace, and we do not ensue it."

This application of Darwin's great theory to commercial competition is more than a parable. It is the scientific explanation of causes which have wrecked civilizations in the past and may wreck them in the future.

The struggle must go on while men are impelled by the desire for a greater profusion of what sustains life or makes it happier. It often has been, and often is, carried on by the sword, but important victories may be won, and disastrous defeats sustained, by more peaceful means. The discovery of the passage round the Cape transferred the trade of the East from the Mediterranean to London and Amsterdam, and most merchants in the City affirm that the cutting of the Suez Canal has once more deprived England of the advantage of situation. The commercial success of Switzerland, however, proves that national characteristics are at least as important as geographical position, and it is well from time to time to ask if we are doing all that in us lies to train those who shall follow us to maintain what our predecessors have won.

It is from this point of view that the second of the two utterances we have referred to is specially interesting. Mr. Goschen is at one with Prof. Huxley as to the severity of the struggle in which we are engaged. "Our position in the race of civilized nations," he told the undergraduates at Aberdeen, "is no longer what it was. We had a great start in industries and commerce, and by virtue of that start we attained to a station of unprecedented and long unchallenged supremacy. That supremacy is no longer unchallenged. Others are pressing on our heels. We require greater efforts than formerly to hold our own." Theory and experience agree. The biologist tells us that a state of struggle is the normal condition of man as of all other living beings, and that it must become keener as our numbers augment. The Chancellor of the Exchequer, with his hand on the pulse of English trade, is witness that the strife is growing in severity.

And this is not all. Mr. Goschen is not satisfied that we have as a nation all the qualifications for success. In a powerful address, which evidently expressed a matured conviction, he insisted that Englishmen lack "intellectual interest" in their work. They regard their business as a necessary evil, from which they delight to sever themselves as often and as completely as possible. They are ignorant of the general principles which underlie the conduct of trade, or at least are careless in noting their application to particular instances. It is quite in accord with this that they regard education not so much as an essential to fit a man for the battle of life as an ornament for his leisure hours. And here again Professor and politician are at one. The highest intellectual ideal of our University men, says Mr. Goschen in effect, is, or at all events until very lately was, perfection of literary form. Our public schools have aimed chiefly at turning out scholars who could write Latin verse. Our educational systems, echoes Prof. Huxley, were fashioned "to meet the wants of a bygone condition of society. There is a widespread and, I think, well justified, complaint that [our system of elementary education] has too much to do with books and too little to do with things."

To discuss the whole question thus opened—an indictment of University and Board-school alike—would be impossible in the limits of space at our disposal, but regarding it from the point of view in which our readers, like ourselves, are specially interested, we cannot but note a sad corroboration of Mr. Goschen's words. In no trades could a genuine intellectual interest be more easily excited than in those which involve a knowledge of science, and in none have Englishmen more conspicuously failed. It is needless to recapitulate stories like that of the discovery of the aniline dyes in an English laboratory, and the wholesale appropriation of the trade to which that discovery gave rise by German manufacturers. The fact is patent and obvious to all who have studied the question. Science can only be successfully cultivated by men who take an "intellectual interest" in their work; and in trades which depend upon a knowledge of science, it is the foreigner who achieves success. Where does the fault lie? For the masters and foremen, the colleges which are springing up all over the country may do much. They are, we believe, slowly creating a class of men who have a sound foundation of scientific knowledge, and a genuine interest in scientific progress. But for the rank and file, for the clerk and artisan, it is upon evening classes that Prof. Huxley thinks we must chiefly rely, and here the main difficulty seems to be to secure good teachers for classes in science and technology. They are, says Prof. Huxley, "not to be made by the processes in vogue at ordinary training colleges." "As regards evening science teaching"—we quote from the Report of the Royal Commissioners on Technical Instruction—"there seems to be nowhere in Europe any organization for systematic evening instruction comparable, as regards the number of subjects taught, and the facilities afforded for the establishment of classes, and for the examination of the students' work, with that undertaken by the Science and Art Department in this country, and recently supplemented, in the application of science to special industries, by the City and Guilds of London Institute.

"At the same time it must be borne in mind that in many towns visited by the Commissioners the evening science teaching was conducted by Professors of higher standing than, and of superior scientific attainments to, the ordinary science teachers who conduct courses in some of the largest and most important of the manufacturing centres of this country."

Here, then, appears to be at all events one weak point.

The Science and Art Department has a flexible system, capable of application to the wants of town and country. Students are examined by the thousand every May, but though the standard of attainment is rising, there is a general opinion—which is supported by the statements of the Royal Commissioners—that the instruction given by the teachers falls far short of an ideal which might be and ought to be reached. And yet this matter of good or bad teaching is vital. "It is absolutely essential," says Prof. Huxley, "that the mind [of the teachers of scientific subjects] should be full of knowledge and not of mere learning, and that what he knows should have been learned in the laboratory rather than in the library." "This," according to Mr. Goschen, "is the first test of the value of an educational system, whatever its curriculum may be. Is it intelligent? Is it thorough? Above all, is it rousing? Does it excite intellectual interest in those who come under its influence? Does it develop in them the temper which always asks for a reason and struggles to arrive at a principle?"

Teachers competent to work an educational system which satisfies these requirements must be themselves highly-finished educational products. They must have risen above the vulgar pocket-filling ambition of passing so many students per annum. Risen above it, not in the sense of ignoring it, for in this prosaic world a livelihood must be earned, but in the sense that the mere drudgery of bread-winning is for them lit up with a glow of the enthusiasm of the student who has knowledge to impart which he himself values for its own sake.

We want as science teachers not men who have crammed just enough to enable them to cram their pupils in turn, but men—and we believe there are many, though far too few of them—who have learnt to regard themselves as members of the great scientific army the advance of which is the most remarkable movement of the age.

How are they to be got? They cannot be obtained in the requisite numbers without a systematic search and preparation. It may be, as Prof. Huxley hints, that additional pecuniary inducements must be held out to secure them. This is a question on which the Chancellor of the Exchequer may have an opportunity of giving practical aid to English science and education. Or, if this is Utopian, let us suggest to Mr. Goschen that it would be well if his great influence were used to urge the Government to make the most of the machinery it already possesses.

Prof. Huxley has been for years the Dean of the Science Schools which are the centre of the system of evening teaching which the Royal Commission on Technical Instruction has pronounced to be in many respects the best in Europe. Among the highest rewards given to the successful candidates in the May Examinations are free passes for more or less prolonged courses of study at South Kensington.

Teachers in training attend the classes, and year by year batches of science teachers are brought together to receive special instruction in the subjects they are engaged in teaching. One of the great difficulties to be encountered by a provincial College is the fact that the calls upon the Professors are too multifarious. Students of all classes—would-be engineers, doctors, electricians, and a dozen similar groups—all desire courses of instruction designed to meet their particular wants. It has been rightly decided that this obstacle shall not impede the progress of the State-aided system of evening instruction. A special institution is provided to meet the special requirements of those who are engaged in it. The union of the Normal School of Science with the Royal School of Mines has not interfered with the attainment of this end, while it has secured the advantages which result from the mingling of students who are studying the same subjects with different aims.

The State, then, has recognized the need for trained science teachers, just as it feels the necessity for providing properly-educated officers for the Navy. It is admitted that both classes can best receive the instruction they need at special institutions. The Royal Naval College at Greenwich has been provided for the one, the Normal School of Science for the other.

The school gives evidence of vitality and success. Within the last five years the number of students has doubled. A very considerable amount of original research is done in its laboratories. Now, however, its very efficiency is a danger. It has outgrown the buildings which have been assigned to it. By permission of the Commissioners of the 1851 Exhibition, classes are carried on in what was the Colonial Exhibition. But duty to the interests with which they are primarily charged will, before long, compel them to withdraw this hospitality. Driven from the holes and corners in which it has been compelled to seek refuge, the Central School for the training of teachers of evening science classes may be compelled to reduce its numbers, and to limit its usefulness at the very moment when Mr. Goschen, Prof. Huxley, and all competent educationalists are agreed that one of our most pressing national wants is the elevation of our teachers, and of their type of teaching.

We have chosen this as a single example which serves to illustrate the wide generalization which we have been discussing. Is the interest of the average Member of Parliament in the dangers which threaten our trade sufficiently intellectual to lead him to sanction the cost of necessary precautions? In these democratic days the fate of the English people is in their own hands. If they choose that the education of their bread-winners shall be conducted on the principles on which the "accomplishments" were taught in an old-fashioned ladies' school—if they choose to send competent Commissioners all over Europe, and, when they tell them that one of the chief defects of their educational system is the comparative inefficiency of their teachers, they nevertheless deliberately half-close the doors of the school specially provided to remedy this defect—there is no help for it, and but little hope for them.

Wars may be caused by race hatreds which have taken centuries to gather, but success or failure often depends on the placing or misplacing of a few thousand men. Commercial competition may be, as Prof. Huxley tells us, due to causes which affect all living things. The progress or decadence of England will depend upon how it adjusts itself to the altering character of the strife; and we confess that we shall watch with interest to see what amount of practical support the Chancellor of the Exchequer is prepared to give to the views of the Lord Rector of Aberdeen. The test will be applied when the Technical Education Bill is again brought forward, and when the particular need which we have chosen as an illustration has to be met.

THE PROPOSED TEACHING UNIVERSITY FOR LONDON.

WE printed last week the petition which has been presented to the Privy Council by the Association for Promoting a Teaching University in London. We have now before us the petition of University College and King's College, to which is appended a proposed draft charter for the University, under the name of the Albert University of London. If, as seems probable, the promoters have been well advised in claiming no less a surname than that of the Metropolitan district for which the University is to serve, the prefixed name of the late Prince Consort, to whom England is undoubtedly indebted for the encouragement his influence gave to educational and scientific work, is perhaps as good a way as could have been hit upon for avoiding confusion with the existing University. For the rest, the charter appears to be an adaptation to the circumstances of that granted to the Victoria University; the principal differences being—the place reserved for the Royal College of Physicians and Royal College of Surgeons in the University, which is one of complete equality with the governing bodies of the University Colleges themselves; the power conferred upon the legally recognized medical schools of London, as such, to claim, as of right, admittance to the University, on equal terms with the Medical Faculties of University College and King's College; and the greater simplicity of the governing body. In the case of the Victoria University a complicated division of authority was resorted to, with the view of obviating mutual jealousies between the various cities and towns in which, in that case, the several Colleges were to be situated. The Senate proposed for the Albert University consists of three members chosen by the governing body of each College associated with the University; the College of Physicians and College of Surgeons being reckoned among associated Colleges, if willing to accept the position, but the twelve medical schools not being so reckoned; of four members representing the assembly of each Faculty, such assemblies being composed of the teaching staffs of all Colleges or medical schools admitted in respect of the Faculty; and of six representatives nominated by the Crown in the first instance, of whom three are eventually to be replaced by representatives of the graduates in Convocation.

Compared with this body, the composition of the Senate of Physicians and Surgeons proposed in the petition of the two Royal Colleges presents an even greater degree of simplicity. No provision is made for the representation of any other interest than that of the petitioners themselves; and the two Colleges divide the representation equally between their respective governing bodies. It is understood, however, that in the case of the College of Surgeons this proposal has not given satisfaction, even within the limits of the College; and that some representation will be claimed for Fellows of the College other than those who constitute the Council which governs it.

From the point of view which is especially our own, the quarrel about degrees, and the interests of rival institutions, occupy a place secondary in importance to considerations affecting the promotion of knowledge and science, and only important in so far as they are concerned. If the proposal of the Royal Colleges is carried into effect, and a committee of eminent physicians and surgeons is intrusted with the power of examining for and giving medical degrees, there can be little doubt that the great building on the Thames Embankment, and the space behind it shortly to be covered with building, will speedily develop into a teaching institution, with provision for research; and thus knowledge will be increased, and science promoted, by the addition of one more to the number of efficient schools for special purposes which are now open in London. The promoters of the Albert University do not offer us any immediate addition of this nature to the resources which are now available. We have examined the draft charter with care, in order to detect, if possible, the traces of a design to check the foundation or perfecting of new institutions, in the interest of those already existing. But the promoters, we are bound to say, appear to have guarded against all objection, by following, in this respect, the charter of the Victoria University. The appeal which is given to the Privy Council, in case of the refusal of the University to admit a new College, is a satisfactory provision against the spirit of monopoly. In the absence of danger from this point of view, the Teaching University promises more than is offered by the Senate of Physicians and Surgeons, in the interests of science. The prospect of establishing, as a qualification for admission to the University, a general standard of efficiency for Colleges professing to do the work of scientific teaching, has greater attractions for us than that of the opening of a single new school of medical and surgical research. Moreover, by the institution of the Teaching University, we shall secure the first, without rendering it less probable that in time the second also may follow.

We notice that the right of admission offered to all the London medical schools, though absolute so far as the Medical Faculty is concerned, is, in regard to the Faculty of Science, made conditional on efficiency. This is as it should be. Probably some of the smaller hospitals will regard with equaminity the extinction of their pretensions to be recognized as efficient schools of science. Others will be incited to render themselves efficient. In both cases the result to science will be a pure gain. One matter of importance appears omitted in the programme of the Albert University: the position to be assigned within the University, if its admission is contemplated, to the Royal School of Mines and Normal College of Science. It would appear proper that this point should be further considered, if the project ever reaches a more definite stage.

Upon the matters in dispute between the University of London and the University Colleges we desire to maintain an attitude of impartiality. On the one hand, it is urged that the credit of a degree will not stand the strain consequent on the creation of a second degree-giving body in London; and that all the reform desirable, in the interests of education, is the introduction of a larger number of teachers on the governing body of the existing University. On the other, stress is laid upon the importance, for educational purposes, of the independence of teachers from irresponsible external control, and upon the necessity of an organization of teaching for London more thorough than can be afforded by any constitution or reconstitution of an examining body. But whether

the desired reforms are carried out by changing the constitution of the University of London, or by instituting a new University, two things appear in any case to be incontestable: that the open examinations conducted by the existing University shall continue to be conducted by an impartial authority; and that the Colleges shall be allowed to organize their work in the manner best suited to promote their own efficiency.

Sir Philip Magnus, in a letter which appeared in the *Times* on Thursday, appears to consider the dispute as one between the efficiency of "lectures" on the one hand, and of "reading" on the other; and he cites the now well-known dictum of Darwin, in favour of reading, and against lectures. But it would be to mis-read, in a strange manner, the lesson of Darwin's life, if from it were to be drawn a conclusion against the existence of Universities for teaching purposes, and in favour of examinations. If Darwin carried from Edinburgh a profound dislike to unintelligent lecturing, of the epideictic sort, he was at Cambridge known as "the man who walks with Henslow." In Sir W. Hamilton's famous analysis of the work of Universities, examination holds the first place only among no less than seven "exercises" by which study, in a teaching institution, can be promoted; the others being "disputation, repetition, written composition, the practice of teaching, conversation with and interrogation of the learned, and social study." To these must be added, by the student of science, the practice of experiment under competent supervision. Some of these appear to us of more value than examinations, some of less; but it is obvious that an institution which is solely concerned with examinations does not cover the whole ground of institutional aid to study; and it is of no avail, as between one institution and another, to exalt the benefits of "reading," which is not peculiar to either. In conclusion, we trust all parties to the controversy will bear constantly in mind that degrees and examinations, lectures and colleges, are, after all, but means to an end. The end is the spread and advancement of knowledge, through educational methods and research.

MANUAL OF BRITISH DISCOMYCETES.

A Manual of the British Discomycetes. By William Phillips, F.L.S. 8vo, 446 pages, 12 plates. International Scientific Series. (London: Kegan Paul, Trench, and Co., 1887.)

IT is by no means an uncommon misfortune to find that text-books are not written by persons the most competent, or with the widest experience; hence the results are very far from satisfactory, and no one expresses much gratification. Now and then notable exceptions to this rather general rule may be discovered, to the delight of all who are interested in that special branch of science to which the book is devoted, and the great edification of the student. It is beyond our province to inquire why the most suitable men are so seldom engaged in the production of "manuals," or why the most skilful manipulator, with a few months' study and much "coaching," cannot compete successfully with the practical hand well steadied with a twenty years' experience. It will be enough to intimate that no one acquainted with British Cryptogamic botany would for a moment hesitate to pronounce that the most suitable person to undertake a manual of the Discomycetes would be Mr. W. Phillips, of Shrewsbury, if practical knowledge, and persistent investigation, extending over at least two decades of years, are to be accepted as qualifications.

With these preliminary observations it will be at once evident that, in general terms, and as a whole, we feel bound to give this little volume our heartiest commendation; and if, in the course of our remarks, we indicate any weak places, it will be with the desire to act with the tenderness of a friend, and to point out how, in our conception, an admirable manual may be rendered more perfect or more useful.

No apology is needed for restricting a book like the present to a small controllable group of some 600 species, especially when the limits are so well defined that a student may devote himself exclusively to it, with advantage to himself, without any special acquaintance with outside groups. It is generally admitted that the entire British Fungi, with its thousands of described species, is become too unwieldy and extensive for any ordinary individual, not content to become a slave to his subject and a martyr to science. The Discomycetes present an admirable group, capable of isolated study; and for this purpose a careful and trustworthy manual, at a moderate price, is now ready at the student's hands.

"The subject of classification," the author says in his preface, "will not fail to awaken some controversy." "To adhere as closely as possible to the long-accepted Friesian system has been the practice of English authors, but this has been carried a little too far, owing to our 'insular prejudices,' and the time has come when a new departure must be made." We are prepared to accept this paragraph—exclusive of "insular prejudices," which we cannot admit—and with it the "new departure." To our mind this is a most moderate concession, and we doubt not that, if controversy there should be, its direction will be in favour of far greater innovation than Mr. Phillips or ourselves would approve. The details of the new arrangement must be subjected to closer examination and the test of experience, but at present we see no reason to take exception to them. We have long been of opinion that some such modification of the old classification was desirable.

There is, nevertheless, one point on which we have always uttered a protest, and repeat it again, since in two or three instances in the present volume the error has been committed. We allude to the addition to, or alteration of, a generic description, and the appending of the original author's name, with the word "amended" after it. We protest against *amended genera*, because they are nobody's genera; they are not the genera of the original author, but a "thing of shreds and patches." A genus should not be altered or amended, in order to fit any subsequent species which a later author may desire to incorporate. He should keep the new species outside, and accommodate it in other ways, rather than modify or "tinker" the work of a predecessor, and assume the change to be an "amendment," whereas it *may* be something very different, and probably *would* be to the old author himself, if he could be resuscitated to gaze on the freaks of his successors.

As for the number of species described in this volume,

we may remark that it is more than double that which the "Hand-book of British Fungi" included in 1871. One of the many valuable features of the book is, that, wherever possible, measurements are given of the sporidia of the various species, in micromillimetres, in addition to the dimensions of the fungus in its entirety. We specially allude to this feature in order to have an opportunity of adding that in our experience we have never met with a more careful or expert hand at microscopical measurement than the author of the present work, an opinion based on hundreds of observations made in concert during a series of years. Yet we must urge that, however useful the micromillimetre undoubtedly is in spore-measurement, it is not so well to use it for larger bodies, such as the cup of a *Peziza*, when the millimetre or its decimal part would appeal more directly to the eye and experience. 500 μ may be equal to half a millimetre, but the mind more quickly and readily conceives the half millimetre than the 500 μ. We observe a lack of uniformity in dimensions appreciable by the naked eye, which is avoided in measurements under the microscope. For instance "¼ to ½ line broad" (p. 249), "cups 200 to 500 μ" (p. 257), "cups 500 to 800 μ" (p. 321). What relation does the "line" bear to the micromillimetre? If half a line is about 500 μ, why use the two units of measurement? Would it not have been better to follow Stevenson in his "British Fungi," and to reduce all measurements to the centimetre, millimetre, and micromillimetre, which would have been much more consistent, and far better than the mysterious "line," and had the merit of being more intelligible to the foreigner than a unit of which he has no knowledge or experience.

It would be useless to assume that the work is absolutely free from errors, but these are mostly of a trivial character, although more numerous than we could have wished. We doubt whether "conidia" would not have been a better term than "spermatia" in such a connection as *Calloria fusarioides;* and we also doubt whether our author accurately appreciates the value of the terminations in such words as *violascens*, *virescens*, *fuscescens*, *nigrescens*, &c.

As for the general scope of the work, we may say that each species begins with the diagnosis, then follows its synonymy, especially in British works, references to figures, and published specimens. If these are in the main accurate, as we have no reason to doubt, they will be exceedingly valuable, but manifestly only experience can prove this, and figures are very liable to become displaced or transposed. The habitat succeeds the synonymy, which is followed by special notes or comments; then the derivation of the specific name, now and then hardly successfully interpreted, as for instance on pp. 291, 325, and 369, where *ater* would have been better rendered "dark" instead of "black"; and finally a list of localities.

At page 358, *Ephelis* is inserted as a genus of Fries's. The same genus is claimed by Saccardo ("Sylloge," iii. p. 691) for a genus of Sphæropsideæ, and we fear that Phillips will have to give way to Saccardo, as both cannot stand, and there is no evidence that Fries regarded his genus as ascigerous.

Forty pages at the end are most useful appendages to the work, consisting of a glossary of terms, full titles of the various works quoted, and an exhaustive index. To the last page Mr. Phillips has spared no trouble to make his work as complete and useful as practicable, and we trust that he may be rewarded for his labour of love (for such it undoubtedly has been) by being called upon speedily to correct the verbal errors in preparation for a new edition.

M. C. C.

OUR BOOK SHELF.

Physiography: an Elementary Text-book. By W. Mawer, F.G.S. (London: Marshall and Co., 1888.)

THIS is another addition to the steadily increasing number of text-books adapted to the elementary stage of physiography. The usual plan of dividing a book into chapters is not adhered to, but probably the author is of opinion that he is working according to the true spirit of physiography in drawing no hard and fast lines.

In the majority of cases the author has succeeded in his endeavours to explain everything in the simplest way, but in a few cases his anxiety to do so has led him astray. The following may be quoted as examples, and the obvious shortcomings need no further comment:—

"Work is the moving of matter" (p. 8); "Energy, when active—when actually doing work—is in the condition called *kinetic*; when it is passive and only ready to do work, it is *potential*" (p. 9).

With a few exceptions of this kind, the book is admirably adapted to the syllabus which it is intended to cover. That it is not a mere cram-book is evidenced by the mass of useful information which is given. A good general outline of the nebular hypothesis is presented, in so far as it concerns the history of our globe, and there is also an outline of the classification of animals and plants. The astronomical portion of the syllabus also receives a fair share of attention. One omission, however, has been made, and that is the use and meaning of the term "stress": the word apparently does not occur even once in the whole book; this is rather unfortunate now that modern physicists are beginning to regard gravitation, magnetism, &c., as stresses.

Apart from its use as a class-book, it can be recommended to the general reader as an outline of science.

A. F.

Early Christian Art in Ireland. By Margaret Stokes. (Published for the Committee of Council on Education, by Chapman and Hall, 1887.)

THIS is one of the South Kensington Museum Art Handbooks, and it deserves to rank among the best of the series. The Christian antiquities of Ireland are in their own way as remarkable as any group of antiquities in the world, and a satisfactory account of them, such as ordinary readers might understand and appreciate, was greatly needed. In undertaking to supply what was wanted, Miss Stokes devoted herself to a task for which she was well equipped by previous study, and she has produced a little book which can hardly fail to excite interest in her subject, and which will be welcomed even by antiquaries to whom the facts of Irish archæology are already well known. A chapter on illumination is followed by one on Irish scribes on the Continent; and then come chapters on metal-work, sculpture, building and architecture, with a chronological table of examples of Irish art the date of which can be approximately fixed. The work is illustrated by upwards of a hundred good woodcuts. In her treatment of all questions relating to early Christian art in Ireland, Miss Stokes displays a thoroughly scientific spirit, and her style has the merit of being always clear, fresh, and unpretending. She rightly claims for her subject that it has a practical as well as an intellectual

interest. If the higher class of workers in Ireland took the trouble to study systematically the objects here so carefully described, an epoch might be marked in the development of Irish technical skill.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

The Duke of Argyll's Charges against Men of Science.

The Duke of Argyll's singular appetite for besmirching the characters of men of science appears to grow by what it feeds on; and, as fast as old misrepresentations are refuted, new ones are evolved out of the inexhaustible inaccuracy of his Grace's imagination.

In the last two letters which the Duke of Argyll has addressed to you, he accuses me of having charged the members of the French Institute with having entered into a "conspiracy of silence" in respect of Mr. Darwin's views. I desire to say that the assertion that I have done anything of the kind is untrue and devoid of foundation.

My words, in the passage of which the Duke has cited as much as suited his purpose, stand as follows: "In France, the influence of Elie de Beaumont and of Flourens—the former of whom is said to have 'damned himself to everlasting fame' by inventing the nickname of 'la science moussante' for evolutionism—to say nothing of the ill-will of other powerful members of the Institute, *produced, for a long time, the effect of a conspiracy of silence.*"[1] I used the words I have italicized advisedly, for the purpose of indicating that, though the members of the Institute did *not* enter into a conspiracy of silence, the notorious antagonism of some of them to evolution produced much the same result as if they had done so.

If the Duke of Argyll were properly informed upon the topics about which he ventures to speak so rashly, he would know that M. Flourens wrote a book in vehement denunciation of evolutionism. As I reviewed that book not very long after its appearance, I could not well be ignorant of its existence. And being aware of its existence, I could not possibly have charged M. Flourens with taking any part in a "conspiracy of silence."

The "effect" of the known repugnance to Mr. Darwin's views of some of the most prominent members of the Institute, to which I refer, is the effect upon the younger generation of French naturalists. Considering the influence of the Institute upon scientific appointments, the chances of a candidate known to be an evolutionist would have been small indeed; and prudence dictated silence.

Mr. Carlyle has celebrated the courage, if not the discretion, of a certain "Rex Sigismundus," who, his Latin being called in question, declared that he was, as a Royal personage, "supra grammaticam." The Duke of Argyll appears to be of King Sigismund's opinion in respect of the obligations which are felt by humbler persons, who have, wittingly or unwittingly, accused their fellows wrongfully; and I do not suppose that he will descend, on my account, from a position which may be sublime or may be ridiculous, according to one's point of view. The readers of Nature will choose their own.

T. H. Huxley.

Bournemouth, February 4.

[1] "Life and Letters of Charles Darwin," vol. ii. pp. 185-86.

An Explanation.

Since the Duke of Argyll's references to myself have been interpreted in a manner likely to convey an erroneous impression to the readers of Nature, it seems to me to be now necessary to give some explanation of the facts in which I am concerned. I intend, however, to go no further than to establish the position his Grace has taken up as regards myself. Such a step, savouring somewhat of presumption on my part, would not have been taken if Prof. Judd had admitted that, although no paper of mine was ever before the Council of the Geological Society, an offer to present such a paper was, doubtless for sufficient reasons, at once declined.

In the spring of 1885, by the advice of Mr. Murray, who had been for some time engaged in examining my recent geological collections from the Solomon Islands, I offered to Prof. Judd, then Secretary of the Geological Society, to present my observations on the upraised coral-reef formations in the form of a paper, in which, as I stated, Mr. Darwin's theory of coral reefs would be brought under consideration. This offer being declined, my observations were taken up by Mr. Murray and were published in the Transactions of the Royal Society of Edinburgh for 1885. As I saw too plainly that the new view of the origin of coral reefs was very far from being generally accepted, I deemed it advisable in preparing my paper to draw no inferences and to allow the facts to speak for themselves. However, six months after the reading of the paper, whilst going over the proofs, having been assured that the theory of Mr. Darwin was rapidly losing ground, I appended some remarks in which I gave the general bearing of my discoveries.

Had I harboured a desire in my mind to record any disappointment in connection with the appreciation of my work, I might have done so in the preface of my small geological volume recently published. The reflection that I had succeeded, and that Mr. Murray's views, as I was told, were being generally received, gave me ample grounds for satisfaction; and there was therefore no reason why I should refer to any difficulties of a personal character. I must confess, however, I was afterwards deeply disappointed on finding that, although the nature of my discoveries was first announced in the columns of this journal in January 1884, whilst the observations themselves had been nearly two years before the world, my name and work were *studiously ignored* in the recent controversy by those who spoke on behalf of English men of science, and particularly on behalf of the Geological Society. Naturally it was there that I looked most for approval. I soon perceived, however, that it could not be in the want of publicity that the reason lay, nor even in the insufficient lapse of time since the publication of my papers. Long abstracts were given in the columns of this journal of the principal paper (Trans. Ed. Roy. Soc., 1885), and of a paper also read before the Royal Society of Edinburgh (Proc., 1886). At the beginning of 1885 (or perhaps earlier) I sent to Prof. Judd a blue pamphlet published in New Zealand, in which I briefly described the discoveries I had made up to the end of 1883. At the beginning of 1886 I sent to him my principal Edinburgh paper of the previous year.

It then occurred to me that since Prof. Dana's last paper, of September 1885, was the chief rallying point of the opponents of Mr. Murray's views, the cue in estimating the value of my work might have been thence derived. I found, however, that Prof. Dana had only before him, when referring to my discoveries, an extract from a private letter of mine to Mr. Murray written in the midst of my work, and published in Nature in January 1884. Rightly enough, he did not consider such a brief account as at all conclusive. My published observations had yet to come before him. It was not, therefore, from the other side of the Atlantic that in estimating the value of my observations Mr. Murray's opponents had taken their cue.

I was forced, therefore, to the conclusion that the reason lay rather in the competency than in the bearing of my observations. I could find no other explanation of the fact that in the succession of replies to the Duke of Argyll's article, entitled "A Great Lesson," no reference whatever was made to the recent important evidence I had adduced—evidence of which at least one of the writers had been previously aware during a period of two if not three years. Under these circumstances, I accepted the decision which the lapse of nearly three years had not affected; and, having naturally some degree of sensitiveness, I withdrew from the Geological Society.[1]

[1] Mr. Guppy was induced afterwards to withdraw his resignation.—Ed. Nature.

In conclusion, I may say that these circumstances do not alter my conviction of fighting on the winning side. The reasons of my faith I hope to give in the next journal of the Royal Scottish Geographical Society. H. B. GUPPY.

17 Woodlane, Falmouth.

Snow Crystals.

YESTERDAY was very favourable for observing the beautiful appearance of sunlight reflected from snow crystals. As one walked across a field, stars appeared to start forth by thousands from amongst the fresh-fallen snow. They were particularly bright and numerous when one walked in the direction of the sun. They appeared almost at all distances, and almost of all sizes, those near at hand being never very large but of great brilliancy and most exquisite colour. The phenomenon was sufficiently striking to induce me to stop and observe it more closely, and the first thing I noticed on stopping was the permanence of each little star of light, although the snow was dropping melted from the hedges and trees by the heat of the sun. A slight movement of the head was sufficient to change the colour of a red star to green or *vice versâ*. It seemed as if the most brilliant colours were seen when looking in a direction nearly but not quite towards the sun. The level surface of the snow appeared as if strewn with gems—and not only near at hand, for even twenty and thirty yards away a large star would shine forth with a subdued but fine colour. I then noticed a peculiar uniformity of shape in these reflections from snow crystals. The shape never varied from that of a blunt arrow-head. This was very striking in the large stars which appeared at a distance; but once noticed, it was obvious enough that even the minute specks at one's feet were all of this form. Nor did the position of the snow vary to any appreciable extent. The inclination seemed always a little to the right, and this occurred no matter in what direction I looked, whether towards the sun, or away from it, or in any other direction. Wishing to know the absolute size of the larger snow crystals, or combination of crystals, I looked for a fine appearance, and estimated as well as I could its magnitude by covering it with a small object held at arm's length. The distance of the spot where the crystal appeared proved to be forty-three paces from where I stood, and its magnitude could not have been much less than three inches in this particular case. Now if, as I suspect, the form of the star which appears so persistently is due to the upper or lower stem only of a complete arrangement of crystals in an hexagonal shape, these combinations must occasionally be six inches or more in diameter. I did not succeed in recognizing any larger than very minute arrangements of crystals in the snow itself, but it is obvious that the sun's rays reflected from a long distance must single out those faces of crystals which happen to be parallel to one another over a certain limited area. Observation of these reflections, therefore, calls in to our aid a power of analysis in the sun's rays to detect symmetrical arrangements of snow crystals quite unrecognizable by mere inspection. Might I ask for some explanation of the phenomena?

Hull, January 30. A. N. S.

"The Mammoth and the Flood."

MR. HOWORTH's letter does little more than travel again over old ground, and two only of the points raised require any notice on my part; the third—the value to be attributed to the opinion of any particular geologist—being immaterial to the main question. As another President of the Geological Society has said: "Science needs no infallible Church, and admits of no Pope."

In regard to the localities in which mammoth remains have been found, I have not "resuscitated" any theory, but have taken my facts from Mr. Howorth's book. His second letter appears to me to ignore a distinction which I was careful to draw in my reply to his former one. That mammoth *bones* should be found at considerable distances from, and elevations above, the existing rivers, offers no difficulty. Indeed, they could not occur, except accidentally, in deltas which are now in course of formation. But, so far as I can ascertain, there is no reason why these "beds of clay and gravel" should not be deposits of rivers which drained the same regions under different climatal conditions, in the distant ages when the mammoth lived in Siberia. The case is precisely similar in England. We should not expect to find mammoth bones in the mud-flats about the mouths of our southern rivers, but in the old valley gravels which occur sometimes even 90 or 100 feet above the present level of the rivers. But the facts most difficult to explain are the occurrences of the *carcasses* of mammoths. It was of these, and of these only, that I was speaking in my letter, as I think would be clear to most readers. No geologist, so far as I know, would deny that the Siberian climate has considerably changed since the mammoth wandered over its tundras, and very likely not seldom got bogged; but the question is, Has it changed suddenly or gradually? The occurrence of the frozen carcass is undoubtedly most simply explained by postulating a sudden change; but when we begin to consider what this means, the remedy, though apparently so simple, seems as heroic as that of the father "who cut off his little boy's head to cure him of squinting." It is then for the best preserved of these frozen carcasses that I suggest the possibility of a drifting and a gradual entombment by the deposits of the ancient rivers. I have again consulted Mr. Howorth's book, and find, between pp. 82 and 89, notices of the discovery of at least ten mammoth carcasses, mostly occurring very far north in Siberia, and nearly all mentioned in connection with rivers: of one it is even said, "like most of the others, it is found on the bank of the river, which had been undermined by floods."

Mr. Howorth further asserts that I cannot have read his book because I charge him with invoking a series of catastrophes when he argues "in favour of one catastrophe only." But, notwithstanding his disclaimer, I would like to know how we are to bring about a deluge to drown the mammoth and a sudden permanent fall in temperature to freeze his carcass (query, one catastrophe, or two?) without "a series of catastrophes." I presume that, as this is a scientific question, we must not invoke a miracle. If continents gambolled like whales—which would be needed for Mr. Howorth's far-reaching flood—would this, unless there were a very special arrangement of continents, so materially alter the climate? and, if they did so disport themselves, what set them dancing? If a number of insular volcanoes exploded with twenty-Krakatão force, this would be a series of catastrophes, but it would probably leave the climate unchanged. If the earth's axis of rotation were suddenly altered materially in position—perhaps the simplest mode of bringing about the two results—would no catastrophic changes be needed to effect this alteration? Mr. Howorth's retort, in fact, indicates better than anything which I can write how completely he has failed to realize the conditions of the problem which he attempts to solve.

But enough. It is impossible for me to continue this correspondence. The reviewer's task is often not a very pleasant one, but a new terror would be added to the work if it involved an interminable controversy with authors on matters of opinion. Dreading this, I deliberately abstained from signing the review, because I knew from past experience that this was my only chance of escape from the flood of Mr. Howorth's controversial eloquence, which, like the proverbial river, *Labitur et labetur in omne volubilis ævum.* YOUR REVIEWER.

An Incorrect Footnote and its Consequences.

IN following up Baltzer's erroneous reference concerning the "Demonstratio eliminationis Cramerianæ," Mr. Muir, as described in his letter on p. 246, seems at first to have been singularly unlucky. For, on referring to the catalogue of Lord Crawford's mathematical library under "Mollweide," although the work itself was not immediately forthcoming, there was a cross-reference to "Prasse, M. von," under whose name the essay was duly catalogued. The Dun Echt copies, for there are two of them bound up in volumes of mathematical pamphlets, are copies of the original "Demonstratio," in 8 folios, with the pages 4 to 15 numbered, and the last blank. In a gap on the title-page of one copy has been written "auct. Mauricius de Prasse," apparently long ago, and in a German hand. But apart from this the last sentence of the first paragraph identifies the author as the writer of "Usus logarithmorum," which bears the same Latin form of the name in print.

The cross-reference is due to the presence in the library of a little book the title of which is worth giving in full, as it contains the names between which Baltzer's mistake arose, and it also gives the German form of von Prasse's name: it is "Logarithmische Tafeln für die Zahlen, Sinus und Tangenten, neu geordnet von Moritz von Prasse ehemals Prof. der Mathematik in Leipzig, revidirt und vermehrt von Karl Brandan Mollweide ordentl. Prof. der Mathematik in Leipzig. Leipzig,

1821," ix. + 110 pp. 16mo. In the preface Mollweide says that von Prasse was his predecessor in the Chair of Mathematics, as stated by Prof. Virchl. This work is entered under both the title-names in Poggendorff's "Biographisch-literarisches Handwörterbuch," a circumstance that might have given a clue to the authorship of the "Demonstratio." Strangely enough, this is not the only instance in which von Prasse omitted his name in essays written by him for academical celebrations. I can only surmise that this was done with a view to republication in his "Commentationes Mathematicæ," and that the name was written on the copies distributed as invitations to the celebrations. Whatever the reason, it has in this instance obviously added greatly to the trouble ordinarily experienced when dealing with this class of academical essay, the bibliography of which is so complicated, and at the same time often so important.

RALPH COPELAND.

A New Historic Comet?

AT a recent meeting of the Asiatic Society of Japan, a paper was read by Mr. W. G. Aston, H.B.M. Consular Service. This paper will certainly rank high amongst historic papers relating to Japan and Korea. Briefly described, it is a comparison between the ancient records of these two countries and China, and its aim is to establish the relative credibility of these various records. Mr. Aston has so far confined his attention to the period preceding A.D. 500; and his general conclusion is that, as historic writings, the Korean and Chinese chronicles are far superior to the Japanese of the same date.

In the Tongkan, as the ancient records of the Korean kingdoms are called, there is a notice, of which the following is a translation: "Summer, fourth month, Pèkché; comet visible; day-time." The fourth month began on May 14 or 15. At the request of Mr. Aston, I tried to find out if any such comet had been observed elsewhere. The only list of historic comets obtainable in Japan was the list given in Faye's "Astronomy"; and I am not sure if this is meant to be complete. According to Mr. Aston, the Pèkché comet appeared in May or June, A.D. 302. The nearest date in Faye's list is A.D. 295. If this is the same comet, then one *at least* of the dates must be wrong. It is quite possible, however, that both are correct; in which case we shall be indebted to Mr. Aston for having added one more to our list of historic comets. In coming to a conclusion, we must know to what source we owe the knowledge of the 295 comet, and whether this source has greater claims to chronological accuracy than have the Korean records. Not having the references at hand for studying these points, I have written this note to NATURE, in the hope that someone interested in the matter may be able to come to a decision on this question of a possibly new historic comet.

Imperial University, Tokio, Japan, December 19, 1887.

"Is Hail so formed?"

UNDER the above heading in NATURE of January 26 (p. 295) there is a short paper by Cecil Carus-Wilson, in which the writer assumes that under certain conditions, drops of water, whilst falling from the upper branches of a tree, become converted into ice before reaching the ground, whilst other drops falling from the same tree, but at 10 feet less altitude, came to the ground in a fluid state. There is, I think, a simpler solution of this question than the one given. Suppose the following conditions—namely, a frost sufficiently severe as to lower the temperature of the leaves and branches of a tree to a few degrees below the freezing-point; after which a very gradual thaw comes on, accompanied by a fine rain or Scotch mist which freezes on the tree.

Where the leaves and smaller branches hang downwards, small beads of ice would form on their points. As the air became warmer the ice would thaw, and fall to the ground either in the liquid form, or the beads at the ends of the leaves and twigs would become detached in their solid state, and reach the ground as ice-pellets.

Sometimes these ice pellets extend in length, and assume the form of small icicles.

MODERN VIEWS OF ELECTRICITY.[1]

PART III. (*continued*).

VII.

First Representation of the Field due to a Current.

RETURN now to the consideration of a simple circuit, or, say, a linear conductor, and start a current through it; how are we to picture the rise of the lines of force in the medium? how shall we represent the spread of magnetic induction? First think of the current as exciting the field (instead of the field as exciting the current, which may be the truer plan ultimately).

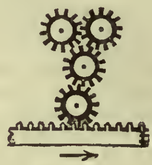

FIG. 34.

If we can think of electricity in the several molecules of the insulating medium connected like so many cog-wheels gearing into one another and also into those of the metal, it is easy to picture a sideways spread of rotation brought about by the current, just as a moving rack will rotate a set of pinions gearing into it and into each other (Fig. 34). But then half the wheels will be rotating one way and half the other way, which is not exactly right.

How is it possible for a set of parallel whirls to be all rotating in the same direction?

FIG. 35.

If there is any sort of connection between them they will stop each other, because they are moving in opposite directions at their nearest points; and yet, if there is no connection, how can the whirl spread through the field?

Well, return to the old models by which we endeavoured to explain electrostatics, and think whether they will help us if we proceed to superpose upon them a magnetic whirl in addition to the properties they already possess. Looking at Figs. 5, 6, and 13, we remember we were led to picture atoms and electricity like beads threaded on a cord. And these cords had to represent, alternately, positive and negative electricity, which always got displaced in different directions.

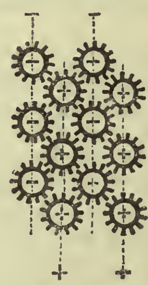

FIG. 36.—Rows of cells alternately positive and negative, geared together; free to turn about fixed axles.

We are forced to a similar sort of notion in respect of the wheels at present under discussion: in order that

[1] Continued from p. 323.

they may co-operate properly, they must represent positive and negative electricity alternately. If they *then* rotate alternately in opposite directions, all is well, and the electrical circulation or rotation in the field is all in one direction. Each wheel gears into and turns the next, and so the spin gets propagated right away through the medium, at a speed depending on the elasticity and density concerned in such disturbances.

It is not convenient at the present stage to ask the question whether the wheels represent atoms of matter or merely electricity. It may be that each atom is electrostatically charged and itself rotates, in which case it would carry its charge round with it, and thereby constitute the desired molecular current.

The apparent inertia of electricity would thus be explained simply enough, as really the inertia of the spinning atoms themselves; and the absence of any moment of momentum in an electro-magnet as tested mechanically would be equally explained by the simultaneous opposite rotation of adjacent atoms. A question may arise as to why the opposite molecules should have exactly equal opposite inertiæ, as they have, else a fluid magnetized medium would bodily rotate; and there may be other difficulties connected with a bodily rotation of electrostatically charged molecules: it is merely a possibility upon which stress must not be laid till it has been proved able to bear it. For our present purpose a spin of the electricity inside each atom, or even independently

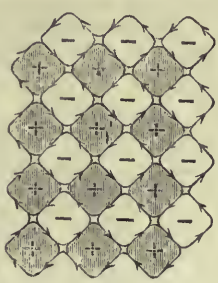

FIG. 37.—Portion of a magnetic field. Another mode of drawing Fig. 36.

of any atoms, is quite sufficient. Besides, since magnetic induction can spread through a vacuum quite easily, the wheel-work has to be largely independent of material atoms.

If any difficulty is felt concerning the void spaces in Fig. 36 it is only necessary to draw it like Fig. 37, which does every bit as well, and reduces the difficulty to any desired minimum.

Representation of an Electric Current.

Now notice that in a medium so constituted and magnetized—that is, with all the wheel-work revolving properly—there is nothing of the nature of an electric current proceeding in any direction whatever. For, at every point of contact of two wheels the positive and negative electricities are going at the same rate in the same direction; and this is no current at all. Only when positive is going one way and negative going the opposite way, or standing still, or at least going at a different rate, can there be any advance of electricity or anything of the nature of a current.

A current is nevertheless easily able to be represented: for it only needs the wheels to gear imperfectly and to work with slip. At any such slipping-place the positive is going faster than the negative, or *vice versâ*, and so there is a current there. A line of slip among the wheels corresponds therefore to a linear current; and, if one thinks of it, it is quite plain that such a line of slip must always have a closed contour. For, if only one wheel slip, then the circuit is limited to its circumference; if a row slip, then the direct and return circuit are on opposite sides of the row. But a large area of any shape with no slip inside it may be inclosed by a line of slip, and this gives us a circuit of any shape, but always closed. Understand; one is not here thinking of a current as analogous to a *locomotion* of the wheels—their axes may be quite stationary,—the slip contemplated is that of one *rim* on another.

Imagine all the wheels inside the empty contour of Fig. 38 to be rotating, the positive clockwise, the negative counter clockwise, and let all those outside the contour be either stationary or rotating at a different rate or in

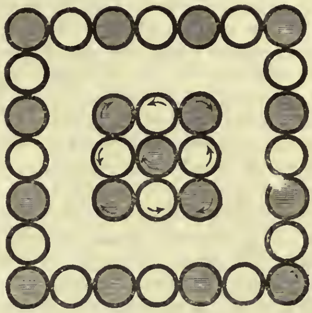

FIG. 38.—Diagram of a peripheral current partitioned off from surrounding medium by a perfect conductor, which transmits no motion, and therefore acts as a perfect magnetic screen.

an opposite direction; then the boundary of the inside region is a line of slip along which the positive rims are all travelling clockwise, and the negative rims the other way, and hence it represents a clockwise positive current.

But it may be said that the spin inside the contour, if maintained, must sooner or later rotate the wheels outside as fast as themselves, and then all slip will cease. Yes, that is so, unless there is a complete breach of connection at the contour, as in Fig. 38 there is. If the outer region has any sort of connection with the inner one the slip at its boundary can only be temporary, lasting during the era of acceleration.

Distinction between a Dielectric and a Metal, as affected by a spreading Magnetic Field.

In a dielectric the connection between the atoms is definite and perfect. If one rotates, the next must rotate too; there is no slip between the geared surfaces; it is a case of cogged wheels. A conduction-current is impossible.

But in a metallic conductor the gearing is imperfect; it is a case of friction-gearing with more or less lubrication and slip, so that turning one wheel only starts the next gradually—it may be very quickly, but not instantaneously—and there is a motion of a positive rim incompletely compensated by an equal similar motion of a negative rim while getting up speed; in other words, there is a momentary electric current, lasting till the wheels have fairly started.

In a perfect conductor the gearing is absent; the lubrication is so perfect that all the atoms are quite free of one another, and accordingly a spin ceases to be transmitted into such a medium at all. The only possible current in a perfect conductor is a skin-deep phenomenon.

A magnetized medium of whatever sort is thus to be regarded as full of spinning wheels, the positive rotating one way and the negative the other way. If the medium is not magnetized, but only magnetic—*i.e.* capable of being magnetized—it may be thought of either as having its wheels stationary, or as having them facing all ways at random; the latter being probably the truer, the former the easier, representation, at least to begin with.

Whether the medium be conducting or insulating makes no difference to the general fact of spinning wheels inside it wherever lines of force penetrate it; but the wheels of a conductor are imperfectly cogged together, and accordingly in the variable stages of a magnetic field, while its spin is either increasing or decreasing, there is a very important distinction to be drawn between insulating and conducting matter. During the accelerating era conducting matter is full of slip, and a certain time elapses before a steady state is reached. A certain time may be necessary for the propagation of spin in a dielectric, but it is excessively short, and the process is unaccompanied by slip, only by slight distortion and recovery. As for a strongly magnetic substance like iron, nickel, or cobalt, one must regard them as constituted in the same sort of way, but with wheels greatly more massive, or very much more numerous, or both.

Phenomena connected with a varying Current. Nature of Self-induction.

Proceed now to think what happens in the region round a conductor in which a current is rising. Without attempting a complete and satisfactory representation of what is going on, we can think of some mechanical arrangements which have some analogy with electrical processes, but do not pretend to imitate them exactly.

Take first a system of wheel-work connected together and moved at some point by a rack. Attend to alternate

FIG. 39.—A provisional representation of a current surrounded by dielectric medium, either propelling or being propelled.

wheels more especially, as representing positive electricity. The intermediate negative wheels are necessary for the transmission of the motion, and they also serve to neutralize all systematic advance of positive electricity in any one direction, except where slip occurs, but they need not otherwise be specially attended to.

Remember that every wheel is endowed with inertia, like a fly-wheel.

Directly the rack begins to move, the wheels begin to rotate, and in a short time they will all be going full speed. Until they are so moving, the motion of the rack is opposed, not by friction or ordinary resistance, but by the inertia of the wheel-work.

This inertia represents what is called self-induction, and the result of it is what has been called the "extra current at make," or, more satisfactorily, the opposing E.M.F. of electro-magnetic inertia or self-induction.

So long as the rack moves steadily forward, the wheel-work has no further effect upon it; but directly it tries to stop, it finds itself unable to stop dead without great violence: its motion is prolonged for a short time by the inertia of the wheel-work, and we have what is known as the "extra current at break."

If the rack is for a moment taken to represent the advancing electricity in a copper wire, then the diagram may be regarded as a section of the complete field: the complete field being obtained from it by rotating it round the axis of the wire. Imagining this done, we see that the axis of each wheel becomes prolonged into a circular core, and each wheel into a circular vortex ring surrounding the rack and rolling down it as it moves forward, as when a stick is pushed through a tight-fitting umbrella-ring held stationary (see Fig. 30 B).

As one goes further and further from the rack the lengths of the vortex cores increase, but there is only a given amount of rotation to be shared among more and more stuff, hence it is not difficult to imagine the rate of spin diminishing as the distance increases, so that at a reasonable distance from the conductor the medium is scarcely disturbed.

To perceive how much rotation of the medium is associated with a given circuit, one must consider the shape of its contour—the position of the return current. Take first a long narrow loop and send a current up one side and down the other. The rotations belonging to each are superposed, and though they agree in direction for the space inclosed by the loop, they oppose each other outside, and so there is barely any disturbance of the medium outside such a looped conductor; very little dielectric is disturbed at all, and accordingly the inertia or self-induction is very small.

If the loop opens out so as to inclose an area, as the centrifugal force of the wheels will tend to make it do,

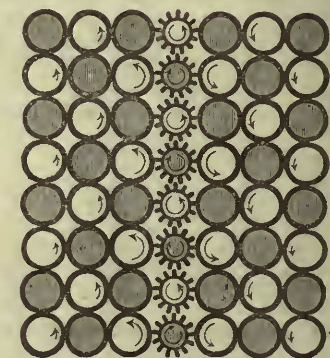

FIG. 40.—Diagram of a direct and return current close together, showing distribution of rotation and of slip in the thickness of the conductor, and in the dielectric between. The dielectric outside is very little disturbed.

then there is a greater amount of rotation, a greater moment of momentum inside it, and accordingly its self-induction is increased. The axis of every wheel is, however, continuous, and must return outside the loop: so the outside region is somewhat affected by rotation, but of a kind opposite to that inside.

Figs. 38 and 41 show the state of things for a closed circuit conveying a current. The free space in Fig. 38 represents a perfect conductor, or perfect breach of connection. Along one side of this space positive electricity is seen streaming in the direction of the arrows, and it may be streaming on the other side also, but nothing happens in its interior—which is therefore not represented.

The corresponding portion in Fig. 41 is intended for an ordinary conductor, full of wheels capable of slip. And slip in this case is a continuous necessity, for the rotation on either side of the conductor is in opposite directions, so the atoms of the conductor have to accommodate themselves as best they can to the conditions; some of them rotating one way, some the other, and some along a certain neutral line of the conductor being stationary. If a conductor is straight and infinitely long, the neutral line of no rotation is in the middle. If it be a loop, the neutral line is nearer the outside than the inside, because the rotation of the medium inside is the strongest. If the

loop be shut up to nothing, the neutral line is its outer boundary or nearly so (Fig. 40). If, again, the circuit is wound round and round a ring, as string might be lapped upon a common curtain-ring to cover it, then the axes of whirl are wholly inclosed by the wire, and there is no rotation outside at all.

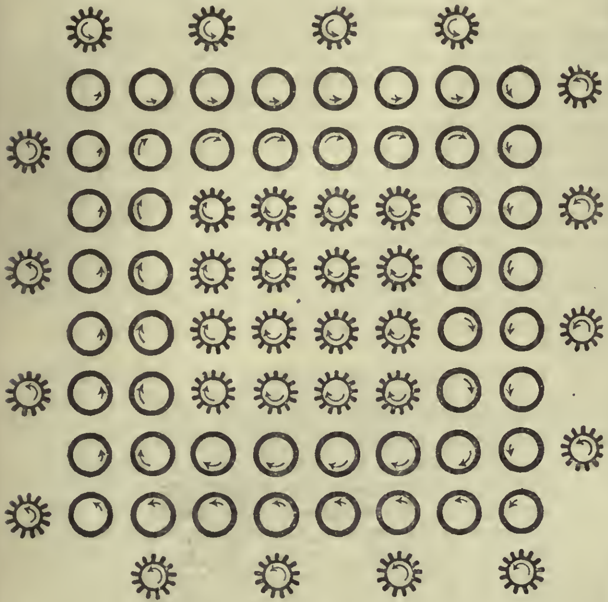

FIG. 41.—Diagram of simple conducting circuit like a galvanometer ring, with the alternate connecting-wheels omitted. The same number of dielectric wheels are drawn outside as inside, to indicate the fact that the total spin is equal inside and out, though the outside is so spread out as to be much less intense.

Fig. 42 shows a section of this last-mentioned condition, and here the wheels of the dielectric outside are not rotating at all. The inside is revolving, it may be furiously, and so between the inner and outer layers of the conductor we have a great amount of slip and dissipation of energy.

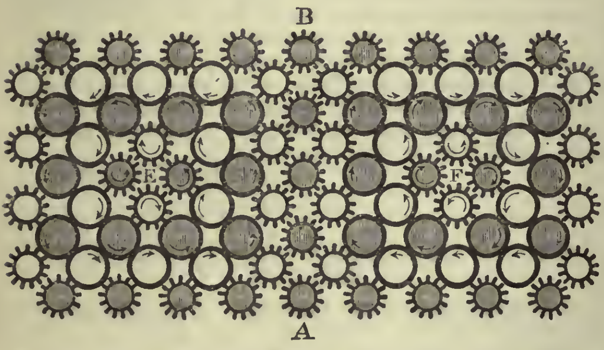

FIG. 42.—Section of a closed magnetic circuit, or electric vortex-ring, or hollow bent solenoid like Fig. 29, inclosing an anchor-ring air-space; the axis of the ring being A B, the sections of the core being E and F. The arrows indicate the intensity of the spin, *i.e.* of the magnetic field, which is a maximum at the middle of each section and nothing at all outside. If the core contains iron instead of air, its wheels have to be from 100 to 300 times as massive: slipping wheels if solid iron, cogged wheels if a bundle of fine varnished iron wires.

The process of slip which we have depicted goes on in all conductors conveying a current, whether steady or variable, and in fact *is* the current. The slip is necessarily accompanied by dissipation of energy and production of heat: only in a perfect conductor can it occur without friction. In a steady current the slip is uniformly distributed throughout the section of the conductor; in the variable stages it is unequally distributed, being then more concentrated near the periphery of the wire.

When a current is started in a wire, the outer layers start first, and it gradually though very quickly penetrates to the axis. Hence the lag or self-induction of a wire upon itself is greater as the wire is thicker, and also as it is made of better conducting substance. If it is of iron, the mass or number of the wheels is so great that the lag is much increased, and the spin of its outer layers is great enough to produce the experimental effects discovered by Prof. Hughes.

One must never confuse the slip with the spin. Slip is current, spin is magnetism. There is no spin at the axis of a straight infinite wire conveying a current, and it increases in opposite directions as you recede from the axis either way; arranging itself in circular vortex cores round the axis. But the slip is uniformly distributed all through the wire as soon as the current has reached the steady state. The slip is wholly in the direction of the wire. The axes of spin are all at right angles to that direction.

Rise of Induced Current in a Secondary Circuit.

To study the way in which a magnetic field excited in any manner spreads itself into and through a conducting medium, look at Fig. 43, and suppose the region inside the contour A B C D to be an ordinary conducting region—that is, full of wheels imperfectly geared together, and capable of slip.

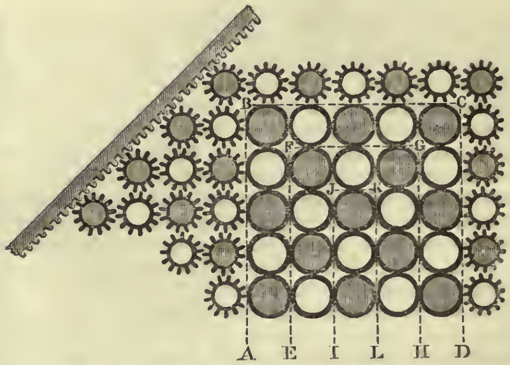

FIG. 43.—Diagram illustrating the way in which an induced current arise in a mass of metal immersed in an increasing magnetic field; also how it decays. The dotted lines A B C D, E F G H, I J K L, are successive lines of slip.

Directly the rack begins to move, all the wheels outside A B C D begin to rotate, and quickly get up full speed. The outer layer of wheels inside the contour likewise begins to rotate, but not at once; there is a slight delay in getting them into full motion. For the next inner layer the delay is rather greater, and so on. But ultimately the motion penetrates everywhere equally, and everything is in a steady state.

But while the process of starting the wheels was going on, a slip took place round the contour A B C D, and round every concentric contour inside it; the periphery of the positive wheels moving in a direction opposite to that of the wheel in contact with the rack, and so suggesting the opposite induced current excited at "make" in the substance of a conductor near a growing current, or generally in an increasing magnetic field.

The penetration of the motion deeper and deeper, and the gradual dying away of all slip, illustrate also the mode in which this induced current arises and gradually dies away, becoming *nil* as soon as the magnetic field (*i.e.* the rotation) has penetrated to the interior of all conductors and become permanently established there as elsewhere.

Suppose the motion of the rack now stopped: all the cogged wheels stop too, though it may be with a jerk and

some violence and oscillation due to their momentum; but those inside the contour A B C D will continue moving for a little longer. The outside layer of this region will slip in such direction as to illustrate the direct induced current at "break," and will begin to stop first; the slip and the stop gradually penetrating inwards, just as happened during the inverse process, until all trace of rotation ceases. This inverse slipping process is the direct induced current at "break."

Through a perfect conductor the disturbance could never pass, for the slip of the dielectric wheels on its outer skin would be perfect, and would never penetrate any deeper. A superficial current lasting for ever, or rather as long as the magnetic field (the rotation of the dielectric wheels) lasts, is all that would be excited, and it would be a perfect magnetic screen to any dielectric beyond and inclosed by it. OLIVER J. LODGE.

(*To be continued.*)

THE BIRDS'-NEST OR ELEPHANT ISLANDS OF THE MERGUI ARCHIPELAGO.

OF the geological structure of this group of islands lying off the coast of British Burmah not much is yet known. Our readers will probably be interested in the following account of a visit to one portion of the archipelago, furnished by Commander Carpenter, R.N., to the Hydrographer of the Admiralty, to whose kindness we are indebted for permission to publish it.

The remarkable group of islands called by the Burmans Ye-ei-gnet-thaik (*lit.* sea-birds' nests) is located on the south-east side of Domel Island, one of the largest of the Mergui Archipelago. It is composed of six marble rocks, the highest and largest of which, 1000 feet in altitude, and about one mile in length, is oval-shaped, and rises very abruptly out of a depth of only 5 fathoms. The islands present a very striking appearance, particularly if the weather is hazy, when they are not seen until within five or six miles, for then they gradually loom out through the mist like some huge misshapen monsters that have strayed away from civilization. Their sides are partly clothed with vegetation wherever a break in the limestone has left a cleft in which moisture and dust can lodge. Conspicuous because of its leaning attitudes is a species of tree-fern which grows at any angle, but only above a height of 200 feet from the water. The face of the rocks is reddish, partly from weathering and partly from soil, and where cliffs exist the most beautiful though uncouth stalactites have been formed, showing grotesque and snake-like patterns varying in hue and shape till one feels as if in some enchanted land. But the great feature of the group is the birds'-nest caverns, which as a rule open into the sea, the entrance being below high-water mark; fortunately I visited them at spring tides, and had plenty of leisure to examine each cavern at low water during two days.

At the south end of the largest island stands a "nine-pin" of gray marble 370 feet high, almost separated from the rest. It is hollow, like a huge extinguisher, and the polished light-blue and yellow sides of the interior seem to point to its having been hollowed by the swell of the sea, which on entering the cave would probably expend its force vertically, the mouth of the cave being open to the direction of the strongest seas. This sea-stack forms the western point of a nearly circular cove, 360 yards in diameter, which runs back into the island, and the sides of the cove rise steeply though not perpendicularly from it. At the head of the cove is a perpendicular wall of rock over which can just be seen the 1000-foot summit in the distance.

At half-tide a tunnel, passable for a canoe, opens under the wall of rock at the head of the cove, but a ship's gig can only enter within an hour of low-water spring tides. This tunnel has a roof covered with large stalactitic knobs except at its narrowest part, where it is apparently scoured smooth by the action of the tidal rush. It is about 250 feet long, and 4 feet deep at low water (the rise and fall of the tide being 16 feet), and is covered with dripping marine life, corallines, small corals, Comatulæ, sponges, and sea-horses. Passing through this submarine passage one emerges into another circular crater-shaped basin with perpendicular sides. This basin is only open to the sky; caves here and there enter it, some of which may perhaps lead by long tunnels to other basins. Water was running freely into it from the foot of the cliffs in several places as the tide fell, showing that water spaces existed, and strange gurgling sounds as of air taking the place of water could be heard now and again. There were hardly any signs of the place being frequented by man except here and there the worn ropes of birds'-nest climbers. It was either not the season for the swallows, or they had deserted the islands, for none were seen. A little reddish guano was noticed in some of the caves. There can be but little traffic through the tunnel by which we entered, for the delicate growth on its sides was hardly injured.

On the west side of the northern large island a lofty cavern is connected at half-tide with another nearly circular basin of about the same size as that we have just described, but in this case the basin also opens into the sea on the east side of the island. After contemplating the cliffs that surround these basins, the general circular contour of the ridges of the islands, the undermining action of the sea at the water-line, which causes in some places an overhang of 20 to 25 feet, and the softening of the marble surface of the cavern roofs by moisture, the conviction gradually forces itself on the mind that these circular basins were themselves at one time the floors of huge caverns; that in days gone by the islands rose far higher, with cavern piled on cavern, and that the work of disintegration by solution and wave-action is slowly going on, pulling down these marble monuments of a giant age. Indeed, here and there a fall of blocks has occurred lately, and, as there is no shoal off the base of the slip, the destructive action is probably rapid.

A small oyster covers the rocks at the water-line. A handsome kingfisher was secured and sent to the British Museum. A few doves and an eagle or two were the only other birds seen, besides a small bat in the caves. By the position of the nest-seekers' ropes, the swallows appear to build only on the roofs of the caves. The islands appeared to be entirely composed of a blue-tinted marble. A vessel could lie alongside them and lower the cut blocks straight into her hold, but it is probably of too poor a quality to be worth shipment.

ALFRED CARPENTER.

PRIZE FOR RESEARCHES IN NATURAL HISTORY.

IN accordance with the intentions of the founder, the Committee of Schnyder of Wartensee's Foundation, Zürich, have decided to offer for the year 1890 a prize for the following researches in natural history:—

"New investigations are desired regarding the relation which the formation of the bones bears to the statics and mechanics of the vertebrate skeleton. The results of the investigations as a whole are to be demonstrated in detail by way of example on the skeleton of a definite species."

The conditions are as follow:—

Art. 1. Competitors for the prize must send in their work in German, French, or English, by September 30, 1890, at the latest, to the address given below in Art. 6.

Art. 2. The award will be made by a Committee consisting of the following gentlemen:—Prof. Hermann von

Meyer, Zürich; Prof. L. Rütimeyer, Basle; Prof. H. Strasser, Berne; Prof. Otto Mohr, Dresden; and Prof. Albert Heim, of Zürich, representing the Committee offering the prize.

Art. 3. The judges are authorized to award a first prize of two thousand francs; and a further sum of one thousand francs is placed at their disposal for distribution in minor prizes according to their discretion.

Art. 4. The work awarded the first prize becomes the property of the Foundation of Schnyder of Wartensee, which will arrange with the author regarding the publication of the same.

Art. 5. Each competing work must bear on the title-page a distinguishing motto, and must be accompanied by a sealed envelope containing the name of the author, and bearing on the outside the same motto.

Art. 6. Competing works are to be sent in by the date named in Art. 1, to the following address: "An das Präsidium des Conventes der Stadtbibliothek in Zürich (betreffend Preisaufgabe der Stiftung von Schnyder von Wartensee für 1890)."

NOTES.

THE death of Sir Henry Maine, F.R.S., has created a great blank in the serious literature of England. He was the first Englishman who applied to the study of law and early institutions the rigid methods of science, and the results at which he arrived marked an epoch in the investigation of these subjects. His literary style, combining as it did extraordinary vigour, lucidity, and grace, was scarcely less remarkable than his grasp of far-reaching principles. He died suddenly, of apoplexy, at Cannes, on Friday evening last. He was in his sixty-sixth year.

IN a letter received from Mr. John Whitehead, dated Labuan December 13, 1887, that gentleman writes:—"To-day or to morrow I start for Kina Balu, and I hope to make this a famous and last expedition into Borneo, for I really am in wonderful health considering everything, but at the same time I am rather tired of Borneo, with its fevers, heat, and mosquitoes. I hope to be back in England in August and September. I do not like to brag of what I hope to do, as things are so uncertain. Natives may refuse to help me, and may perhaps attack me, for the country round this fine mouutain is by no means settled." On the last occasion of his visiting Kina Balu a year ago, Mr. Whitehead was only able to remain a month upon the mountain, but he discovered nineteen new species of birds in that short time, some of them being really wonderful novelties. He now hopes to remain for at least six months, and this he will doubtless be able to do, if he can secure supplies for his hunters, and keep open his communication with Labuan.

MR. WHITEHEAD'S collections from the island of Palawan have now arrived in this country, and a brief account of them will appear in the April number of the *Ibis*. This island has already been visited by Prof. Steere, Mr. Alfred Everett, and Mr. E. Lemprière, all of whom made collections in the neighbourhood of Puerto Princesa. Mr. Whitehead's labours were also confined to the vicinity of this post, as he was prevented from visiting the interior. He has succeeded, however, in procuring specimens of every species met with by the three travellers above-mentioned, and has besides obtained about sixty additional species, several being new to science.

THE Council of the Royal Meteorological Society have arranged to hold, at 25 Great George Street, Westminster, on March 20–23 next, an Exhibition of Apparatus connected with Atmospheric Electricity, including lightning-conductors, photographs of lightning, and damaged objects. The Committee will also be glad to show any new meteorological instruments or apparatus invented or first constructed since last March; as well as photographs and drawings possessing meteorological interest.

A FRIENDLY meeting of employers and working men, to discuss the best means of obtaining technical education, will be held at the Royal Victoria Hall, Waterloo Bridge Road, on Wednesday, February 15, at eight o'clock. The chair will be taken by Sir Douglas Galton. This meeting has been arranged in consequence of the great interest shown in a similar meeting held at the same place on December 14. The speakers will be limited to ten minutes, and those who wish to speak must send in their names the day before the meeting.

THE new American Folk-Lore Society was definitely organized at a meeting held at Harvard College on January 4. The object of the Society is the study of folk-lore in general, and especially of folk-lore in North America. The first President is Prof. F. J. Child, of Harvard, and the acting Secretary is Mr. W. W. Newell, of Cambridge, Mass. It is expected that the first number of the Society's journal will be published in April.

THE Duchess of Albany has become Patroness of the Parkes Museum, of which the Duke of Albany was President until his death.

DURING the coming spring the construction of the North Sea and Baltic Canal will be begun along the whole line. There will be seven camps of workmen, and 4000 men employed.

THE Education Department of Scotland has issued a circular to the various School Boards in that country, in which are embodied the results of the careful inquiries that have recently been made into the existing system of elementary scientific teaching in Scottish schools. Technical instruction is discouraged in primary schools till the boys have reached the higher standards, and even then, the Department thinks, no attempt should be made unless skilled teachers and abundance of scientific apparatus are available. In most instances the thorough teaching of elementary science is beyond the reach of the primary schools; but by various School Boards uniting to employ a trained staff of teachers much of the difficulty will be overcome. School Boards are also recommended to seek the aid of local committees consisting of manufacturers who know what technical education is most needed in the district. The Department also recommends the extension of the system of giving evening lectures, which have been so successful in the past, and the charging of fees low enough to be within the reach of all. Nothing would tend to make technical education more popular than a small rate of charge, combined, as it should always be, with trained help and an abundant supply of scientific instruments.

A STRIKING new experiment, exhibiting the terribly explosive nature of chloride of nitrogen, is described by Prof. Victor Meyer in the current number of the *Berichte*. A few drops of the yellow chloride were prepared in the usual manner by inverting an exceptionally thin flask filled with chlorine gas in a leaden dish containing a solution of ammonium chloride. Instead, however of gently agitating the apparatus so as to cause the drops to fall into a smaller leaden capsule placed beneath the mouth of the flask, they were allowed to float freely upon the surface. The whole apparatus was then inclosed in a cover-box fitted with stout plate-glass sides, through the top of which was passed a bent pipette, turning up below just under the mouth of the flask and connected outside with a dropping funnel containing chloride of ammonium solution and a few drops of turpentine. When sufficient chloride of nitrogen had collected, the tap of the funnel was carefully turned so as to allow a little turpentine to slowly rise in the flask. After a moment or two it reached the surface and mingled with the chloride of nitrogen, causing a brilliant

flash of light and a loud explosion, which Prof. Meyer likens to a thunder-clap, so much more powerful is the detonation in a confined space. The flask of course was shattered, not into powder, but into tolerably large fragments; the plate-glass box, however, even after many repetitions of the experiment, remained intact, a small door on the side away from the observers having been left ajar so as to prevent any notable increase of pressure. Curiously, the chloride of nitrogen never entirely exploded; a part remained in the distorted leaden dish and maintained an incessant fusillade for more than a minute.

AT the last meeting of the Göttingen Chemical Society, Dr. Gattermann read a preliminary note upon his recent researches as to the nature of chloride of nitrogen. From his analyses it appears pretty clear that the yellow liquid is a mixture of at least two distinct chlorides, which he has hopes of being able to separate. During the course of the experiments the reason of its capricious behaviour, the cause of so many painful accidents in the past, was happily discovered. It is decomposed by the actinic rays of light, being rapidly acted upon by sunlight with periodic spontaneous explosion, and is at once fired by exposure to the rays of burning magnesium. Hence further light upon this difficult and dangerous subject can only emanate from the dark room, a paradox the truth of which Dr. Gattermann is endeavouring to demonstrate.

ON the morning of Tuesday, January 31, a distinct shock of earthquake is said to have been felt near Birmingham. In and around Coventry, too, several persons say that they experienced sensible vibrations of their houses and heard rumbling noises. At Hartshill the ceiling of a house was cracked by the shock. On Thursday, February 2, a sharp shock of earthquake was felt over a large part of Scotland. The following details regarding this shock are taken from the *Times* of Friday, February 3:—"The shock was distinctly felt at a quarter past 5 o'clock in Perth. The tremor lasted about one minute, and consisted of five or six slight, wave-like motions from west to east. In the Breadalbane and Grantully districts of Perthshire the shock lasted six seconds. It was also felt very distinctly in Aberfeldy, Acharn, Kenmare, and Strathay. It is twenty years since these districts were similarly affected. In Strathearn two shocks were felt, the first about half past 3 o'clock, and the second about 5 o'clock. Further north, in Inverness-shire and Ross-shire, a shock was felt about 5. It was sharper and seemed to travel from south-west to south-east. The tremor in Dingwall is likened to the vibration caused by a heavy waggon passing along a road, while at Crieff it was like a very heavy body thrown to the ground. In Beauly and Strathglass people were greatly alarmed. Their houses shook, dishes fell, furniture was broken, and numbers of people rushed from their beds and out of houses without dressing. On the west coast the shock was very violent. It was also felt at Mull. From Fort William it is reported that there was a slight shock at 5 a.m., which affected the old Caledonian valley, and extended down to the line of the Moray Firth."

THE February Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, contains a list of such hardy herbaceous annual and perennial plants as have matured seeds under cultivation in the Kew Gardens during the year 1887. "These seeds," it is explained, "are available for exchange with colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew. But the seeds are for the most part only available in moderate quantity, and are not sold to the general public. In the years 1885 and 1886 the list was printed as an independent publication. It has now been thought more convenient to issue it as a number of the Bulletin. Every effort is made to correctly determine the nomenclature of the plants in the list. As far as it goes, it will serve as a record of the herbaceous species cultivated at Kew. It must, however, be remembered that a considerable proportion of herbaceous plants do not mature seeds in the climate of England, and these are necessarily not included in the list."

MUCH inconvenience is caused by the fact that lists of recent additions to public libraries are not always readily accessible to persons who would like to make use of them. Readers at the Darwen Free Public Library may congratulate themselves that in their case this difficulty has been overcome. The other day the *Darwen News* printed the first instalment of a list of books which have been lately added to the collection belonging to that institution, and which are not to be found in the catalogue. Two similar instalments will follow, and afterwards lists will be given as books are purchased. If readers will take the trouble to cut out these lists and place them at the end of their copies of the catalogue, they will know exactly what works have been secured for the library. From the instalment just issued, it is obvious that the managers of the Darwen Free Public Library exercise great discretion in their choice of books, and we are glad to see that among the works selected by them science is very fairly represented.

SEVERAL correspondents have written to us about Mr. John Morison's letter, printed last week (p. 321), on what he supposed to be a case of untimely insect development. Mr. Edward Buckell, of Romsey, writes:—"Surely Mr. Morison has overlooked the fact that *Vanessa urticæ* hibernates in the imago state, selecting for that purpose houses and such other warm quarters as it can find. I have counted nine in one house. During hibernation the insect is naturally in a semi-torpid condition. As to the 'abnormal appearance' of the antennæ, I think that if Mr. Morison observes other specimens, both during the winter months and after sundown in the summer, he will find the position noted by him to be the usual one."

WE referred last week (p. 328) to M. Lancaster's work on the climate of Belgium in 1887; we are also indebted to him for an elaborate discussion of the barometer observations taken at Brussels Observatory during the fifty years 1833–82. That Observatory owes its origin to the efforts of the late L. A. J. Quetelet, President of the International Maritime Conference held at Brussels in 1853, to which Conference our own Meteorological Office owes its origin. The Annals of the Observatory contain one of the most complete series of climatological and phenological observations extant. The barometrical results, which M. Lancaster has carefully resumed, are drawn from the eye observations taken up to June 1841, and since that time from self-recording instruments, one of which is a photographic barograph of the Kew pattern. In addition to the usual monthly and annual means, the tables contain summaries of the days on which the barometer was above or below certain values, the epochs of all remarkable falls and rises, five-day and seasonal means. The mean for the whole period was 29·766 inches (not reduced to sea-level); the greatest height was 30·753 inches on January 17, 1882; and the lowest, 28·367 inches, on December 10, 1872. The mean diurnal range for the year was 0·023 inch. The diurnal and monthly variations are greatest in winter and least in summer; the highest and lowest absolute readings occur generally in the month of January.

MR. R. H. SCOTT delivered a lecture on British and Atlantic weather, at the London Institution, on the 2nd instant. After some interesting remarks on the effect of difference of height upon vapour, the dependence of our weather on the upward or downward movement of the atmosphere in cyclonic and anti-cyclonic systems, and on the cause of fogs, he discussed the utility of the present American reports in forestalling storms, based on a consideration of their movements as shown by the Atlantic Weather Charts lately published by the Meteorological

Council. These charts showed that only a small proportion of storms travelled across the Atlantic. The track of the depressions is determined by the distribution of pressure over the ocean, and of this distribution we are ignorant at the time of despatch of telegrams from America. The lecturer stated that in their present incomplete form the telegrams were of no assistance to the Meteorological Office in issuing storm warnings.

DR. BILLWILLER reports the establishment of a permanent observatory on the summit of the Santis, in October last. This observatory ranks as the third in height in Europe, being at an elevation of 8200 feet, and 108 feet higher than the temporary station at the Gasthaus, on the Santis, where the observations have been taken for the last five years. The results of these observations are published in a *Neujahrsblatt*, by the scientific Society of Zürich. The lowest temperature during the five years was $-9°$ F. on March 13, 1883, and the highest, 69°, on July 21, 1886. The prevalent winds were westerly and south-westerly, which usually occur on high mountains in these atitudes.

ACCORDING to the last annual report on the Dutch East, Indies, rainfall was measured at 183 stations in these possessions. The military portion of the report, the topographical survey of Java, on a scale of 1 : 200,000, is completed, and the members of the Survey have been sent to the west coast of Borneo, where a preliminary survey to join certain points already astronomically determined has been undertaken. The survey on the west coast of Sumatra will also be continued. A considerable part has already been triangulated, and 344 positions have been determined. The definitive calculation of the triangulation work of Java, on which Prof. Oudemans, of Utrecht, has been at work for five years, is not yet completed.

RECENT Java journals give particulars of a remedy for coffee-leaf disease, discovered by Dr. Burck, manager of the Government [Botanic Gardens at Buitenzorg, near Batavia. The specific is said not only to cure the disease, but also to prevent its recurrence. For preventive purposes, he makes use of a highly attenuated solution of chloride of iron applied to the under portion of the leaves by means of a pulverisator. The sticky nature of the solution enables it to adhere two months to the coffee-leaves. It is a powerful antidote to the *Hemileia vastatrix*. To stay the progress of the latter when it has once taken hold, a different method is employed. The coffee-leaves in which the *Hemileia* first manifests itself in the form of orange-coloured spots are at once taken in hand. Holes are pricked in the spots with a needle dipped in a strong solution of sulphuric acid, which kills all the germs of the disease in the leaf. Dr. Burck estimates the cost of the preventive specific at 2½ guilders per 133 lbs., and the healing remedy at 4 guilders. He anticipates that the price of coffee will be enhanced in consequence. The second specific in particular is said to have yielded good results and to be easy to administer. The economic value for Java of the discovery of the remedies, should they prove successful, can scarcely be over-estimated. In Ceylon the disease in the coffee-plant produced a revolution in planting; year after year the coffee crops were failures, many planters were ruined, and ultimately tea-growing took the place of coffee with results which are just now astonishing the world. But the period of transition from one staple to the other was one of economic disaster, from which perhaps Dr. Burck has saved Java.

WE have received the recent issues of the *Journal of the Asiatic Society of Bengal*. Vol. lv. Part 2, No. 5, is wholly occupied by the second instalment (Rhopalocera) of the Lepidopterous insects collected in Tavoy and Siam during 1884–85, under the superintendence of Mr. Pitman, the Chief Superintendent of Telegraphs. Of this list nearly 100 species are quite new. The list is drawn up by Messrs. Elwes and L. de Nicéville. Vol. lvi. Part 2, has numerous and varied contributions. The first paper is by Mr. Blanford, on the influence of Indian forests on the rainfall. The other papers are: the changes in the density of sea-water, by S. R. Elson; notes on Indian Rhynchota, Heteroptera, Part 1, by E. T. Atkinson; new species of Ficus from New Guinea and Sumatra, by G. King, where eleven new species are spoken about; the mammals and birds collected by Captain Yate with the Afghan Boundary Commission, each species briefly described and commented on by J. Scully; the species of Loranthus indigenous to Perak, by G. King; Étude sur les Arachnides de l'Asie meridionale, by M. Eug. Sîmon; the differential equation of a trajectory, by H. Mukhopadhyay.

THE current number of the *Folk-Lore Journal* (vol. vi. part i.) contains a most interesting collection of Aino tales and legends, made by Prof. Chamberlain, the well-known Japanese scholar. We are glad to see that he was encouraged to publish the collection by certain observations contained in a review, in these columns, of his recent monograph on the Ainos. The collection consists of fifty-four tales (a few being omitted as unfit for general publication), classified under the headings—tales accounting for the origin of phenomena, moral tales, tales of the Panaumbe and Penaumbe cycle, miscellaneous tales, and, finally, scraps of folk-lore. These were all taken down from the mouths of Ainos. The other papers in the number include a continuation of one on Irish folk-lore collected from a "Statistical Account or Parochial Survey" of that country published more than seventy years ago; and a collection of the traditions of a race as curious in its way as the Ainos, the Mentra, or aborigines of Malacca and the adjoining States.

THE January number of the *Auk* announces that the affairs of the American Ornithologists' Union have considerably brightened, and that by the public spirit of some of its members the Association begins the new year free from debt. The new part also strikes us as full of vigour, and of more than ordinary interest, and it is evident that the recent exertions of the Americans in getting collections from little-known parts of the Western world, such as Texas and Northern Mexico, are being amply rewarded. The reviews are as good as ever, and some of the original papers are excellent. Mr. Sennett describes a new finch from Arizona, and gives an account of the North American species of *Peucæa*, but not one word is said respecting the "Biologia Centrali-Americana" of Messrs. Salvin and Godman, where all Mr. Sennett's facts were duly set forth a year ago. The new Arizona finch, *Peucæa ruficeps scotti*, of Mr. Sennett, was also described some months ago by Mr. Bowdler Sharpe as *Peucæa homochlamys* in the twelfth volume of the "Catalogue of Birds," but as this work has only just appeared, Mr. Sennett's name secures priority of publication. Mr. Brewster's new species from Mexico seem to rest on somewhat trivial characters, at least in the case of the small owls (*Scops*) and the *Aimophilæ*.

AMONGST the subjects of special interest referred to in the report of the Smithsonian Institution for the past year is the exploration for a collection of skeletons and skins of the now almost extinct American bison or buffalo. The exploraton was very successful, a small herd being found in a wild part of Montana, from which the officers of the Institution secured a series of skins, as well as sixteen complete skeletons, and fifty-one dry skulls. The herd appears to have been completely exterminated by the settlers soon afterwards. An expedition was also despatched to the Swan Islands in the Caribbean Sea, which are said to abound in land birds in great variety, and also in large iguanas and other reptiles. The National Museum

collections are extending so rapidly that the provision of additional and adequate space for their exhibition is becoming a matter of pressing importance. In 1884 the number of specimens was estimated at 1,471,000; the number is now increased by more than a million. At the beginning of the present decade there was only one curator with a few assistants; now there are thirty-one regularly organized departments and sections, under the care of twenty-six curators and numerous assistants. The work of the Ethnological Bureau in all its branches—mound explorations, general field studies, and office work—appears to proceed as vigorously as in previous years. The most important forthcoming work of the Bureau appears to be a report by Mr. E. W. Nelson, on the Eskimo of Northern Alaska. During 1886 the vocabularies of twelve Eskimo dialects were arranged in the form of a dictionary, which will form one part of his report; the other will contain chapters on Eskimo life and customs in Alaska, illustrated by photographs taken on the spot.

AN elaborate review of the mineral industries of the United States during the year 1886 has just been issued by the United States Geological Survey. It is the fourth of a series of volumes entitled "Mineral Resources of the United States." The first three volumes contain the statistics from 1882 to December 31, 1885.

THE U.S. Bureau of Education has issued the first of what promises to be a most interesting series of "Circulars of Information." The present Circular is by Dr. H. B. Adams, who has chosen as his subject the College of William and Mary. This College was founded in 1693 by Royal grant, and was long supported by popular legislation in Virginia. The greater part of its property was destroyed during the Civil War, and since that time the institution has been allowed to decline almost to ruin. Dr. Adams' aim, as explained in a prefatory letter, has been to discover the historical beginnings of the higher education in the South; to trace the causes of the early prosperity of William and Mary College; to show its influence upon Virginia statesmen and the Southern States, its relation to the University ideas of Jefferson and Washington, and its significance to the whole country; to point out the causes of the decline of William and Mary College; to explain the rise of the University of Virginia, and the necessity of popular support for the higher education.

POPULAR editions of the late Dr. Parkin's volumes—"Are Epidemics Contagious?" and "The Volcanic Origin of Epidemics" (Sampson Low)—have been published. Dr. Parkin died nearly two years ago at the age of eighty-five, and it is explained in an editorial note that "his long and strenuous life had been devoted to the study of cholera and similar epidemics." His attention was first specially directed to the subject of cholera more than fifty years ago, when he was visiting India and China. A prolonged series of observations and experiments satisfied him that "the cause of the disease was atmospheric, and that carbonic acid gas was its antidote." The editor of these volumes admits that Dr. Parkin's theories have met with comparatively limited acceptance in England. This fact he attributes in part to the comparative mildness of cholera outbreaks in England, in part to "an erroneous notion that the results of Dr. Parkin's teaching were hostile to sanitation."

MESSRS. LONGMANS have just issued the ninth edition of Mr. William Jago's "Inorganic Chemistry, Theoretical and Practical." In this edition the paragraphs are numbered, and have side-headings. The more important statements and definitions are printed in bolder type. A number of students and teachers have pointed out to Mr. Jago that they have been using his book in preparing for the Matriculation Examination of the London University, and have been inconvenienced by its not covering the whole syllabus of that examination. Chapters have now been added to supply this want.

AT the last meeting of the Society of Science of Christiania Prof. Schöyen exhibited and described four species of Lepidoptera new to the Norwegian fauna; viz. *Agrotis præcox*, L., found as larva in the Hval Islands, in the Christiania Fjord; *Asopia glaucinalis*, L., produced from larva at Christiania; *Tortrix inopiana*, Haw., from southern Aurdal; and *Cerestoma nemorella* from Christiansand. At the same meeting Prof. Blytt read a paper on the alterations of the so-called "Strandlinjer," or shore-lines, in Norway, maintaining that the changes in the division of land and sea might have been caused by an alteration in the length of day and night.

A RESIDENT in the isolated little island of Bornholm, in the Baltic, writes to a Danish journal that a curious Christmas custom is observed in that island. When the so-called "Christmas table" has been spread on Christmas Eve, a large long loaf of rye bread is laid at the upper end of it. In this loaf, before it is baked, two transverse grooves are made about 3 inches from each end. On the top of the loaf a large cheese and various articles of food are laid. This is the so-called "*Julegalt.*" It remains untouched throughout Christmas, and when the table is not in use, the cloth is gathered from the other end and laid over the "*galt.*" This curious custom is believed to have been handed down from Pagan times, the *galt* (pig) having reference to Frey's *galt* or pig "Gyldenbörste" ("Gold bristle"). Frey was the god of rain, sunshine, harvest, and general felicity.

THE acclimatization of the so-called "American" trout in Norwegian waters has been very successful. Attempts are now about to be made to acclimatize black bass obtained from America.

THE Danish Government has decided upon forming an oyster bank in the Limfjord, in Jutland, and has despatched the inspector of the Danish fisheries to Norway to obtain all possible information respecting the artificial banks formed in that country during the last few years.

THE manner in which the spruce and pine forests of Norway are being exterminated, is becoming so serious that the Government is called upon to put a stop, by legislation, to the deforestation of the country. At present there is no law to prevent the purchaser of a forest from felling everything, even down to the tiniest saplings. It is urged by forest officials that trees under a certain diameter should not be permitted to be cut, and that the branches of the trees should not be left in the forest (as is now nearly always done), because they stifle the growth of the young trees. Apart from the wanton exhaustion of this commercial wealth, it is maintained that wholesale felling has the effect of changing the climate in the forest localities.

THE strict preservation of the eider fowl on the south-east coast of Sweden during recent years has had the effect of greatly augmenting the number of these valuable birds. The penalty for killing one is very heavy, and informers receive a considerable reward.

DURING the present winter term there are 26,945 German students at the German Universities. Of this number 5791 study theology, 5769 law, 6650 medicine, and 8735 belong to the Philosophical Faculty. 1644 students are foreign. The Vienna University has 238 theologians, 2569 law students, 1565 medical students, and 634 of the Philosophical Faculty. In Graz there are 1305 students, and in Innsbruck 863. Prague has 3805, Cracow 1234, Lemberg 1112, and Czernowitz 259. At Berne University there are 637 students, 51 theologians, 158 law students, 287 medical students, and 141 physical science students. At Zürich there are 70 female students, 40 being medical.

THE *Bulletin Pharmaceutique* states that a new remedy for Phylloxera has been discovered by M. Laffon, of Capendu, and it has proved successful. It consists of a weak solution of nitrate of mercury.

THE additions to the Zoological Society's Gardens during the past week include a Red-winged Parrakeet (*Aprosmictus erythropterus*); eight Peaceful Doves (*Geopelia tranquilla*) from Australia, presented by the Hon. Stormont Finch-Hatton; a Fulmar Petrel (*Fulmarus glacialis*) from Norfolk, presented by Mr. H. M. Upcher, F.Z.S.; a Jardine's Parrot (*Pæocephalus gulielmi*) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE ROYAL ASTRONOMICAL SOCIETY'S MEMOIRS.—The first part of vol. xlix. of the Memoirs of the Royal Astronomical Society has just been published, and contains a new General Catalogue of nebulæ, by Dr. J. L. E. Dreyer. Sir John Herschel's General Catalogue, published in the Philosophical Transactions for 1864, was almost entirely founded upon his own and his father's observations, and hence, since several observers have devoted themselves to the work of searching for nebulæ since that catalogue was prepared, the number known to us has been very largely increased. D'Arrest's great work on nebulæ, which appeared three years later than the General Catalogue, gave the means of correcting many of its positions, and hence Dr. Dreyer had been induced as early as 1876 to compile a supplement to the General Catalogue, which he published in the Transactions of the Royal Irish Academy in 1878 (vol. xxvi.), containing a list of corrections to it, and a catalogue of recently-discovered nebulæ. In 1886, Dr. Dreyer presented a second similar supplement—in which the later discoveries of Messrs. Stephan, Swift, Ormond Stone, and other observers had been incorporated—to the Council of the Royal Astronomical Society; but the Council, considering that the General Catalogue was practically out of print, and that the use of three catalogues and two lists of corrections would be very inconvenient, proposed to Dr. Dreyer that he should prepare from the whole of his materials a single new General Catalogue. This work he has now carried out, and the present catalogue contains 7840 objects, the positions of which have been as thoroughly corrected and revised as the materials available permitted. The epoch of the first General Catalogue, and of D'Arrest's final positions—1860—has been retained, as it is close to the epochs of the great star-charts of Argelander, Schönfeld, Chacornac, and Peters, and nearly all the modern micrometric observations of nebulæ are referred to an epoch but little later. The precessions have been given for 1880, as done by Sir John Herschel, and the descriptions have been carefully revised. The work also contains an index to published figures of nebulæ and clusters, and an appendix giving the places of several new nebulæ discovered by Prof. Safford and Mr. Swift, but published too late to be incorporated in the catalogue itself. These are added that the volume may contain a complete record of all nebulæ of which the places have been published up to December 1887.

PUBLICATIONS OF DUNSINK OBSERVATORY.—The sixth part of the observations of the Observatory of Trinity College, Dublin, at Dunsink, has just been published, and contains the separate results reduced to 1885·0, and the mean places for 1012 southern stars observed with the transit circle by Dr. Dreyer, the late, and Mr. Rambaut, the present, Assistant Astronomers. These stars are nearly all in the Southern Durchmusterung Belt, between S. Decl. 2° and 23°, and were suggested for observation by Prof. Schönfeld on account either of their proper motion or of discordances between their places as given in different catalogues. A few other stars were observed either at the request of Prof. Peters or Dr. Auwers. The work had been commenced by Dr. Dreyer in September 1881, who continued it until his appointment to the Armagh Observatory in May 1882, and Mr. Rambaut took it up, on succeeding to Dr. Dreyer's position, in November of the same year. Mr. Rambaut gives the probable error of a single observation—most of the stars were observed only once—as ± 0·065s. in R.A., ± 0″·864 in Decl.; the faintness of the objects and their low altitude at meridian passage making observation somewhat difficult. A plate at the end of the volume shows a portion of one of the chronograph sheets, and illustrates a convenient method of making notes whilst at the telescope by sending special signals to the chronograph.

ROUSDON OBSERVATORY.—Astronomical observations have been steadily carried on during the past year at Mr. Peek's private observatory, Rousdon, Lyme Regis. The principal work undertaken, besides transit observations for time, has been the observation of twenty long-period variable stars. It is proposed, so soon as any star has been observed over several complete periods, to publish a memoir with plates showing the variations in the light curve. The record of the Observatory shows that there were 165 good observing nights in 1887, as against 146 in 1886.

β DELPHINI.—Mr. J. E. Gore published two years ago elements for this difficult and interesting binary (NATURE, vol. xxxiii. p. 518), in which he gave the period as 30·91 years, a value fairly corresponding to that found by Dubiago a couple of years earlier, viz. 26·07. Sig. Celoria having been placed in possession of Prof. Schiaparelli's observations made in 1875 and 1886–87, and those of Engelmann made in 1885 and 1886, has re-investigated the orbit, and deduced elements differing widely from these two earlier sets, particularly in the period, which he finds to be a little short of seventeen years (*Astr. Nachr.* No. 2824). If this last orbit be correct, the star has already been watched through nearly a complete revolution. There is, however, a considerable divergency between the recent observations of Schiaparelli and Engelmann, and those of the latter would accord better with a longer period. It is, therefore, much to be desired that astronomers who possess sufficient optical power should give early and careful attention to this star. The following are Sig. Celoria's complete elements:—

$$T = 1868{\cdot}850 \quad \ldots \quad \epsilon = 0{\cdot}09622$$
$$\Omega = 10^\circ{\cdot}938 \quad \ldots \quad a = 0''{\cdot}46000$$
$$\lambda = 220{\cdot}952 \quad \ldots \quad P = 16{\cdot}955 \text{ years}$$
$$\gamma = 61{\cdot}582$$

OLBERS' COMET.—The following ephemeris for Berlin midnight is in continuation of that given in NATURE, vol. xxxvii. p. 234:—

GEOGRAPHICAL NOTES.

THE French traveller, M. Thouar, who was believed to have perished on his way to the Gran Chaco, has returned to Port Pacheco with his companions. This news was lately sent from Buenos Ayres to Chuquisaca (Sucré).

IN the new number of *Appalachia* Mr. F. H. Chapin describes his ascent of a glacier on Mummy Mountain, Northern Colorado, lying directly north of Long's Peak, and in line with the centre of Estes Park. A single glance at the series of crevasses convinced Mr. Chapin that it was really a glacier, and not a mere accumulation of snow. To the same number Mr. S. H. Scudder contributes a paper on the White Mountains as a home for butterflies.

IN the paper contributed to the Berlin Geographical Society by Dr. H. Meyer on his ascent of Mount Kilimanjaro, he modifies his first statements as to the height which he attained; according to a statement of his companion, Dr. Meyer did not get within 2000 feet of the top.

IN the new Bulletin of the American Geographical Society will be found a useful paper by Mr. A. S. Packard, in which he brings together a *précis* of what was known of Labrador. Accompanying the paper is a good map, in which Mr. Packard has embodied information hitherto unpublished. Dr. Fr. Boas gives the results of his year's sojourn among the Eskimo.

IN the last number of the Proceedings of the Victoria Branch of the Australasian Geographical Society will be found a detailed account of Mr. Cuthbertson's expedition to explore the highlands of British New Guinea. The accompanying map gives a good idea of the nature of the country. Mount Obree was found to be only 8000 feet high, 2000 feet lower than previous estimates.

WE learn from the *Izvestia* of the East Siberian Branch of the Russian Geographical Society (vol. xvii. fasc. 1) that the vertical section of the Angara at its issue from Lake Baikal is 17,920 feet, and that the volume of water discharged from the great Siberian lake reaches 121,353 cubic feet per second. If this outflow were checked, the level of the lake would rise 7 feet in thirteen months.

DR. ROBERT SIEGER contributes to the Geographical Society of Vienna University a paper in which he discusses what information exists as to the changes of level in the African lakes. This shows clearly that for the last ten years at least these have been lowering in level, and, in the case of Tanganyika, to the extent of many feet. The changes which take place are almost entirely dependent on rainfall, and the probability is that there are periods of depression and periods of elevation. It is important that observations should be carried on both in African lakes and African rivers for a period sufficiently long to afford data numerous enough to warrant any conclusion to be drawn.

PROF. EUARD SÜSS, the able author of "Das Antlitz der Erde," recently read a paper to the Vienna Geological Society, on the history of the ocean, which is to some extent supplementary to that work. In this he points out that from the mouths of the Ganges all round the Pacific coasts of Asia and America to Cape Horn, the coasts are outlined by mountain-ranges which close in upon each other in great curves. From Cape Horn, again, all round the Atlantic and the Indian Oceans to the mouths of the Ganges, the coasts are unconnected with mountain-ranges, but are encircled by table-lands or broken mountain patches. We have thus, then, so far as the structure of the ocean basins is concerned, to distinguish between a Pacific and an Atlantic type. As regards the age of the oceans, Prof. Süss concludes from the geological formations that the Pacific is the oldest, next to that the Indian, and last of all the Atlantic. The oceans, he points out, are areas of depression. Each new depression would form a fresh receptacle for water, and so the shore-line of the land would be lowered. Prof. Süss seems to maintain that it is to this, and not to the actual rising of the land, that the elevation of the coast-line in certain regions is due.

MR. J. F. NEEDHAM has been engaged to conduct an expedition from Sadiya to the Hukeng Valley, and thence to Bhamo on the Upper Irrawady. His previous achievements in the Abor Hills, and the country lying between the Brahmaputra and the Zayal Chu, and his success in conciliating the unfriendly tribes on that frontier region, marked him out for selection as the proper officer to conduct the present mission.

THE new part (Nos. 133–34) of the *Zeitschrift* of the Berlin Geographical Society is mainly occupied with Dr. W. Sievers's account of the results of his exploration of the Sierra Nevada of Santa Marta in the north-east of the United States of Columbia, an excellent large-scale map accompanying the number. A considerable section of the paper deals with the geology of the region, after which Dr. Sievers treats of the surface formation, altitudes, climate, vegetation, and agriculture, the land-snails population.

NEWS from Victoria, in the Cameroons, states that the African traveller, Dr. Zintgraff, started for Rio del Rey in the steamer *Nachtigal*, accompanied by thirty porters. He is on his way to the Elephant Lake in order to establish a scientific station. The other half of the Expedition, under the command of Lieut. Zeuner, is to proceed up the Mungo River to Mundame, to reach the Elephant Lake from that part.

OUR ELECTRICAL COLUMN.

IF a platinum plate be immersed in a porcelain or glass vessel containing dilute sulphuric acid, and another similar plate be immersed in another vessel containing caustic potash solution, then if the two vessels be connected by a siphon tube or a cotton wick, a current will be set up, but which rapidly diminishes owing to the polarization of the metal plates by the deposition of oxygen and hydrogen upon them. Becquerel removed the hydrogen by using nitric instead of sulphuric acid, and increased the current considerably. Dr. Alder Wright and Mr. C. Thomson (Royal Society, February 2, 1888) have been examining this form of battery, and have found many other acids which act in the same way, such as potassium permanganate, potassium bichromate, potassium ferricyanide, and bromine dissolved in sulphuric acid, ferric chloride, hydrochloric acid and chlorine. Moreover, they have removed the oxygen by using a concentrated solution of sodium hyposulphite made strongly alkaline with caustic soda, strong caustic soda with pyrogallol, cuprous chloride, ferrous sulphate, and ammonium chloride dissolved in ammonia. They also found the quantity of oxygen

and hydrogen evolved exactly proportional to the current passing. If a silver voltameter were included in the circuit, for every milligramme-equivalent (108 milligrammes) of silver deposited, 1 milligramme-equivalent of hydrogen occupying 11·2 cubic centimetres and 8 milligrammes of oxygen occupying 5·6 cubic centimetres at 0° C. and 760 millimetres, were liberated.

ALTHOUGH Sir William Thomson did not publish any electrical theoretical work in 1887, he perfected during that year his practical electrical measuring instruments. They are in use at the Grosvenor Gallery central station in London. There are no more beautiful or accurate instruments in the world, and they reach over an enormous range both of potential and of current measurement. They were admirably illustrated and described in *Industries* of January 27 by Prof. Fleming.

HERTZ (*Wiedemann Ann.* 1887), has shown that the ultra-violet rays have an influence on the passage of sparks. E. Wiedeman and H. Ebert have been repeating and verifying his experiments. The effect of light falling on the spark region was to lower the potential required to produce it. If a succession of sparks be sent, and a telephone be used, the effect of light falling on the sparks was to change not only the note but the whole character of the sound heard in the telephone. If a Geissler's tube were used, an intermittent and irregular discharge became steady and continuous. The effect was evident only on the negative pole.

IT is known that the magnetic qualities of iron diminish considerably when raised to 525° C. (red heat), but iron remains magnetic up to 650° C. Nickel loses its magnetic properties suddenly at 300° C. Lodeboer recently (January 9) read a paper before the Académie des Sciences, in which he showed that with magnetizing forces of 35, 100, and 200 C.G.S. units the iron retains its magnetic properties up to 680° C.; that beyond this temperature it rapidly loses them; that at 750° C. they scarcely exist, and at 770° C. they entirely disappear, to reappear only on cooling. It is known that the specific heat of iron undergoes a change of condition between 660° and 720° C., and the coincidence of these two changes is very interesting.

THE treatment of sewage by electricity is, it seems, likely to receive a practical test at the Metropolitan Board of Works' outfall at Crossness. Mr. Fewson, of Buckingham, made some experiments in this direction at Wimbledon last summer, and now Mr. W. Webster is about to do the same thing at one of the large tanks on the Thames. The electric current is said to have a wonderful disinfecting and purifying influence. The evolution of gas stirs up the liquid, the nascent oxygen is brought into rapid contact with the impurities and reduces them, precipitation is expedited, and the whole cleansed. It is to be hoped that the cost will not swamp this new and useful field for electricity.

THE extraordinary rise in the price of copper has attracted much attention to the use of iron for lightning conductors. Prof. Silvanus Thompson advocates iron in preference to copper under all circumstances. Iron is much used by the War Department to protect magazines. Dr. L. Weber recommends it even in a solid form rather than as a stranded rope, but the latter form is much more portable and workable; moreover, Prof. Hughes showed it to be less subject to self-induction than a solid rod—an obstruction not to be neglected. Iron conductors are stronger, much cheaper, less easily fused, and less liable to theft than copper. There can be no objection to the use of iron.

THE electro-deposition of aluminium has attracted much attention since the introduction of the Cowles process. Herman Reinbold has proposed the following solution, with which he has obtained good but small results: alum 50 parts, water 300 parts, aluminium chloride 10 parts. This solution is heated to 200° F., and after cooling 39 parts of potassic chloride are added.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THIS Society held its forty-first annual general meeting in the theatre of the Institution of Civil Engineers on Thursday and Friday of last week. After the Annual Report had been presented and accepted, Mr. John Richards' paper "On Irrigating Machinery on the Pacific Coast" was read and discussed. The need of irrigation in this district arises from three causes: the lack of rain, which ceases altogether along the coast in summer-time; the want of surface-water; and the free percolation into the sandy soil beneath. The whole of the land in the country, excepting the low-lying sedimentary plains near the mouths of the rivers, and around the Bay of San Francisco, where water reaches the surface by capillary saturation, requires irrigation. Nearly all the land upon which water can be led, either by training small mountain streams, or by leading long canals from the rivers, has been occupied, so that the only remaining resource for getting water will be by lifting it from the rivers or the gravel strata by machinery. The paper is descriptive of the various pumps and hydraulic rams employed, and was illustrated by means of thirty-five figures.

Mr. William Geipel's paper "On the Position and Prospects of Electricity as applied to Engineering" refers to those branches of electric engineering which involve the employment of considerable power, and are in some way or other connected with the use of dynamos. They comprise electric transmission and distribution of power, and electric lighting, locomotion, and metallurgy.

In the author's opinion the transmission and distribution of power by electricity will occupy in the near future most of the attention of the electric engineer. Owing to its simplicity, the ease with which an electric motor can be applied to any purpose requiring power, and its high efficiency, it is certainly an approach to an ideally perfect system of transmission. In the United States great strides have been made in the applications of electric motors, which already rival those for lighting purposes. One of the great advantages of these applications is due to the low efficiency of belts and shafting where high speed is required and the demand for power is variable. By getting rid of shafting the necessity for additional stability in buildings is obviated, and constant lubrication is done away with. The distribution of power by electricity from a central station to small users can be effected from the same mains and generators as are used for electric light purposes; as to whether gas through the medium of gas engines or electricity by means of electric motors should be used, will become entirely a question of economy and convenience. On the one hand the electric motor can be started and stopped with the greatest ease, it requires little attention, occupies little space, and can be placed anywhere, while against the use of the gas engine, the author brings forward its irregularity of speed owing to the intermittent impulse and the wear and tear in the valves and working parts. Shunt motors, which are now almost exclusively used, possess a practically perfect power of self-control, not only over their rate of speed with varying load, but over the energy absorbed, for they help themselves, as it were, to only such an amount of energy as will enable them to deal with the work imposed upon them. Another advantage in shunt motors, first pointed out by the late Sir William Siemens in 1880, is that they act as generators when themselves driven by any extraneous power, without any complication of the switch gear required with series motors. The author refers to various installations which have already taken place in Europe and America, which are paying their way, whilst at the Falls of Niagara plant is being put down to distribute power obtained from the Falls to neighbouring towns, including Buffalo, which is twenty miles distant; the amount of power is stated at 15,000 h.p., of which 10,000 h.p. is contracted for at £3 per h.p.

Electricity has been applied with efficiency in collieries for underground hauling, pumping, ventilating, and drilling; in ship-yards and similar works it has been proved to be a suitable and economical means of transmitting power for riveting, drilling, &c.

In its application to the transmission of power to great distances, electricity is found to be more economical than either hydraulic, pneumatic, or wire-rope transmission, and comparative tables are given showing the first cost of plant per horse-power transmitted, and also the working cost per horse-power transmitted per hour. For a distance of 22,000 yards the cost of installation for the transmission of 100 h.p. is £87, £310, £192, and £162 per h.p. for electric, hydraulic, pneumatic, and wire-rope transmission respectively; whilst the cost per h.p. transmitted per hour is 4·08, 6·84, 4·50, and 9·73 pence.

Amongst many interesting applications, that made by the Marquis of Salisbury at Hatfield may be specially referred to. The River Lea is utilized to generate electricity by means of turbines, the electricity being transmitted to the house and over the estate for a variety of purposes. The motors at the house

drive pumping and ice-making machinery and an air-propeller fixed in the roof for ventilating; on the farm the motors are used for elevating hay and corn sheaves to the top of the stacks, for thrashing, for cutting rough grass with a chaff-cutting machine for ensilage, in fields extending to a distance of two miles, for grinding corn, &c., to make fodder, and for other purposes. The motors have also been used for pile-driving, for making coffer-dams where necessary in the river, and also for dredging the river and clearing it of weeds, and for pumping the town sewage into a tank at the height of thirty feet for irrigation. The conductors are carried overhead on poles about the farm and underground in wooden troughs to the house. The practical methods employed for electric locomotion—being those of a third insulated rail, an overhead conductor, an underground insulated conductor, and storage batteries—are described, and examples of the application of all are given. To the first belong the Portrush Railway, and Besbrook and Newry Tramway; to the next the electric railway at Moedling, near Vienna, and the Frankfort-Offenbach railway. This plan has been most largely adopted in America, where there are probably not far short of one hundred electric railways at work and projected. Of the underground conductor, the most important example is the electric tramway at Blackpool, while storage batteries are being employed on the North Metropolitan Tramway in London. The ordinary rails have been used as conductors in the short electric railway at Brighton, where the expenses amount to twopence per car-mile.

The plan of transporting material in skips on overhead wire-ropes by means of electricity, introduced under the name of telpherage by Prof. Fleeming Jenkin, has been employed with success for two years past at Glynde, near Lewes, for transporting clay to the railway over a distance of 1600 yards, and is applicable for use in places where material has to be conveyed across hilly districts. In the author's opinion a modification of this plan might be advantageously applied to alleviate the heavy street traffic in our larger cities.

The author considers the question of electric lighting under the three aspects of comfort, convenience, and economy. As regards the first two, electric lighting has the advantage over other systems; whilst as regards cost, although electric lighting, and especially incandescent electric lighting, is still heavy, yet for lighting main streets and railway stations, or other places where concentrated light is required, the arc light is cheaper than gas. As its use extends, the cost of working becomes reduced. Thus in the Waverley Station, Edinburgh, on the North British Railway, thirty-three arc lamps, with 41,884 lamp hours, cost 2·77 pence per lamp hour from July to December 1884; whilst in 1886, thirty-nine arc lamps, having 55,068 lamp hours, cost 1·79 penny per lamp hour.

The cost of incandescent lighting is especially variable, and affected by the local conditions of the installation. The chief of these are the average number of hours of lighting each lamp, and the average distance of the lamps from the generating station. Where conditions are favourable, incandescent lighting can already compete with gas. Messrs. George Jager and Sons' yearly cost of lighting their sugar refinery at Leith is given as an example, it having been £347 with gas and £204 with incandescent lamps. The author draws special attention to the circumstance of the much larger application of electricity to lighting in the United States as compared with this country. In the United States there is hardly a city or town of 20,000 inhabitants which has not a central station for arc or incandescent lamps; and many towns of 3000 to 4000 inhabitants are also supporting them.

The efficiency of dynamo machines being as high as 95 per cent., and there not being much likelihood of material improvement in steam engines, the author draws attention to the importance of improving the lamps by making them with a higher resistance and greater efficiency, the voltage having a great effect on the cost of working distant lamps. Transformers, by means of which high tension currents of electricity, sent from a distant generating station along a small conductor with comparatively small percentage of loss, can then be converted into low tension currents for the supply of ordinary incandescent lamps, are receiving a large amount of attention, the loss by conversion being as low sometimes as 5 per cent. Efforts are also being made to introduce the system of secondary batteries, charged in series by a high tension current, and discharged in parallel circuit, and if it can once be demonstrated to be economical, there would be a large field of application. At Leamington an extensive central station is now at work, the cost of the undertaking being £30,000; while the Bradford Corporation have recently voted a sum of £15,000 for erecting a central station in their town. Both these are instances of direct supply without transformers or secondary batteries. Electric metallurgy is a branch of electric engineering to which attention was first drawn by the late Sir William Siemens, whose death occurred before he had perfected his invention. The electro-chemical separation of ores on a commercial scale by the electric furnace has been recently put to the test, chiefly in obtaining aluminium from conundrum. The furnace designed by Prof. Mabery is built of fire-brick and lined with powdered charcoal; electricity is conducted to the ore by carbon rods, meeting near the centre. The ore mixed with charcoal and granulated copper surrounds and covers the carbons; the furnace is closed with a layer of charcoal and a lid lined with fire-brick. A current of 50 volts electromotive force is supplied and melts the metal around the electrodes, which are moved apart gradually until the whole is melted. The conundrum becomes gradually deoxidized, the aluminium combining with the copper, while the oxygen with the carbon escapes as carbonic oxide, about five hours sufficing to complete the reduction. Aluminium, being only one-third the weight of iron, and possessing great strength, its production at a cheap rate would probably cause a revolution in engineering construction.

The meeting was presided over by Mr. E. H. Carbutt, the President, who was re-elected to the chair, whilst Sir Douglas Galton, K.C.B., was the new member elected on the Council. The meeting was as usual of a very successful character.

THE NATIONAL SMOKE ABATEMENT INSTITUTION.[1]

In presenting the Report to the members for the year 1887, the Council consider it desirable to reprint from the Memorandum of Association the objects for which the Institution was established. These are the following:—

To promote the abatement of coal smoke and other noxious products of combustion in cities and other places, in order to render the atmosphere as pure and as pervious to sunlight as practicable. To check the present serious waste of coal, and the direct and indirect loss and damage accompanying the over-production of smoke and noxious products of combustion. To continue, organize, and extend the public movement inaugurated and hitherto carried on by the Smoke Abatement Committees (otherwise known as the Joint Committees for Abatement of Smoke, appointed by the National Health Society and Kyrle Society of London, and the Smoke Abatement Committee of Manchester), and to take up and proceed with any work undertaken or commenced by such Committees. To advance the aforesaid objects by promoting and encouraging the better and more economical use of coal and coal products, and the selection of suitable fuel, as well as general improvement in the various modes of obtaining, applying, and using heat and light for domestic and industrial purposes. And in connection with such objects to obtain and provide such buildings, appliances, and assistance as may be deemed expedient. And without prejudice to the advancement of the objects aforesaid by other means to advance the same by the following means more particularly:—

(*a*) By calling public attention to the serious pecuniary loss and injury, to the health and comfort, which arise from coal smoke, and from defective heating, ventilating, and lighting arrangements.

(*b*) By stimulating, assisting, and encouraging inventors, manufacturers, traders, and others to bring forward, develop, and perfect new or improved fuels, substances, methods, and appliances for the generation or application of heat or light, and for consuming or lessening the production of smoke and noxious products of combustion.

(*c*) By conducting practical trials of fuels, apparatus, and systems connected with the generation or application of heat or light, and causing reports to be made thereon for the guidance, assistance, or information of inventors, traders, intending users, and the public generally.

(*d*) By granting awards, certificates, medals, or prizes in connection with approved fuels, methods, or apparatus.

(*e*) By establishing, or assisting in establishing, public exhibitions, either periodical or otherwise, of appliances pertaining to heating, ventilating, or lighting.

[1] Report of the Council for the year 1887.

(*f*) By collecting and recording statistics and information, and making, assisting, or encouraging experiments or researches as to the effects upon the atmosphere, and upon life, health, and property of the use of coal and other fuels and means employed or to be employed in connection with heating or lighting; and by printing, publishing, and circulating any such statistics or information, including the intended report of the Committees aforesaid, or any similar composition or literary work.

(*g*) By imparting information, instruction, and assistance to local authorities, manufacturers, workmen, householders, servants, and the public generally whether by means of lectures, demonstrations, pamphlets, written articles, or otherwise in relation to the subject of smoke prevention or abatement.

(*h*) By joining or concurring with any other institution, society, or persons, in doing or causing, or procuring to be done, any of the things aforesaid.

To promote the abatement of noxious vapours arising from manufactures or manufacturing processes, and to resort to and use for that purpose powers and means analogous to those hereinbefore contemplated with reference to Smoke Abatement and any other reasonable means. For all or any of the purposes aforesaid, either alone or in conjunction with others, to promote legislation and parochial and other regulations, and to assist in the enforcement thereof, and of any existing or future legislative, parochial, or other regulations.

In reporting upon the business transacted by the Institution during the past year, it is essential that the members should be reminded of the urgency for further legislation on the subject of smoke prevention.

The Institution has been in communication with the medical officers of health and chief constables throughout the country, and the most valuable information obtained with reference to the working of existing by-laws is given as supplements Nos. 1, 2, 3, 4, 5, and 6, to a paper on Smoke Abatement, read at the Bolton Congress of the Sanitary Institute. These supplements are published in the Transactions of the Sanitary Institute of Great Britain, and by reference to them it will be seen that the municipal authorities of Liverpool are much more alive to the necessity of prosecuting offenders against the Smoke Abatement Acts than the authorities in any of the other places from which reports have been obtained.

By comparison with the Report issued by the Commissioner of Police for the Metropolis of 1886, it will be seen that the number of cases in which fines were imposed in Liverpool was 545, whereas the number of convictions in the metropolis amounted only to 82. It might further be noted, however, in respect to the penalties imposed, that the average of all the fines in Liverpool was 19*s.* 11¼*d.* The average in London was £1 17*s.* 5*d.* The inadequacy of the fines imposed is a serious obstacle in dealing with police prosecutions, and the fines have little effect, if any, in the prevention of smoke, in consequence of the amount of the penalty being so disproportionate to the financial positions of the persons on whom they are imposed.

During the year attention was prominently called by Lord Stratheden and Campbell to the provisions in the Bill introduced by him to the House of Lords "To amend the Acts for abating the nuisance arising from the smoke of furnaces and fire-places within the Metropolis," and resulted in a Select Committee being appointed to consider the terms of the Bill, and to report to the House of Lords. The minutes of evidence were laid before the House of Lords on the 15th of July, 1887, and the published Report contains much valuable information with respect to the working of the Smoke Abatement Acts:—The nuisance created by steamers on the Thames; the necessity for extension of the metropolitan area to be within the Acts; the necessity for controlling the emission of smoke from club-houses, hotels, private residences, and other buildings not within the scope of the existing Acts; the usual course followed by the police in instituting prosecutions; a return showing the number of police employed in carrying out the Smoke Nuisance Abatement Acts; the effect of the increase of smoke on the health of the people, and the advantages from a sanitary point of view to be derived by the prevention of smoke; also particulars regarding the commercial advantages to be derived by the consumption of smoke; particulars of the methods which might be adopted for the complete combustion of fuel in domestic grates; and generally, a great mass of information dealing with the subject laid before the House of Lords by the following gentlemen: Mr. W. R. E. Coles, the engineer appointed by the Home Secretary to examine furnaces in the metropolis; Mr. James Edward Davis, of the Home Office, legal adviser to the Commissioners; Mr. Charles Cutbush, Superintendent of Police; and Mr. Ernest Hart, Chairman of Council of the National Smoke Abatement Institution.

By reference to the Police Orders and Regulations reprinted at the end of this Report, it will be observed in paragraph 36 that hotel-keepers in the metropolis not using steam-engines can only be proceeded against under Section 19, Sub-Section 3, of 29 and 30 Vict., cap. 90, and be guilty of an offence under that Section. In consequence of this Act of Parliament, Section 19, Sub-Section 3, stipulates that any chimney (not being the chimney of a private dwelling-house) sending forth black smoke in such quantity as to be a nuisance is exempt from the working of the Act and it is left to the justices to dismiss the complaint if they are satisfied such fire-place or furnace is constructed in a manner to consume, *as far as practicable*, all smoke arising therefrom, but it does not state any standard smoke shade or any degree to be fixed upon as the limit, and therefore the justices may or may not convict at their option.

The purpose of Lord Stratheden and Campbell's Bill is to prohibit or regulate the emission of smoke from any building, no immunity being granted to hotels, club-houses, or domestic fire-places now exempted from the existing Acts. The effect of the general evidence brought before the Select Committee of the House of Lords was a resolution to await the results of the further operation of the existing Acts, the purpose and intention of which should, it was held, be more fully carried into effect.

The Council invite the careful consideration of members to the necessity for legislation, and on an early date will arrange for a series of meetings to be held, at which it is expected the sanitary inspectors from the leading provincial towns will assemble, in order to compare and suggest revisions for the existing municipal by-laws, as well as for the purpose of drafting propositions to submit to the authorities on the subject of improved legislation in the metropolis.

The Council having considered the desirability of taking the first opportunity for conducting simultaneous tests of the furnaces of a large number of steam-boilers under equal conditions, thought that such an opportunity might be offered at the forthcoming Exhibition to be held in Glasgow. They accordingly directed the Secretary to write to the Lord Provost of Glasgow, laying the outlines of their scheme before him, and suggesting its adoption by the Exhibition authorities. Briefly stated, the proposal was: That the whole range of boilers to be used for working the machinery of the Exhibition should be erected in such a manner that each boiler should have its setting and chimney independent of the other boilers, so that the several systems of stoking and arrangement of furnaces could be fully tested under identical conditions of fuel, atmosphere, and time; while the results as regards smoke would be evident to the public.

It is to be regretted that the authorities in charge of the Glasgow Exhibition have not been able to see their way to co-operating with the Smoke Abatement Institution as proposed. Simultaneous tests on such a large scale have never previously been made. Many tests of great value have been made on furnaces, but these have been at separate times, and under different atmospheric conditions, and the results, however favourable in themselves, have been incapable of classification for comparison. The proposal of the Council, if adopted, would have supplied what is wanting by making these tests of several boilers at the same time, and under the supervision of an impartial body.

With reference to this subject, a correspondence has taken place with Mr. Fletcher, Chief Inspector under the Alkali Acts, as he has in preparation a report upon the injurious effect of the impurities of the air and water on the Clyde. Mr. Fletcher was asked to furnish a copy of the report, but replied that it was in the hands of the Secretary for Scotland. Application has been made to the Secretary for Scotland, and attention drawn to the importance of the series of tests which the Council proposed. The Secretary for Scotland in his reply stated that Mr. Fletcher's report has not yet been brought before Parliament, and with respect to the testing of the boilers, said that he would inform the Committee of the Glasgow Exhibition that he considers the suggestion of the Institution to be deserving of consideration and adoption.

At a meeting of the Institute of Engineers and Shipbuilders in Scotland, on the 8th of December, a very comprehensive paper

was read by Mr. George C. Thomson on "Smoke," and in the discussions which followed, Mr. W. R. W. Smith, Chairman of the Health Committee of the Glasgow Corporation, urged upon the members present the desirability of doing all in their power to secure that at the forthcoming International Exhibition in Glasgow each of the boilers be supplied with a separate chimney, so that a series of exhaustive trials may be made with mechanical stokers, &c., and other means for the purpose of showing what might be done in the way of smoke prevention.

With reference to the subject of testing, the Committee are of opinion that arrangements should be made as soon as possible for obtaining the use of three testing-rooms for testing stoves, grates, and ranges, the rooms being conveniently accessible for such articles, and having gas connections under command. The tests made in these rooms, under the same conditions of chimney and cubic capacity, would then become of greater comparative value than tests made in independent rooms.

Arrangements will be made as soon as practicable for procuring such accommodation for testing, and also for providing the necessary instruments used for testing; and as the system develops, attention will be given to the establishment of a chemical laboratory, the analysis of gases, and testing-rooms for testing-apparatus incidental to the work of the Institution.

SCIENTIFIC SERIALS.

American Journal of Science, December 1887.—On the destruction of the passivity of iron in nitric acid by magnetization, by Edward L. Nichols and W. S. Franklin. From the experiments described in this paper, which was originally read before the Kansas Academy of Science, November 1885, it appears that the action of the magnet tends to lower the temperature of transition to the active state, and that the intensity of the magnetic field necessary to convert passive into active iron at a given temperature increases rapidly with the concentration of the acid. An account is promised of further researches offering a satisfactory explanation of the manner in which the chemical behaviour of iron is modified, and its passivity destroyed in the magnetic field.—On a method of making the wave-length of sodium light the actual and practical standard of length, by Albert A. Michelson and Edward W. Morley. The preliminary experiments recently carried out according to the method here proposed seem to confirm the anticipation that it would furnish results more accurate than any of those hitherto suggested. The apparatus for observing the interference phenomena is the same as that used in the experiments on the relative motion of the earth and the luminiferous ether.—The work of the International Congress of Geologists, by G. K. Gilbert. This is a reprint of an address delivered before the Section of Geology and Geography of the American Association for the Advancement of Science at the New York meeting, August 10, 1887. It deals largely with a revised system of geological terminology, the substance of which has already been published. The question of geological coloured maps is also considered, and practical suggestions made for their greater efficiency and economy.—On the existence of certain elements together with the discovery of platinum in the sun: contributions from the physical laboratory of Harvard University, by C. C. Hutchins and E. L. Holden. These investigations, carried on with Prof. Rowland's magnificent diffraction grating, deal with cadmium, lead, tin, silver, potassium, and several other elements, including platinum, the presence of which in the solar atmosphere is here for the first time determined. Between 4250 and 4950 were found sixty-four lines of platinum, sixteen of which agree with the solar lines.—The flora of the coast islands of California in relation to recent changes of physical geography, by Joseph Le Conte. A careful study of these insular groups, at present from 20 to 30 miles distant from the coast, shows that they at one time formed part of the mainland, from which they were undoubtedly separated during the Quaternary period. That they still formed part of the continent during later Pliocene times is shown by the remains of the mammoth found on Santa Rosa, one of the largest and furthest off of the whole group.—A new instrument for the measurement of radiation, by C. C. Hutchins. The instrument here described and illustrated presents great advantages over the thermopile as an accurate measurer of radiations. It is much more sensitive and requires no longer time to return to zero than for the galvanometer needle to come to rest. A lighted match at 6 feet drives the needle round to its stop.—Mineralogical notes, by George F. Kunz. Descriptions with analyses are given of a rhodochrosite from Colorado, of crystals of hollow quartz from Arizona, of hydrophane from Colorado, and of a remarkable silver nugget weighing 606 ounces from the Greenwood mines of Michoacan, Mexico.

January. — The speed of propagation of the Charleston earthquake, by Prof. Simon Newcomb and Captain C. E. Dutton. A careful comparative study of the reports from all parts of the disturbed area shows a general average speed of $3 \cdot 214 \pm 0 \cdot 072$ miles, or 5171 ± 116 metres per second.—History of the changes in the Mount Loa craters, Hawaii; Part 1, Kilauea, by James D. Dana. The first paper embraces the whole period from 1823 to 1886, during which there appear to have been at least eight discharges from Kilauea. The general dynamical conclusions are that the cycle of movement is simply (1) a rising in level of the liquid lavas, and of the bottom of the crater; (2) a discharge of the accumulated lavas down to some level in the conduit determined by the outbreak; (3) a down-plunge of more or less of the floor of the region undermined by the discharge. It is further shown that Kilauea is a true basalt volcano in its normal state, the rock material being dolerite or basalt, and the heat sufficing for the perfect mobility of the lavas.—The analysis and composition of tourmaline, by R. B. Riggs. The methods of analysis are described, with results for various specimens from different parts of North America and Brazil. The general inference is that there are three types, lithia, iron, and magnesia tourmaline, with an indefinite number of intermediate varieties, iron appearing to be the connecting link between the whole series. The special formulas of the three distinct types are:—

(1) Lithia: $12SiO_2$, $3B_2O_2$, $4H_2O$, $8Al_2O_2$, $2(NaLi)_2O$.
(2) Iron: $12SiO_2$, $3B_2O_3$, $4H_2O$, $7Al_2O_3$, $4FeO$, Na_2O.
(3) Magnesia: $12SiO_2$, $3B_2O_3$, $4H_2O$, $5Al_2O_3$, $\frac{2.8}{3}MgO$, $\frac{2}{3}Na_2O$.

—On the different types of the Devonian system in North America, by Henry S. Williams. It is shown that in North America the Devonian system offers at least four distinct types in four corresponding areas, blending somewhat at their borders, but in their central parts presenting marked peculiarities. The four areas are: (1) Eastern Border, mainly in Northern New England; (2) Eastern Continental, including New York, thence southwards to West Virginia and north-westwards to Canada West and Michigan; (3) Interior Continental, chiefly Iowa and Missouri, extending northwards probably to the Mackenzie basin; (4) Western Continental, in Nevada and conterminous States.—On the law of double refraction in Iceland spar, by Charles S. Hastings. The general inference from these researches is that Huyghens' law of double refraction in uniaxial crystals is probably true to less than 1 part in 500,000, and consequently that there is no known method by which any error in it can be detected by observation alone.—In the Appendix, Mr. O. C. Marsh describes a new genus of Sauropoda and other new Dinosaurs from the Potomac formation; also a new fossil Sirenian from California.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 19.—"Notes on the Spectrum of the Aurora." By J. Norman Lockyer, F.R.S.

I exhibited to the Society on November 17, 1887, a tabular statement showing the bright lines seen in the spectra of various celestial bodies, and I also gave those recorded in the spectrum of the aurora, showing many remarkable coincidences.

I now find that the connection is closest between the auroral spectrum and that of stars III.*a*, and, in anticipation of a subsequent communication of details, I send on the accompanying table, showing the origin of Dunér's bands, so far as I have at present made them out, and their connection with the spectrum in question.

The individual observations which I have used in the table are those collected by Mr. Capron and Mr. Backhouse (NATURE, vol. vii. pp. 182 and 463).

TABLE OF WAVE-LENGTHS OF AURORAL LINES.

Geological Society, January 25.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read :—On *Ailurus anglicus*, a new Carnivore from the Red Crag, by Prof. W. Boyd Dawkins, F.R.S. The specimen described is a small fragment of the right lower jaw with the last three molar teeth in position, and belongs to the Crag collection of the Yorkshire Philosophical Society. It differs in a marked degree from all fossil European Carnivores, and presents no important points of difference when compared with a series of jaws of recent *Ailurus*. The author gave a description of the fossil, and comparison of it with *Ailurus fulgens*, and also a table giving the comparative measurements of the teeth and jaws of the fossil and of recent *Ailuri*. The species from the Crag was a more powerful animal than any recent *Ailuri* in the British Museum. The paper concluded with a notice of the range of *Ailurus* in space and time. After the reading of this paper the President remarked that seldom had a fact of greater interest in its bearing upon geographical distribution in past times been brought before the Society. Some comments on the paper were also made by Mr. Lydekker, Prof. Seeley, Mr. Newton, and Mr. Blanford.—A contribution to the geology and physical geography of the Cape Colony, by Prof. A. H. Green, F.R.S.—On two new Lepidotoid Ganoids from the early Mesozoic deposits of Orange Free State, South Africa, by Mr. A. Smith Woodward. The results presented in Prof. Green's and Mr. Woodward's papers were discussed by the President, Prof. Rupert Jones, Mr. Blanford, Dr. Geikie, Mr. Clement Reid Prof. Hughes, and Mr. Irving.

* This line is seen as a pretty bright line in the spectrum of the Limerick meteorite, but its origin has not yet been determined, although comparisons have been made with most of the common elements. So far, it has not been observed in any other meteorite.

Royal Microscopical Society, January 11.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—The President referred to the death of Dr. Arthur Farre, a former President of the Society, and one of its earliest Fellows.—Prof. C. Stewart exhibited specimens of *Thecalia concamerata*. In this genus the female shell exhibited a peculiarity which was quite unique. As age advanced the mantle became folded back upon itself in a very curious manner, and simultaneously with this there occurred a similar in-folding of the contiguous portions of the shell by which two depressions were produced, forming a fusiform chamber when the two valves came together. In this cavity the embryonic shells were found.—Edmond's automatic mica stage rotating by clockwork was exhibited and described.—Mr. A. W. Bennett gave a *resumé* of his paper on freshwater Algæ of the English Lake District, with a description of a new genus of *Capsulococcus* and five new species, in continuation of his previous communication on the same subject.—Dr. G. Gulliver read a paper on *Pelamyxa palustris*. The large size of this amœboid organism had enabled it to be cut into sections, and the granulated structure of its exoplasm thus revealed was described. As regarded its classification, it was thought that ultimately it would be found to have a nearer relationship to the true Heliozoa than to the more lowly Amœbæ.—Mr. E. M. Nelson handed round for inspection two photographic positives ; one of *Amphipleura pellucida*, and the other of a fungus growth which attacked calcareous sand, as described by Mr. J. G. Waller in the Journal of the Quekett Microscopical Club, i. p. 345. This object presented some photographic difficulty because of its non-actinic colour. With regard to the other he remarked that in resolving diatoms with oblique light it was essential to decide whether they intended to focus upon the real surface or upon the optical image produced in a higher plane, in consequence of the double nature of the structure of the valve. In the latter case they would obtain a result such as he exhibited, which was a photograph of the optical image and not of the real diatom.—Mr. Nelson also called attention to a curious optical effect for which at present he was unable to account. In a flat box he had placed a glass positive of *A. pellucida* which was viewed as a transparency through a piece of tube fitted at right angles to the surface. If this was looked at when held towards a surface of light such as an optical lamp-shade or a sunlight gas-burner, the black lines appeared to be slightly smaller than the white lines ; but if it was turned towards a small light at a distance, then the black lines appeared very

large and the white ones were reduced to mere threads. The scale of the photograph showed that the effect was not due to the operation of the first diffraction spectrum, and it was still more curious to note that in the case of another positive taken from the same negative and upon the same scale this optical illusion was not observed.

Anthropological Institute, January 24.—Anniversary Meeting.—Prof. Flower, C.B., F.R.S., Vice-President, in the chair.—The following were elected Officers and Council for the ensuing year:—President: Francis Galton, F.R.S. Vice-Presidents: J. G. Garson, Prof. A. H. Keane, F. G. H. Price. Secretary: F. W. Rudler. Treasurer: A. L. Lewis. Council: G. M. Atkinson, E. W. Brabrook, C. H. E. Carmichael, Hyde Clarke, A. W. Franks, F.R.S., Lt.-Col. H. H. Godwin-Austen, F.R.S., T. V. Holmes, H. H. Howorth, M.P., Prof. A. Macalister, F.R.S., R. Biddulph Martin, M.P., Prof. Meldola, F.R.S., Rt. Hon. the Earl of Northesk, C. Peek, Charles H. Read, Lord Arthur Russell, M.P., Prof. A. H. Sayce, H. Seebohm, Oldfield Thomas, M. J. Walhouse, Lieut.-Gen. Sir C. P. Beauchamp Walker, K.C.B.

Paris.

Academy of Sciences, January 30.—M. Janssen in the chair.—Note on the first volume of the *Annales de l'Institut Pasteur*, presented to the Academy, by M. L. Pasteur. This volume contains the first twelve numbers of a monthly serial established and directed by Prof. Duclaux, of the Sorbonne, and entirely devoted to the progress of the new branch of pathological physiology to which M. Pasteur gives the name of "Microby" or "Microbiology." His remarks were mainly confined to the important memoir by MM. Roux and Chamberland, entitled "Immunité contre la septicémie, conférée par des substances solubles." In this memoir is contained the rigorous demonstration of the far-reaching fact that the septic vibrion, a living ferment analogous to the butyric vibrion, develops soluble chemical products, which gradually act as an antiseptic on the organism itself. These products, introduced in sufficient quantities into the body of the guinea-pig, confer absolute immunity from the deadly attacks of the virus, to which that animal is specially susceptible.—Note on the total lunar eclipse of January 28, by M. J. Janssen. The observations taken at the Observatory of Meudon were mainly directed towards determining a point of telluric spectroscopy connected with the absorption bands of oxygen. They were necessarily of a somewhat preliminary character, and will be continued during future total eclipses of the moon.—Researches on ruthenium, by MM. H. Debray and A. Joly. The paper deals more especially with hyperruthenic acid, its purification, physical properties, behaviour in the presence of water, and under varying temperatures.—An apparatus adapted for experiments at high temperatures in the presence of gases under high pressure, by M. L. Cailletet. For this apparatus, which the inventor has had in use for some years, it is claimed that it enables experimenters to raise substances to temperatures near the fusion of platinum while keeping them in a gaseous atmosphere, the nature and pressure of which may be varied at pleasure.—On double dielectric refraction; simultaneity of electric and optical phenomena, by M. R. Blondlot. These experiments have been undertaken in order to determine whether the double dielectric refraction of a condenser is produced and ceases simultaneously with the charge, or whether there exists an appreciable interval of time either between the production of the electric phenomenon and that of the luminous phenomenon, or between periods of cessation of both phenomena. The conclusion seems to be that, if there is any difference in point of time between these several manifestations, it cannot exceed 1/40000 of a second.—On the laws of chemical equilibrium, by M. H. La Chatelier. It is shown that the numerical laws of chemical equilibrium, such as they are deduced from the two principles of thermodynamics, may be expressed in a very simple way by means of M. Massieu's characteristic function H′, which may be regarded as the true measure of chemical force.—On cinchonigine, by MM. E. Jungfleisch and E. Léger. The authors describe the process of preparation, the chemical properties, and the salts of this substance, whose composition is expressed by the formula $C_{28}H_{22}N_2O_2$.—Persistence of the virus of rabies in dead bodies, by M. V. Galtier. These researches show that the virus retains all its virulence in the bodies of dogs that have been dead seventeen and buried fifteen days. Inoculation from the bulb produces rabies in ten and kills in fifteen days after trepanation.—On the antiseptic properties of naphthol-α, by M. J. Maximovitch. The experiments here described show that, owing to its feebler toxic and stronger antiseptic properties, this substance is in every way superior as an antiseptic to M. Bouchard's naphthol-β.—On the presence of primordial fauna (Paradoxidian) in the neighbourhood of Ferrals-les-Montagnes (southern slope of the Montagne Noire), Hérault: (1) stratigraphic study by M. Jules Bergeron; (2) palæontological study, by MM. Munier-Chalmas and J. Bergeron. Considerable interest attaches to the recent discovery of these organisms by M. Bergeron, for the first time in any part of France. They belong to the earliest forms of the Silurian group, forms which were not known to exist when that group was first established by Murchison in 1835. These first French Trilobites of the primordial fauna, as it was named by Barrande, include some exceptionally fine specimens of the genera Conocephalites and Paradoxides, the latter closely allied to the *P. rugulosus* of Bohemia, and the *P. Pradoanus* common in the Cambrian of Spain.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Astronomical Observations and Researches made at Dunsink, sixth part (Hodges, Dublin).—A Student's Manual of Psychology, adapted from Kirchner by E. D. Drought (Sonnenschein).—The Cardinal Numbers: M. Hopkins (Low).—Civilization and Progress; new edition: J. B. Crozier (Longmans).—Lessons on Prescriptions and the Art of Prescribing; new edition: W. H. Griffiths (Macmillan).—Lehrbuch der Entwicklungsgeschichte des Menschen und der Wirbelthiere, Zweite Abthg.: Dr. O. Hertwig (Jena).—Practical Forestry: C. E. Curtis.—South African Butterflies; two vols: R. Trimen, assisted by J. H. Bowker (Trübner).—Journal of the Society of Telegraph-Engineers and Electricians, No. 69, vol. xvi. (Spon).—Journal of the Royal Statistical Society, December (Stanford).—Annalen der Physik und Chemie, 1888, No. 2 (Leipzig).—Beiblätter der Physik und Chemie, 1888, No. 1 (Leipzig).—Brain, parts 39 and 40 (Macmillan).

THURSDAY, FEBRUARY 16, 1888.

KINEMATICS AND DYNAMICS.

An Elementary Treatise on Kinematics and Dynamics. By James Gordon MacGregor, M.A., D.Sc., &c., Munro Professor of Physics, Dalhousie College, Halifax, N.S. (London: Macmillan and Co., 1887.)

THE logical order of arrangement has been carefully attended to in this book: Part I., on "Kinematics," building up a new subject on the foundation of Euclid's axioms in conjunction with the idea of the variables, such as velocity and acceleration, due to the flow of time; while Part II., on "Dynamics," requires three new axioms —Newton's Laws of Motion—to make a fresh start and connect mechanical effects with their causes.

But it is doubtful if the strictly logical order is the best order for the student to make his first acquaintance with a new mathematical subject: the ideas must grow in his brain by accretion round simple fundamental problems. A student would master the present treatise more easily by reading Part II. first, and referring back to Part I. as occasion required, for the explanation of the details of the mathematical calculations. There is nothing to prevent this order of study here, although the author has, from logical considerations, placed the kinematical part first.

One defect of the logical system is that it places some of the most difficult parts of the subject in the way of beginners: for instance, the theory of the change of units, a theory of which the importance can only be appreciated by those who have made considerable progress in the subject.

In Part I., "Kinematics," the treatment is simple and concise, but we should like to see more examples of phenomena on a large scale, such as those of physical astronomy, or even of railway-train problems.

In questions involving the size of the earth (pp. 74 and 80) it is the circumference and not the diameter which should be given in metres, the circumference being 40,000,000 metres, a kilometre being a centesimal minute of latitude. Or, if the size of the earth is given in miles, it is the nautical mile which should be used, the circumference of the earth being $360 \times 60 = 21,600$ nautical miles, a nautical mile being a sexagesimal minute of latitude.

The expression "knots an hour" (p. 60) is irritating to a sailor, as emanating from the engine-room; the proper nautical expression is "knot" simply, a speed of 10 knots being 10 nautical miles an hour.

The formula $\frac{1}{2}v^2 = \frac{1}{2}v_0^2 + as$ is to be preferred to that on p. 34, $v^2 = v_0^2 + 2as$; in all cases the factor $\frac{1}{2}$ should go with the v^2 in the equation of energy, so that the objectionable expression "*vis viva*" may finally be stamped out from all dynamical treatises.

In dealing with rotation, in Chapter V., the author would do well to study Maxwell's geometrical representation of the direction by means of the screw, right-handed or left-handed; and to discard all attempts by comparison with a clock-wise or counter-clock-wise rotation, requiring as these do a specification of the aspect of the plane of motion.

Pure homogeneous strain is analyzed in Chapter VII. as far as is possible by simple geometrical methods; such a strain may be produced by the superposition of three linear strains in directions at right angles to one another. In a linear strain the increment of distance of two points in the line of the strain is properly their *elongation;* while the ratio of the elongation to the original distance is called the *extension*, not the *elongation*, as on p. 167.

In Part II., "Dynamics," we find in Chapter I. the discussion on the units of measurement of weight, mass, and force customary in mathematical treatises, and of the usual unsatisfactory nature. The author, disregarding the vernacular use of the word "weight," defines the weight of a body as the force with which it is attracted by the earth, but is at variance with his own definition in the statement of the majority of the subsequent examples, relapsing into the language of ordinary life. A collection of 500 different ways of spelling the name of the town of Birmingham has been made, and a similar collection could be made from the present treatise of different ways of expressing the simple ideas of the pound *weight* and the pound *force*, to use the ordinary language of practical men. The attraction of the earth on a pound is, in the vernacular, "the force of a pound," not the "weight of a pound," the latter implying what the mathematician likes to distinguish as the "mass of a pound." Thus a mathematical precisionist, to express the simple idea of a force of 10 pounds, to be consistent should call it "a force equal to the weight of the mass of 10 pound weights," the absurdity of which is evident.

Again, in straining after the equation $F = ma$, when using the gravitation unit of force, the mathematician in the F.P.S. (foot-pound-second) system of units is obliged to use the variable unit of mass of g pounds to measure the invariable quantity, the mass of the body; while what he calls the weight of the body, and denotes by w, measuring it in pounds, is, although variable with g, always measured by the same number.

Next we have the equation $w = mg$, the source of all the confusion in dynamical teaching, and only to avoid writing the dynamical equation with gravitation units in the form

$$F = w\frac{a}{g}.$$

This terminology culminates in the solecisms that on p. 477 we must suppose pressure to be measured in poundals on the square foot in hydrostatical problems; and that if the equation $w = mg$ is supposed to be used with absolute units, that the weight of a body is measured in poundals; as if a mathematician asked in a shop for "half a poundal of tea, or tobacco." Ordinary people measure weight in pounds, so that if mass is also measured in pounds, then $w = m$.

It is time now, as Prof. Minchin has pointed out, that "the astronomical unit of mass," defined in § 315, should disappear, and that in all problems of physical astronomy the gravitation constant k should be retained, while m, the mass, is measured in terms of the ordinary units.

Although the author does not allow himself the use of the methods and notation of the Calculus, still he has managed to discuss a number of interesting problems in the dynamics of a rigid body, usually proved by the methods of Analytical Mechanics.

Working under these restrictions, he has given elegant elementary proofs of the chief properties of the common catenary; but here, again, it is time that the equation

should be presented in the form $y/a = \cosh x/a$, using the notation of the hyperbolic functions; which might also be employed with advantage in the statement of the results of the examples on p. 302. Chains of 5000 feet span, and 400 feet versed sine, are in existence, providing striking numerical examples in this part of the subject.

Most of the examples are carefully chosen, but the author by diligent search could easily add more interest to the collection, particularly to the examples on parabolic trajectories, and problems concerning the motion of railway-trains. Ex. 85, p. 499, certainly requires careful revision. The diagrams of the simple machines are of the usual academic nature; the author should consult Prof. Kennedy's "Mechanics of Machinery" for better illustrations, especially of the differential pulley, and of pulley tackle in general. If the differential screw is given (p. 435), why not also the integral screw, which is to be met with more commonly in real life—for instance, in railway couplings, and in the rigging of ships.

Except for the parts criticized above, on the units of weight, mass, and force, the present treatise shows that the author has read with profit and discrimination the most recent treatises on dynamics; he has produced a very useful work, suitable for instruction in technical colleges, and likely also to prove a necessary corrective to the very abstract treatment of the subject of mechanics too common in the character of University instruction.

A. G. GREENHILL.

ATLAS OF THE DISTRIBUTION OF PLANTS.

Atlas der Pflanzenverbreitung. (Berghaus's "Physikalischer Atlas," Abtheilung V.) Bearbeitet von Dr. Oscar Drude. (Gotha: Justus Perthes, 1887.)

THE history of the science of the distribution of plants begins with Linnæus, who was the first to cite systematically the countries and situations in which the plants he described grew. This we find carefully done in the first edition of the "Species Plantarum," published in 1753. No perceptible advance beyond this was made before the appearance of Humboldt and Bonpland's "Essai sur la Géographie des Plantes" in 1805, which work may be designated the real foundation of the science. It was followed in 1823-24 by the Dane, Schouw's "Grundtræk" and "Plantegeographisk Atlas," the latter containing twenty-two maps illustrating the vegetation of the world, and especially the distribution of plants cultivated for food. There is also a German edition of both the "Outlines" and the "Atlas." From this date onward many of the most eminent botanists investigated distribution in connection with classification of plants, notably R. Brown, A. P. De Candolle, H. C. Watson, C. Darwin, A. De Candolle, J. D. Hooker, Edward Forbes, Von Martius, and Grisebach, to say nothing of the younger botanists. But the results of their labours ars still scattered, or at least only partially elaborated; for Grisebach, in his "Vegetation der Erde," deals with the facts from a peculiarly narrow stand-point.

It is true that both Drude and Engler ("Versuch einer Entwicklungsgeschichte der Florengebiete") have attempted something beyond this, but neither, we suspect, regards his work as more than a preliminary effort. The primary geographical divisions of these two writers are essentially the same, though their nomenclature differs; but, considering the complexity of the subject, probably no two persons would agree exactly on these points; yet it is highly desirable that there should be something approaching uniformity in the names of the divisions. Grisebach designates his primary divisions "Gebiete," and Drude his "Reiche"; whilst Engler's four primary divisions are designated "Reiche," and his secondary ones "Gebiete." Let us now briefly examine the main features of Drude's Atlas. Following the most authoritative English writers on zoological and botanical geography, we will call the primary divisions regions, and the secondary divisions sub-regions.

Drude divides the world into fourteen floral regions, and each of these into a number of sub-regions, indicating by lines and dots the overlapping of the elements of contiguous sub-regions. The regions are: (1) Northern, (2) Central Asia, (3) Mediterranean, (4) East Asia, (5) Middle North America, (6) Tropical Africa, (7) East African Islands, (8) Indian, (9) Tropical America, (10) Cape, (11) Australia, (12) New Zealand, (13) Andes, (14) Antarctic.

While agreeing in the main with the foregoing divisions, we cannot but regard some of them as including too, much or too little, according to the number of primary divisions adopted. We recognize the difficulties of the task, and admit that it is practically impossible to divide the vegetation of the world into regions of equal value and importance, even leaving out of consideration the mountain flora within the tropics. Instead, however, of giving Madagascar and the neighbouring islands the rank of an independent region, we should treat it as a sub-region of the tropical African flora. On the other hand, the Indian region seems too comprehensive, as it includes the whole of tropical India, Malaya, Cochin-China, the Malayan Archipelago, New Guinea, North Australia, and Polynesia, even to the Sandwich Islands. The very extensive recent collections of Madagascar plants, made by various English and French travellers, prove that the flora is really a sub-region of the tropical African flora. With regard to the flora of Polynesia, it is true that the littoral element consists almost exclusively of species common to the Malayan Archipelago and North Australia, many having an even wider range; but the Australian and American affinities of the endemic element are certainly too pronounced, in our opinion, to treat this flora as a sub-region of the Indian; and the Sandwich Island flora is as highly specialized, to say the least, as that of New Zealand. Perhaps it would be more convenient to make it an independent region. Again, the purely Australian types surely predominate largely over the Asiatic in North Australia, especially if we eliminate the widely-dispersed coast plants. Dr. Drude's New Zealand region includes the surrounding islands, except the more southern Macquarie; yet, of the eighteen vascular plants recorded from this island, sixteen are common to the New Zealand group. The Auckland and Campbell groups should be reckoned in the Antarctic region rather than New Zealand; and St. Paul and Amsterdam Islands, as well as the Tristan d'Acunha group, do not belong to the same category. Further, the higher mountain flora of Central America and South Mexico has certainly a greater claim to be included in the Andine region than has that of the Galapagos, though Dr. Drude separates them.

We have called attention to these defects or incon-

sistencies in the limitation of the regions, because we believe that the latest and fullest data relating to the regions in question clearly indicate that it is not a matter of opinion.

The Atlas as a whole is a most laborious and careful compilation, and we do not doubt that it will meet with the favour it deserves. The second sheet of maps illustrates the areas of certain important natural orders and genera; the third, the horizontal zones of vegetation of the world; the fourth, the flora of Europe; the fifth, the floras of Europe and Asia; the sixth, the floras of Africa and Australia; the seventh, the floras of America; and the last represents the areas of plants cultivated for their economic products.

It would be easy enough to find fault with some of the details of the limitation of Dr. Drude's sub-regions, those of tropical Africa and Eastern Asia for example, though it would not always be so easy to suggest more satisfactory ones; but we prefer judging the work by its merits rather than by its real or assumed defects.

This Atlas, it should be added, is a cartographical development of Dr. Drude's "Florenreiche der Erde," which appeared in 1884, and formed the Ergänzungsheft 74 to *Petermann's Geographische Mittheilungen*; that is to say, it is a development so far as the maps are concerned, but the explanatory letterpress has been reduced to four pages folio. The maps, sixteen in number, are admirably executed, and exceedingly elaborate; indeed, the only fault we find in them is an excess of detail, with perhaps too little explanatory text for beginners.

As the author very truly observes, the material available for such a work is now almost inexhaustible, and the task of selecting from it for the purposes in view was no easy one. He brings into contrast the position of botanical geography in 1848, when the first edition of Berghaus's "Physical Atlas" was published, and there was nothing approaching a complete flora of any of the larger areas outside of Europe in existence. Even in 1855, when De Candolle gave to the world his now classical work, "Géographie Botanique Raisonnée," he could only deal with fragments of floras. Now, though it may safely be asserted that future discoveries can in no way affect the main theories of distribution based upon what is already known, very much remains to be done in fossil botany before we shall be able to trace in detail the early migrations of plants. Therefore the only thing that can be successfully accomplished yet is to work out more completely the present distribution of plants, which is practically all that Wallace has done for animals. But he deals specially with the quality and probable origin of the zoology of his regions; and it is just this aspect of botanical geography that awaits further development.

OUR BOOK SHELF.

Tenants of an Old Farm. By Henry C. McCook, D.D. (London; Hodder and Stoughton, 1888.)

THE object of this book is to present "a series of exact truths from natural history in a popular form." The author's original intention was to write a number of essays upon insect life, and particularly upon the life of ants and spiders, which he has especially studied. Friends, however, persuaded him to give the essays a colloquial form, so that they might appeal to as wide a circle of readers as possible. We are not sure that the change was in all respects an improvement, for, as Dr. McCook says, "the truths of Nature are attractive enough in themselves, and need not the seasoning of fiction." The book is very popular in the United States, and there can be little doubt that it will also be appreciated on this side of the Atlantic. The author is a keen and accurate observer of Nature, and his enthusiasm for his subject is so steadily maintained that it cannot but exert some influence on the minds of young students. For the present edition a brief introduction has been written by Sir John Lubbock, who bears cordial testimony to the fidelity and skill with which Dr. McCook has carried on his researches. The work is remarkably well illustrated.

Digging, Squatting, and Pioneering Life in the Northern Territory of South Australia. By Mrs. Dominic D. Daly. (London: Sampson Low, 1887).

THIS is an interesting account of a part of South Australia which is sure to become more and more important. The writer spent three years—from 1870 to 1873—in the Northern Territory, and by far the best chapters are those in which she records her own experiences. The history of the district during the last fourteen years has, however, been carefully compiled from the most trustworthy sources. She has, of course, a good deal to say about the natives, her accounts of whom are freshly and brightly written. Mrs. Daly is of opinion that, so far as the treatment of the aborigines is concerned, only one rule holds good—"firmness accompanied by kindness, fair play, and an honest payment for work done." If they make themselves disagreeable, they must be kept "in their proper place," "for," she says, "when a native shows signs of sulkiness and defiance, it is perfectly certain some mischief is brewing."

Photography Simplified. (London: Mawson and Swan, 1887.)

THIS is a third edition, considerably revised and enlarged, of an elementary and practical treatise, intended chiefly for amateurs and those about to become acquainted with the subject. The earlier chapters deal with the purchasing of apparatus, followed by the various processes of taking the negative, developing, printing, &c., and are written in a very plain and intelligent way. The book concludes with an appendix containing additional useful formulæ, together with a set of labels for the photographic laboratory.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

An Explanation explained.

I AM glad to find that Dr. Guppy has at last enabled us to get to the bottom—I cannot say to the foundation—of the story which was related by the Duke of Argyll on November 17 in last year, to the discredit of Prof. Bonney and the authorities of the Geological Society. It is now admitted that the paper, said to have been "offered to," and "refused by," the Society, never came before the President and Council in any form whatever; and that in fact the paper was not only never presented, but was never even written!

Dr. Guppy's references to myself are capable of the simplest explanation. During the whole time that he was absent in the Solomon Islands, I was in the habit of receiving specimens

and letters from him; and, as he has acknowledged in his book, I carefully studied these specimens and gave him all the advice and assistance in my power in carrying on his geological investigations. Upon his return we had several conversations, always of the most friendly character, concerning the best mode of embodying his observations for communication to different Societies; and until the present time I had not the smallest idea that he was in any way dissatisfied with anything I had ever said or done in connection with the subject.

With respect to a particular conversation referred to by Dr. Guppy as having occurred in the spring of 1885, I have no recollection whatever; but I unreservedly accept his statement as to the *facts* of the case, and only demur to his *interpretation* of them. If Dr. Guppy or anyone else asked my opinion as to the fitness for the Geological Society of "a paper in which Mr. Darwin's theory of coral reefs would be brought under consideration," I should undoubtedly point out to him that the Geological Society had always been averse to publishing papers dealing with such broadly theoretical questions as the origin of coral reefs, and I should advise some other means of publication as more appropriate.

That the Geological Society is not partial in its reluctance to publish papers of a theoretical character will be seen from the fact that although Mr. Darwin in 1837 read a paper to the Society, embodying the chief points of his theory of coral reefs, yet the Society never published the paper in their Transactions. At the time that this occurred Darwin was a member of the Council, and a few months later he became Secretary of the Society.

It is surely unnecessary for me to remark that in any advice which I gave to Dr. Guppy, I was acting simply on my own judgment and individual responsibility. Dr. Guppy was a Fellow of the Society at the time, and had precisely the same right to present papers to it which I had myself. Dr. Guppy chose to ask my advice; I gave it to him as to a friend, and he was perfectly free to act upon it or to reject it as he thought fit. I may add that the Secretary of the Geological Society has nothing to do with the acceptance or rejection of papers, except as a member of the Council, and then only when the question has been brought up by the President for the approval or condemnation of his own action.

How my unofficial act of friendly advice concerning the destination of an unwritten paper came to be represented as the refusal of a paper offered to the Society I am at a loss to conceive! Why the Duke of Argyll, having received the statement which is now before us, should proceed to formulate the very grave accusation against Prof. Bonney personally, and the authorities of the Geological Society, it is for his Grace to explain.

With respect to Dr. Guppy's complaint that his memoirs have been "studiously ignored" during the recent controversy, I cannot help thinking that he has been unduly sensitive. Writing to Prof. Huxley in October last year, and pointing out that the Duke of Argyll was mistaken in supposing there had been no discussion on Mr. Murray's theory, I said "it would be an endless task to attempt to give references to the various scientific journals which have discussed the subject," but in penning these words I had not the smallest idea of speaking slightingly of any of the memoirs which want of space prevented me from citing, and least of all concerning those which contain the facts and observations of Dr. Guppy, of the value and importance of which I had such good opportunities of judging.

JOHN W. JUDD.

Reason and Language.

PROF. MAX MÜLLER has been so kind as to favour the readers of NATURE with his views on language and reason, concisely expressed in a letter to an American friend. As one grateful reader, I much desire both to express my thanks, and also to beg for yet a little further information with respect to matters of such extreme interest.

The Professor says: "Because we reason—that is, because we reckon, because we add and subtract—therefore we say that we have reason." Now, in the first place, I should be glad to be told why "reason" is to be regarded as identical with such "reckoning"? I have been taught to distinguish two forms of intellectual activity: (1) acts of intuition, by which we directly apprehend certain truths, such as *e g.* our own activity, or that A is A; and (2) Acts of inference, by which we indirectly apprehend others, with the aid of the idea "therefore"—evolving into explicit recognition a truth previously implicit and latent in premisses. The processes of addition and subtraction alone, seem to me to constitute a very incomplete representation of our mental processes.

The Professor also identifies language and reason, denying to either a separate existence. As to "reason" he says: "We have only to look into the workshop of language in order to see that there is nothing substantial corresponding to this substantive, and that neither the heart nor the brain, neither the breath nor the spirit, of man discloses its original whereabouts." The expression "whereabouts" would seem to attribute to those who assert the existence of "reason," the idea that it possesses the attribute of extension! In order to understand clearly the passage quoted, we should learn what Prof. Max Müller really means by the term "spirit," which here figures as one species of a genus also comprising the breath, the brain, and the heart. Reason, however, is not represented as being simply language "as we now hear it and use it," but "as it has been slowly elaborated by man through all the ages of his existence upon earth." Thus understood, the Professor "cannot doubt" "the identity of reason and language." Nevertheless, he immediately proceeds to point out a striking want of identity between them. He says, quite truly, "We have two words, and therefore it requires with us a strong effort to perceive that behind these two words there is but one essence,"—namely, that denoted by the Greek word *logos*—"the undivided essence of language and thought." Now, the intimate connection of language (whether of speech or gesture) with thought is unquestionable; but intimate connection is not "identity." If thought and language are "*identical*," how came two words not to have two meanings, or two thoughts to be expressed by one word? The plain fact that we have different words with one meaning, and different meanings with one word, seems to demonstrate that thought and language cannot be "identical."

"No reason without language—no language without reason" is a statement true in a certain sense, but a statement which cannot be affirmed absolutely. Language (meaning by that term only *intellectual* expression by voice or gesture) cannot manifestly exist without reason; but no person who thinks it even *possible* that an intelligence may exist of which ours is but a feeble copy, can venture dogmatically to affirm that there *is* no reason without language, unless he means by reason, mere "reasoning," which is evidently the makeshift of an inferior order of intellect unable to attain certain truths save by the roundabout process of inference.

But I demur to the assertion that truly intellectual processes cannot take place in us apart from language. In such matters our ultimate appeal must be to our own reflective consciousness. Mine plainly tells me that I have every now and then apprehensions which flash into my mind far too rapidly to clothe themselves even in mental words, which latter require to be sought in order to express such apprehensions. I also find myself sometimes expressing a voluminous perception by a sudden gesture far too rapid even for thought-words, and I believe that other persons do the same. A slight movement of a finger, or the incipient closure of an eyelid, may give expression to a meaning which could only be thought in words by a much slower process.

It is the more remarkable that Prof. Max Müller should deny the existence of reason, since he unequivocally affirms, in rather lofty language, the existence of truth. Yet surely the existence of truth, in and by itself, is inconceivable. What can truth be, save a conformity of thoughts and things? I affirm, indeed, the certain existence of truth, but I also affirm that of reason, as existing anteriorly to language—whether of voice or gesture. What is the teaching of experience? Do men invent new concepts to suit previously coined words, or new words to give expression to freshly thought-out concepts? The often-referred-to jabber of Hottentots is not in point. No sounds or gestures which do not express concepts would be admitted by either Prof. Max Müller or myself to be "language."

The Professor speaks of the "alarmingly small" number of primitive concepts; but who is to be thereby alarmed? Not men who occupy a similar stand-point to mine. I fully agree with Prof. Max Müller in saying, "After the genesis of the first concept, everything else becomes intelligible."

We come now to the supreme question of the origin of languages. As to this, the Professor observes: "No one who has not himself grappled with that problem can appreciate the complete change

that has come over it by the recognition of the fact that roots are the phonetic expressions of the consciousness of our own acts. Nothing but this, our consciousness of our own repeated acts, could possibly have given us our first concepts. Nothing else answers the necessary requirements of a concept, that it should be the consciousness of something manifold, yet necessarily realized as one. . . The results of our acts become the first objects of our conceptual thought." The truth of these statements I venture to question. After noting the dogmatic nature of the assertion "Nothing but this *could*, &c.," I must object to the statement of fact as regards human beings now. I do not believe that the infant's first object of thought is "the results of its own acts." In the first place, no object of our early thoughts is merely the "results of our own acts," but a combined result of our own activity and of the action on us of our environment. Secondly, my observations lead me to believe that the infant's first thoughts relate to things external, and certainly not to the results of its own activity as such, which is a highly complex and developed thought. It may be that the Professor, when he says "The results of our acts *become* the first object of our conceptual thoughts," means that such acts in remote antiquity *became* the object of man's first thought. This is probably the case, since, with respect to the origin of thought and language, Prof. Max Müller has adopted Noiré's crude notion that they sprang from sounds emitted by men at work, conscious of what they were doing, in the presence of others who beheld their actions and heard the sounds; the result being the formation of a conceptual word, to attain which five stages had to be gone through, as follows :—

"(1) Consciousness of our own repeated acts.

"(2) *Clamor concomitans* of these acts.

"(3) Consciousness of our *clamor* as concomitant to the act.

"(4) Repetition of that *clamor* to recall the act.

"(5) *Clamor* (root) defined by prefixes, suffixes, &c., to recall the act as localized in its results, its instruments, its agents, &c."

But, if language and reason are identical, reason could not exist before a single conceptual word existed. Nevertheless, to attain to this first single word, we see, from the above quotation, that man must have had the notion of his own acts as such; the notion of their repetition; the notions of clamor, action, and the simultaneity of clamor and action; the will to recall the act (yet *nihil volitum quia præcognitum*); and finally the notions of consequence, instrumentality, agency, or whatever further notions the Professor may intend by his "&c."

Thus he who first developed language must be admitted to have already had a mind well stored with intellectual notions! But can it for one instant be seriously maintained, close as is the connection of language with reason, that their genesis (miracle apart, of which there is no question) was *absolutely* simultaneous? He must be a bold, not to say a rash, man who would dogmatically affirm this. But if they were not *absolutely* simultaneous, one must have existed, for however brief a space, before the other. That intellectual language could have existed without reason is absurd. Reason, then, must, for however short a period, have preceded language.

In conclusion, I desire to point out a certain misrepresentation with respect to natural selection. The Professor says: "In the evolution of the mind, as well as in that of Nature, natural selection is rational selection; or, in reality, the triumph of reason, the triumph of what is reasonable and right; or, as people now say, of what is fittest." But, we may ask in passing, if reason has no existence, how can it "triumph"? The misrepresentation of natural selection, however, lies in his use of the word "fittest." When biologists say that the "fittest" survives, they do not mean to say that that survives which is the most "reasonable and right," but that that survives which *is able to survive*. What there is less "reasonable and right" in a Rhytina than in a Dugong, or in a Dinornis than an Apteryx, would, I think, puzzle most of our zoologists to determine; nor is it easy to see a triumph of reason, in the extermination of the unique flora of St. Helena by the introduction of goats and rabbits.

ST. GEORGE MIVART.

Mechanical Equivalent of Heat.

I FIND that the mode of regarding J advocated in my letter in last week's NATURE (p. 320) is not quite new, for my brother, Dr. Oliver Lodge, writes to tell me that Clerk-Maxwell, on p. 298 of his "Theory of Heat," has called J the specific heat of water. However, he has not done so throughout the book, and I do not think it is the meaning generally attached to the symbol, though it seems to me that it should be so; that is to say, J should always be considered as denoting the specific heat of water at the temperature 0° C.

ALFRED LODGE.

Coopers Hill, Staines, February 6.

"Is Hail so formed?"

I CANNOT accept Dr. Rae's explanation as a "simpler solution" of the phenomenon described by me in NATURE of January 26 (p. 295), because it is based upon meteorological conditions that were at the time non-existent.

My own observation of the pine-tree convinced me that at or near the summit there was no adherent ice or rime; and had there been beads of ice upon the leaves I should still have failed to see what should have caused them while frozen to become detached and change from beads to pellets.

There was a fine mist during the whole of the day, and I observed the phenomenon at 3.30 p.m.

A letter appeared in NATURE upon the same day as mine, drawing attention to the unusual atmospheric conditions observed about that time, and containing facts which manifestly support my theory.

CECIL CARUS-WILSON.

Bournemouth, February 11.

The New Army Regulations.

THE new regulations for the Woolwich entrance examination have been very unfavourably received by men of science. This hostile criticism is in some respects the consequence of the absence of clear discrimination between them and those already in force for the Sandhurst examination.

It must be remembered that candidates for Woolwich cadetships must be between the ages of 16 and 18; that 6000 marks are awarded for mathematics, with 1500 more for drawing and English composition; and that in both the last June and December competitions less than 4000 marks sufficed to place a student among the successful competitors. Since candidates can pass in these subjects alone, it appears unreasonable to complain that youths of scientific power are excluded from the Royal Military Academy. Classics are sufficiently discouraged by the fact that they have no mark value after the cadet has entered the Academy. The 5000 marks offered in the entrance examination for Latin and Greek merely serve to encourage candidates who have been educated on the classical sides, which are almost always the stronger at our public schools. They really tend to widen rather than to narrow the sources from which candidates are drawn.

After a quarter of a century of continuous experience as a student and teacher of elementary science, I find myself reluctantly forced to the conclusion that chemistry, physics, and geology are not good educational subjects for lads under 16 years of age. I believe that it is in most cases desirable that youths intended for a scientific career should not specialize too early. A sound foundation of mathematics and modern languages is almost necessary to enable them to attack their scientific subjects efficiently. With minds trained to the use of the exact and powerful processes of mathematical reasoning, and able to readily appreciate and avail themselves of the wealth of scientific literature in France and Germany, they will probably become more useful officers than if they had acquired a smattering of science.

On the other hand, your wise censure of the discouragment of science in the Sandhurst regulations must commend itself to all thoughtful men. The case is even stronger than at first sight appears in the studious moderation of your judicious article. The limits of age are higher for Sandhurst, being 20, or in some cases 24. The training of the Line cadets is less complete. As they only spend one year at Sandhurst, they are obliged to confine their attention more strictly to professional subjects. Officers of the Line have often more leisure than those in the scientific corps, and there are many reasons why even a slight acquaintance with science would be helpful to them. It also seems hard that a candidate should be handicapped by not taking up Latin. Sometimes it has been discontinued for a considerable period, and a candidate can ill afford to take up "a 2000 subject," considering the severity of the competition.

I would wish respectfully to suggest that a memorial should be presented to the War Office by all interested in the teaching of science, praying that, if a candidate for an army examination

wishes to substitute for Latin one of the sciences enumerated in Group II., it should be allowed a maximum of 3000 marks.

2 Powis Square, W. HENRY PALIN GURNEY.

"British and Irish Salmonidæ."

As your reviewer allows that he "intentionally omitted" five words from a sentence of mine which he quoted in order to criticise, I may well leave comments on such a proceeding to your readers. I willingly acquit him of having purposely made me to suggest utter nonsense, as I cannot help thinking that his knowledge of fish-culture was such that he was unaware he was doing so.

As to the second point he says, "I doubted and still doubt if there is any method practised in which layers of moss are used and are separated from the eggs by muslin and similar material." As he rejects the Howietoun account which I gave, I now submit extracts from two standard works, one American, the other English, which will, I believe, be conclusive to those who are ignorant of fish-culture, for every fish-culturist is aware that this plan is commonly adopted. Livingstone-Stone ("Domesticated Trout," ed. 3, 1877) remarked :—"Theodore Lyman recommends placing each layer of eggs in a fold of mosquito netting to keep them from mixing with the moss and so facilitate the unpacking of them. *This is a great improvement. By all means use mosquito netting*" (p. 149). Mr. Andrews, of Guildford, wrote thus in the Badminton Series ("Salmon and Trout," 1885) :—"The plan of packing does not vary much with trout breeders. The eggs are placed in alternate layers between moss, and protected by a covering of mosquito netting, muslin, swans' down, calico, or butter cloth, so arranged that the eggs shall not be crushed or escape" (p. 447).

As regards the third point, your reviewer now appears to be convinced that *Salmo namaycush* is a char, as I stated it to be. It must be a matter of regret that he omitted to investigate the foregoing questions prior to authoritatively writing upon them in such a well-known publication as NATURE.

Cheltenham, February 4. FRANCIS DAY.

IN his last letter Mr. Day has certainly proved the correctness of the statement in his book that salmonoid eggs are packed with layers of moss from which they are separated by muslin or other textile fabric. If I had known as much about salmon-culture as he, I certainly should not have questioned the statement; it is to be noted that I only questioned and did not deny. If I had been as completely versed in the knowledge of Salmonidæ as Mr. Day, I should have written a book on the subject instead of reviewing his. But the essential point, which Mr. Day seems incapable of appreciating, is this: that there was nothing in the notes on the subject of packing in his book which confirmed the statement in the text; and although my doubts as to the correctness of that statement are removed by his letter, they were perfectly justifiable in a reader of his book. Mr. Day does not apparently suspect that people interested in the subject, including the reviewer, read his book for the sake of gaining information, and not because they already know as much about the subject as himself. All I had to do was to give my impressions of the book as I found it: the fitness of my criticisms is only the more established by the lengthening appendix to his book which Mr. Day is now publishing in your correspondence columns. YOUR REVIEWER.

MODERN VIEWS OF ELECTRICITY.[1]

PART III. MAGNETISM—(*continued.*)

VIII.

IT will now be perceived that a fly-wheel in rotation is the mechanical analogue of magnetism, or more definitely of a section of a line (or tube) of magnetic force; and that a brake applied to such a fly-wheel, with consequent slip, dissipation of energy, and production of heat, is in some sort a mechanical analogue of an electric current.

The field is regarded as full of geared elastic vortices or whirls, some of which are cogged together, so to speak, while others are merely pressed together by smooth rims. It is among these latter that slip is possible, and in the regions occupied by them that currents exist; the energy dissipated here being transmitted through the non-slippery or dielectric regions from the source of power, just as energy is transmitted from a steam-engine through mill-work or shafting to the various places where it is dissipated by friction.

[1] Continued from p. 348.

Mechanical Force acting on a Conductor conveying a Current.

In Fig. 41 the conducting portion is shown with opposite rotations on either side of it. Now superpose a uniform rotation all in one direction upon this, so as to increase the spin on one side and diminish it on the other. Immediately the extra centrifugal force on one side will urge any movable part of the conductor from the stronger to the weaker portion of the field.

The field for a direct and return circuit may be similarly drawn by superposition of their separate whirls (see Fig. 40); and so it becomes evident why a circuit tends to expand so as to inclose the largest possible area, even if no other magnetic field than its own be acting on it.

Also if two circuits are arranged near each other in a plane, with their currents in opposite directions, they will more or less neutralize each other's effect on the space between them, causing (if equal) a region of no spin there. Their neighbouring portions will thus get urged together by the unbalanced pressure on the other side: or, currents in the same direction attract.

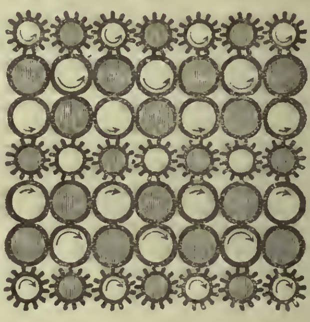

FIG. 44.—Two parallel conductors conveying equal currents in one direction and getting pushed together by the centrifugal force of the outside whirls, no whirl existing between them. The length of the arrows again suggests the distribution of magnetism in the conductors. Fig. 40 showed the correlative repulsion of opposite currents.

As for the effect of iron introduced into a circuit, it brings into the region of space it occupies some two or three hundred times as many lines of whirl as were there before, and these naturally contribute mightily to the effects, both those exhibiting mechanical force and those exhibiting inertia.

When one says, as roughly one may do, that iron brings 300 fresh lines into the field, one means that for every whirl otherwise excited, 300 more are faced round in the iron. And this process goes on while the field is increasing in strength until the total number of whirls in the iron begins to be called upon; when this point is reached the rate of addition is not maintained, and the iron is said to show signs of saturation. Ultimately, if ever all its whirls were faced round, the iron would be quite saturated; but long before this point is reached another cause is likely to make itself felt, viz. the falling off in the strength of the whirls already faced round, by the action of the strong magnetic induction, which is all the time acting so as to weaken the iron currents so far as it is able. And thus at a certain point hitherto unreached by experiment the iron may not only fail to increase the strength of the field any more, but may actually begin to diminish it.

The easiest way to picture the effect of iron is to think of its wheels as some two or three hundred times as massive as those of air, so that their energy and momentum are very great.

That which is commonly called magnetic permeability may in fact be thought of as a kind of inertia, an inertia per unit volume; though how it comes to pass that the ether inside iron is endowed with so great inertia one cannot say. Perhaps it is that the iron atoms themselves revolve with the electricity, perhaps it is something quite different. Whatever the peculiar behaviour of iron, nickel, &c., be due to, it must be something profoundly interesting and important as soon as our knowledge of their molecular structure enables us to perceive its nature.

Induction in Conductors not originally carrying Currents but moving in a Magnetic Field.

To explain the currents induced in a conductor moving through a uniform magnetic field is not quite easy, because none of the diagrams lend themselves naturally and simply to the idea of circuits changing in form or size.

If we take a rigid circuit in a magnetic field, like Fig. 45, and revolve it out of its plane 180°, it is obvious that a current will be excited in it, for the process is essentially the same as if the conductor were kept still and the field reversed.

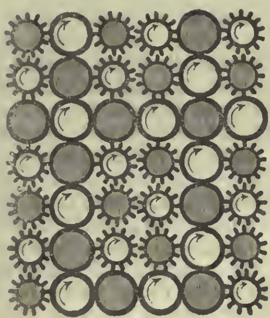

FIG. 45.—Section of a uniform magnetic field with two rails and a slider in it. If the slider be moved to or fro, the wheels inside get initially, compressed or extended, and thereby gain or lose energy respectively thus exciting the state of slip known as induced current.

But to understand the current excited in a closed circuit when a portion of it moves across the lines so as to embrace a greater number of them, one has to take into account the fact that the inside whirls are expanding and doing work in forcing the conductor away, while the outer whirls are resisting the motion, and being thereby compressed and rendered more energetic. Thus the wheels inside revolve slightly slower as the circuit expands, and those outside revolve slightly quicker. Both these processes cause a slipping of the gearing, first all round the inside and then all through the substance of the wire, whereby positive electricity moves forward in one direction round the circuit, the negative moving oppositely; and so a current is accounted for. It is not to be supposed, however, that any finite expansion of the wheels really occurs: the motion is rapidly equalized by diffusion through the wire, and fresh wheels come in round it from outside; hence directly after the conductor has stopped moving the field is again steady, but with many more wheels inside the contour than it possessed at first.

Representation of an Electrostatic Field again, and superposition of it on a perpendicular Magnetic Field.

An electrostatic strain is, we know, caused by a displacement of positive electricity one way along the lines of force, and by an equal displacement of negative the other way. Half the process was indicated crudely in Fig. 6; we may now represent it rather more fully with the help of our elastic cells by Fig. 46.

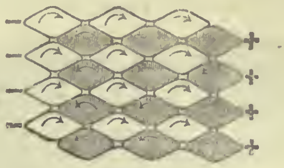

FIG. 46.—A portion of an electrostatic field between two oppositely charged bodies, with its lines of force going from right to left, and showing a tension along and a pressure at right angles to them, due to the elasticity of the cells (which elasticity may be due to their containing fluid in a state of whirl). Magnetic lines of force perpendicular to the paper are also shown in section. While this magnetic field was being excited and propagated from below upwards, a slight strain would be produced in the elastic cells, like but immensely less than that shown; as contrasted with its normal condition (Fig. 37). Conversely, while this electrostatic strain was being produced, the positive whirls would be infinitesimally quickened and the negative ones retarded during the displacement, thus producing a minute magnetic effect. If the medium is not magnetized, the whirls are not necessarily absent, only faced all ways.

Here the positive cells have been pulled one way, the negative the other way; and when the distorting force is removed, the medium tends to spring back to its normal condition, exerting an obvious tension on bodies attached to it in the direction of its lines of force, its elongated direction, and an obvious pressure in all perpendicular directions, its compressed directions.

Now, if all the cells are full of parallel whirls, as in the preceding magnetic diagrams, it is not improbable that this electrostatic distortion or "shear" of the medium may affect its magnetic properties slightly, and that, if the direction of electrostatic strain were rapidly reversed, a small magnetic oscillation would also ensue; but the exact details of these mutual actions are difficult to specify at present.

Disruptive Discharge.

Disruptive discharge may be thought of as a pulling of the shaded cells violently along past the others; the process being accompanied by a true disruption—a sort of electrolysis—of the medium, and a passage of the two electricities in opposite directions along the line of discharge.

Consider the locomotion of any one horizontal row of shaded cells in Fig. 46 during the occurrence of such a disruption of the medium. The cells slide on towards the right, and, as they slide, the spin of the negative cells above them is retarded while that of those below them is accelerated; consequently a true magnetic effect is produced, just like that accompanying a current, and a disruptive discharge has therefore all the magnetic properties of a current.

Effects of a Moving Charge.

This locomotion of a set of positive cells, or of negative cells the other way, as just considered, is very near akin to the motion of a charge through a dielectric medium.

A charge can only exist at the boundary between a dielectric and a conductor, or at least between one dielectric and another of greater density. So, when a charged body moves along with extreme rapidity, it can be thought of as exciting a rotation in the cells most closely in contact with it greater than that which it excites in the opposite kind of cells, and thus produces the whirl proper to a magnetic field. Thus does a moving charge behave just like a current of a certain strength.

It may be, indeed, that this is the customary way of exciting a voltaic current; for the chemical forces in a cell cause a locomotion of charged atoms, and thus set

up a field, which, spreading out in the way Prof. Poynting has sketched, reaches every part of the metallic circuit and excites the current there.

Electrostatic Effects of a Moving or Varying Magnetic Field.

Just as we have seen that a moving or varying electrostatic field may produce slight magnetic effects, so one can perceive that a moving or varying magnetic field brings about something of the nature of an electrostatic strain.

For a spreading out field is continually propagating the rotation on from one layer of wheels to the next. If there is any slip, we thus get induced currents, and the rate of propagation is comparatively slow, being a kind of diffusion; but even if there is not any slip, yet, unless the wheel-work is absolutely rigid, the rate of propagation will not be infinite. The actual rate of propagation is very great, which shows that the rigidity of the wheels is very high in proportion to their inertia, but it is not infinite; and accordingly the propagation of rotation is accompanied by a temporary strain. One part of the field is in full spin, another more distant part is as yet unreached by the spin; between the two we have the region of strain, the wheel-work being distorted a little while taking up the motion. Thus does a spreading out magnetic field cause a slight and temporary electrostatic strain, at right angles both to the direction of the lines of force and to the direction of their advance.

Generation of a Magnetic Field. Induction in Closed Circuits.

Picture to oneself an unmagnetized piece of iron: its whirls are all existent, but they are shut up into little closed circuits, and so produce no external effect. Magnetize it slightly, and some of the closed circuits open out and expand, with one portion of them in the air. Magnetize it strongly, and we have a whole set of them opened out into vortex cores, still with the whirl round them, and constituting the common magnetic lines of force. There is no need to think of iron and steel in this connection. In air or any substance the whirls are still present, though much fewer or feebler, and their axes ordinarily form little closed circuits—it may be inside the atoms themselves. But wrap a current-conveying wire round them, and at once they open out into the lines of force proper to a circular current.

Again, think of an iron ring, or a hank of wire as bought at an ironmonger's: wrap a copper wire several times

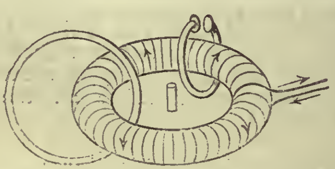

FIG. 47.—Closed magnetic circuit like Fig. 42, with a single-ring secondary circuit, and another open secondary loop; also with a short conducting-rod standing up in it.

round it, as a segment of a Gramme ring is wound (Fig. 47), and pass a current. The closed vortices in the iron at once expand: a portion of each flashes out and across the air-space inclosed by the ring (not by any means confining itself to a plane, of course), and enters the ring on the opposite side; so that directly the current is steady the lines all lie inside the iron again, but now inclosing an area—the area of the ring—instead of being shut up into infinitesimal links. In a sense the iron is still unmagnetized, for its lines of force still form closed contours within it, and none protrude any part of themselves into the air, except for irregularities. But in another sense it is highly and permanently magnetized round and round in itself, the magnetism being not easy to get out of it again, except by judiciously arranged reverse currents.

It is now like one great electric vortex ring instead of like a confused jumble of microscopic ones. Its section was shown in Fig. 42.

During the variable period, while the current is increasing in strength, or while it is being reversed, the region inclosed by the ring and all around it is full of myriads of expanding lines of force flashing across, broadside on, from one side of the iron to the other, and there stopping. It is the presence of these moving lines, changing rapidly from a "simply-connected" into a "multiply-connected" state, or *vice versâ*, which causes the powerful induced currents of "secondary generators."

In every case of varying magnetic field, in fact, we have lines moving broadside on, propagating their whirl, and more or less disturbing the medium through which they move.

Next consider a moving or spinning magnet. Its lines travel with it, and, being closed curves, they also must move broadside through the field, so that in this case we may expect just the same effect as can be obtained from a varying magnetic field.

If a broadside-moving line of force cut across a conductor, its motion is delayed, for its wheels slip and only gradually get up a whirl inside the ill-geared substance; thus, as we know, causing an induced current (see Fig. 43).

If a conducting ring is looped with the iron ring previously mentioned, as a snap-hook is looped with an eye, then every expanding vortex, while the ring is being magnetized, has necessarily to cut through the conducting ring once and no more, no matter what its shape or size. The electromotive force of induction is in this case therefore perfectly definite, and simply proportional to the number of turns made by the secondary round the core of the ring (Fig. 47).

Instead of supposing a closed conducting secondary circuit, imagine an open one: there is still an E.M.F. in it, though rather less than before because a few of the expanding lines flash through the gap and produce no effect, so the electricity must surge to and fro in the conductor as water surges up and down in a tilted trough, and a small condenser attached to the free ends will be alternately charged and discharged. The gap might become so large that nothing is left but a short rod (Fig. 47): in this also similar oscillations would occur.

But now suppose no secondary conductor at all; nothing but dielectric inclosed by the ring. In it there must be an electric displacement excited every time the magnetism of the ring is reversed. It may be an oscillatory displacement, but still on the whole in one direction during rise of magnetism, and in an opposite direction during reversal of magnetism. A charged body delicately suspended within the ring may feel the effect of the minute electrostatic strain so magnetically produced.

To see the mode in which an electrostatic displacement arises in the space embraced by the ring we have only to turn to Fig. 42, and look at the set of wheels along the line A B separating one half the section from the other. They cannot steadily rotate either way, for they are urged in opposite directions by the two halves; in other words, there is no magnetic field near such a ring, as is well known; but, nevertheless, during a change of magnetism, while the whirls inside are changing in speed, the rub on the dielectric necessary for checking the outer wheels of the conductor is either increased or diminished; and if the wheels have any elastic "give" in them, as we know they have, the electrostatic strain in the field is thereby altered during the varying stage of the magnetism.

OLIVER J. LODGE.

END OF PART III.

(*To be continued.*)

THE MECHANISM OF THE FLIGHT OF BIRDS.

THE following is a translation of an article in *La* 5 *Nature* (December ~~3~~, 1887), on the mechanism of the flight of birds, by Prof. E. H. J. Marey. Through the courtesy of the editor of our French contemporary we are able to reproduce the figures illustrating M. Marey's interesting paper.

In a preceding article [see NATURE, vol. xxvi. p. 84], I showed that photography could represent the successive positions of a bird's wing, at different moments in its

FIG. 1.—Sea-gull. Transverse flight. Ten images per second.

flight; that there might be obtained at the same time the positions of the bird in space at equal and known intervals of time; and I expressed the hope of solving by this method the obscure problem of the mechanism of flight.

Since that time, the photographic method has been perfected, and the number of species of birds to which my researches have extended has been multiplied.

From the comparison of the several species which I have had at my disposal, the results show that, except in certain differences in details, they all execute movements

FIG. 2.—Small heron. Transverse flight. Ten images per second.

of the same nature; in all, the wings bend up at the moment of ascension, spread out quickly when at the wished for height, are then lowered, carried in front, and approached to the body; at the close of the descent, the ioints anew bend up, and the ascent recommences.

The illustrations 1, 2, 3, 4, and 5 represent the flight of the sea-gull, the heron, the pigeon, and the pelican.

These illustrations reveal curious attitudes which the eye has not time to seize, and with which we are not familiarized in the artistic interpretations of birds. According

FIG. 3.—Pigeon. Transverse flight. Ten images per second. (Fac-simile of instantaneous photographs taken by the author.)

to a just remark of Mr. Muybridge, the European painters almost always represent birds flying with their wings elevated; the Chinese and Japanese, on the contrary, represent them indifferently with wings both raised and lowered. That does not, however, mean that the artists of the extreme East have faithfully reproduced the different attitudes of birds: the comparison of their representations with those of instantaneous photography shows clearly that no more in China than here does the eye perceive actions which last only for a very brief moment.

Seen only under one aspect, representations of a bird

on the wing do not give us correct ideas or the movements of the wings; we must photograph the bird under several aspects in order thoroughly to comprehend this mechanism. We have made several arrangements in order to procure this effect. One of these, placed at a height of 12 metres (nearly $13\frac{1}{2}$ yards), gave representa-

Fig. 4.—Crested heron. Transverse flight. Ten images per second.

Fig. 5.—Pelican. Transverse descending flight. Ten images per second.

Fig. 6.—Sea-gull seen from above. Ten images per second. (Fac-simile of instantaneous photographs taken by the author.)

tions of the bird as seen from above (Fig. 6); others, variously placed, showed it from the side, or flying in the direction of the photographic apparatus (Fig. 7). These representations, taken under different conditions, complement each other. Thus, the birds seen from above show a singular curvature in the flat surface of the

wing, the existence of which one would not suspect from the profile representations. This curvature appears at the end of the depression of the wing, at the moment in which the joints begin to bend upwards in order to prepare for an ascent. Hence results a spiral aspect of the wing, recalling the form which Mr. Pettigrew considers the essential element in a bird's propulsion. But we must observe that this form is only produced at the very close of the act of descent, at the "*point mort*" of the wing's action, as we say in mechanics, and at a moment in which it, having become passive, is about to remount by the resistance of the air. These figures also show a fact wholly unforeseen—namely, that the movements in flying are not symmetrical. It had been previously supposed that the bird, when desirous of turning laterally the direction of its flight, executes movements more extended from the side which is to progress most rapidly; that is to say, that it gives more amplitude to the movements of the right wing if it wishes to turn to the left, and reciprocally. It is scarcely needful to say that photochronography condemns entirely the hypothesis in which it was supposed that one of the wings of the bird could bend more frequently than the other; the movements of the two wings are perfectly synchronous, if not equal, in extent. It is seen, in short, from these representations, that the body of the bird inclines and moves in different ways, so as to carry its centre of gravity to one side or the other, according to the necessities of the equilibrium. The bird whose attitudes are portrayed in Fig. 6 seemed careful to bear the weight of its body to the left on account of the smaller surface of its right wing, from which some feathers were missing.

The representations taken in front and a little obliquely, as in Fig. 7, give also useful information. They show that the extremity of the wing—a part of the organism in full activity, since it strikes the air with greater speed—presents, at the time of lowering, changes of surface which the secondary *rémiges* extending from the carpus to the shoulder do not offer. There exists in the wing feathers of the different orders a species of separation, showing that the carpal articulations are the seat of a light twisting movement favourable to the bending of the surface of the carpal *rémiges*. In these representations may also be readily seen the bending and convergence of the wings at the close of their lowering, the depression which the anterior side of the wing presents at this moment from the effect of a flexion beginning at the elbow. In order to follow in all their details the changes of movement in the

Fig. 7.—Sea-gull flying obliquely in the direction of the photochronographic apparatus. (Fac-simile of instantaneous photograph taken by the author.)

wings, it has been necessary to make many experiments, so as to obtain, during a single stroke of the wing, ten or twelve successive views of the bird seen under each of these different aspects.

These representations having once been obtained, I was in possession of all the elements necessary to understand completely the motions of the wings according to the three dimensions of space. But in order to represent them, figures in relief were necessary; and circumstances were favourable to this. At Naples, where I then was, the almost lost industry of casting bronze in wax has been preserved from the most remote antiquity. I modelled in wax a series of figures representing the successive attitudes in a single revolution of the wing, ten for the sea-gull, eleven for the pigeon: these models, when given to a skilful moulder, were reproduced in bronze with perfect fidelity.

Fig. 8 represents, disposed in a series, and following each other in their order of succession, at intervals of 1/88 of a second, the phases of one stroke of a pigeon's wing.

These bronze figures were made white, in order to render more apparent the effects of light and shade. Thanks to the multiplicity of the attitudes represented in this series, all the phases of the motion of the wings are easily followed: it is seen how they fold, rise, expand, and sink.

In order the better to understand how the movements of the bird's wing follow each other, of which photochronography gives an analysis, I have had recourse to the use of the zootrope, which recomposes them, and gives to the sight the impression of a bird flying.

The zootrope, represented in Fig. 9, offers this speciality, that it is formed by figures in relief. This is a great advantage from the point of view of the impression which it gives; in fact, these small figures of birds, arranged in a circle in the apparatus, present themselves to the observer under various aspects.

At the beginning of the movement the bird's backs are seen; then, in their circular course, they present their sides, pass across in full view, and at last return to the observer. Besides, the movements of the wings, which in nature are extremely rapid, and consequently imperfectly seen, are here much slower, so that the phases may be easily followed, and in an instant, more may be perceived than the most attentive observer of the flight of birds could discover by the most careful observation...

Fig. 9 shows the arrangement of the zootrope; it

cannot unfortunately give an idea of the effect produced by the apparatus in motion.

But it may be said that this rotatory method interprets the movements of the bird without indicating the forces which produces them. While it would be well to know that force, it is better still to measure the mechanical labour expended in order to sustain and transport itself in the air.

Let us see whether our photographic images reveal to us anything in regard to this.

When one knows the mass of a body, and the speed with which it moves, one can calculate the force

FIG. 8.—Bronze figures representing eleven successive positions at successive moments in the stroke of a pigeon's wing.

which has set this body in motion, and the labour expended by this force. If we take a projectile of a certain weight, and throw it before the photochronographic apparatus, and take a series of images of this projectile at intervals of 1/100 of a second, Fig. 10 shows the trajectory curve followed, and the space which separates the images from each other shows the space traversed by the projectile in each of the hundredth parts of a second during which its movement has lasted. From ten to ten a more brilliant image has been produced by an aperture in the diaphragm larger than the others: these marks are useful in order to facilitate the numbering of the images,

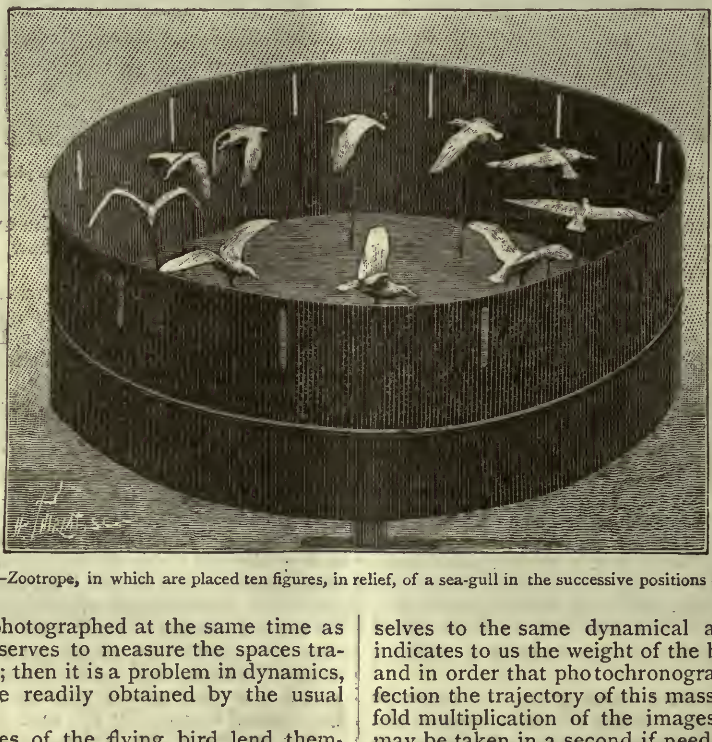

FIG. 9.—Zootrope, in which are placed ten figures, in relief, of a sea-gull in the successive positions of flight.

a fixed metrical scale, photographed at the same time as the object in motion, serves to measure the spaces traversed at each moment; then it is a problem in dynamics, whose solution may be readily obtained by the usual methods of calculation.

The successive images of the flying bird lend themselves to the same dynamical analysis. The balance indicates to us the weight of the bird; we know its size; and in order that photochronography may give us to perfection the trajectory of this mass, it only requires manifold multiplication of the images obtained (a hundred may be taken in a second if need be). But those images

will be partially confused, because the bird, in the hundredth part of a second, only traverses a space equal to the length of its body: the image of the second will therefore partly cover that of the first, the third that of the second, and so on. In this confusion one can scarcely distinguish the moment in which the wing lowers itself, or that in which it is raised. But this is of no importance: we fix on the head of the bird a small but very brilliant metallic point, and the image of this point, clearly seen in the series of figures, reveals the trajectory of the bird, together with its speed, and the accelerations and slackening of speed produced by the movements of the wings. One may then face the dynamic problem of flight. It is granted first that the bird does not oscillate sensibly in the vertical sense, whence one must conclude that the resistance of the air under its wings is precisely equal to its weight. On the other hand, it is to be observed that the motion of the animal presents alternations of speed and slowness, showing that the propelling force and the resistance of the air predominate

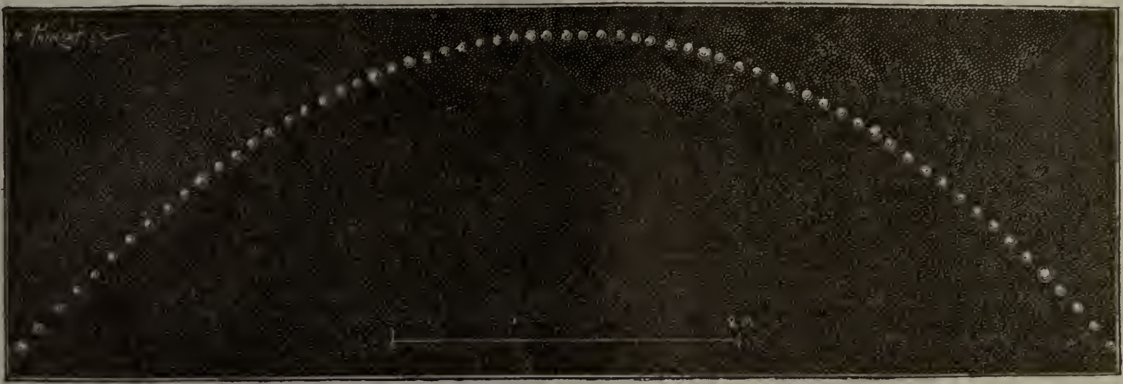

FIG. 10.—Trajectory of a white ball thrown in front of a black screen. The interval between two successive images is measured on the metrical scale. The time taken to travel over this interval is 1/100 of a second.

by turns. From the value of these accelerations there must be deducted the value of the horizontal component of the bird's motion, and that of the resistance of the air.

The calculations based on these experiments have given the following results for the forces which act during the flight of the sea-gull:—

Vertical component	0·623	kilogramme
Horizontal component	0·898	,,
Total ...	1·521	,,

These forces develop themselves during the act of lowering the wings; the ascent is passive, and is due to the pressure of the air upon the lower surface of the wings, which act then for the support of the bird, as in a paper kite.

As the resistance of the air under the wings acts at a point a considerable distance from the articulation of the shoulder, and as the pectoral muscles, by which the wings are lowered, act very near the articulation—that is to say, on the arm of a very unfavourable lever—it results

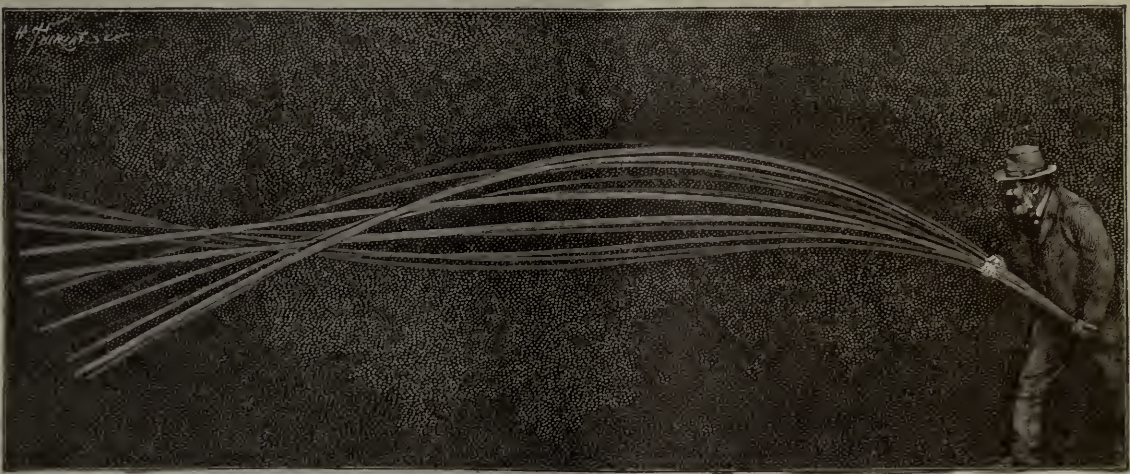

FIG. 11.—Curves and nodes produced by a vibrating stalk, one end of which is fixed. (Fac-simile of instantaneous photographs taken by the author.)

that the effort of the muscles is much greater than the resistance of the air which they surmount. For the pectorals of the sea-gull, the effort developed would be 19 kilogrammes.

It is frequently asked whether the muscles of birds have not a specific strength greater than those of other animals—that is to say, whether two bundles of the same thickness of muscles belonging, one to a bird, the other to a mammal, would have different powers. In the sea-gull which served for my experiments, one transverse section of the pectoral muscles arranged perpendicularly to the direction of their fibres had about 11 centimetres square of surface, or about 1·600 kilogramme per square centimetre. Other birds had formerly given me nearly similar returns for their specific strength; thus, the buzzard developed 1200 grammes per square centimetre, the pigeon 1400 grammes.

Aëronauts hope that they will one day invent a machine

capable of transporting man through the air, but many of them are troubled by a doubt; for they ask themselves whether the force of the bird does not exceed that of the known motors. The experiments on that subject may reassure them, for, if we compare the muscular force of the bird with that of steam, we see that one muscle would be comparable to an engine at very low pressure. In fact, the steam which would develop 1·600 kilogramme per square centimetre would scarcely have more than an atmosphere and a half of pressure. But the true comparison to establish between the animated motors and the engines consists in measuring the work which each of these motors can furnish, with equal weight, in the unity of time.

The measure of the work of a motor is obtained by multiplying the effort put forth, by the path which the point of application of that effort traverses. Photochronography expresses at each moment the spaces traversed by the mass of the bird and the displacement of the centre of pressure of its wings, giving thus the factor path in the measure of the work. In this way it is found that for the five strokes of its wing which the sea-gull gives every second, at the moment when it flies away, the labour done would be 3·668 kilogrammes. This calculation is very high; it corresponds to that which an engine would make in raising its own weight to a height of more than 5 metres in a second.

But that is only a maximum which the bird does not attain to except at the moment of flight, when it has not attained much speed. In fact, according as the passage of the bird is accelerated, the air under its wings presents a more resisting fulcrum. I have previously experimentally demonstrated this fact, announced by the brothers Planavergue, of Marseilles, and of which the following is the theory.

When the bird is not yet in motion, the air which is struck by its wings presents, in the first instance, a resistance due to its inertia, then enters into motion, and flies below the wing without furnishing to it any support. When the bird is at full speed, on the contrary, its wing is supported each moment upon new columns of air, each one of which offers to it the initial resistance due to its inertia. The sum of these resistances presents to the wing a much firmer basis. One might compare a flying bird to a pedestrian who makes great efforts to walk on shifting sand, and who, in proportion as he advances, finds a soil by degrees firmer, so that he progresses more swiftly and with less fatigue. The increase of the resistance of the air diminishes the expenditure of labour; the strokes of the bird's wing become, in fact, less frequent and less extended. In calm air, a sea-gull which has reached its swiftest, expends scarcely the fifth of the labour which it had to put forth at the beginning of its flight. The bird which flies against the wind finds itself in still more favourable conditions, since the masses of air, continually renewing themselves, bring under his wings their resistance of inertia. It is, then, the start which forms the most laborious phase of the flight. It has long been observed that birds employ all kinds of artifices in order to acquire speed prior to flapping their wings: some run on the ground before darting into the air, or dart rapidly in the direction they wish to take in flying; others let themselves fall from a height with extended wings, and glide in the air with accelerated speed before flapping their wings; all turn their bill to the wind at the moment of starting.

My experiments have, up to the present, only been able to apply to the flight of departure. In order to study the full flight there are conditions difficult to realize. With a courtesy for which I thank him, M. Eiffel has offered to me on the gigantic tower which he is erecting (at Paris) a post of observation which will leave nothing to be desired. From that enormous height, birds photographed during a long flight will give photochronographic images much more instructive than those which I have hitherto been able to obtain.

Without entering into the dry details of experiments and calculations made,[1] I have aimed at showing that the movements of birds, if they escape the sight, may be faithfully recorded by a new method which is applicable to the most varied problems of rotation and of mechanics.

Photochronography, in fact, gives experimentally the solution of problems often very difficult to solve by calculation.

Imagine a certain number of forces acting in different ways upon a known mass; the complicated way in which those forces are arranged sometimes renders long calculations needful in order to determine the positions which the moving object will occupy at successive moments; whilst if the body itself, submitted to those different forces, can be placed before the photochronographic apparatus, the path which it will follow expresses itself upon the sensitive plate.

Distinguished physicists disputed lately as to the form the free extremity of a vibrating stalk ought to present in which are produced curves and nodes: the greater number of them supposed that between the last node and its free extremity the stalk would present a bent form. Experiment has shown that it is not so, and that the last elements of the vibrating stalk are perfectly rectilinear (Fig. 11).

How many problems whose solution has formerly cost efforts of genius might be solved by a very simple experiment! Galileo in our day would not have needed to lessen the speed of the falling body in order to observe its motion. He would let fall a brilliant ball before a dark field, and would receive from it photographically successive images. Upon the sensitive plate he would have read, in the simplest way possible, the laws of space, of the speed and the accelerations which he has had the glory to discover.

To return to our subject, the laws of the resistance of the air to the living creatures of different forms which move in it ought to be searched into by photochronography. Already interesting results have been acquired: we have been able to determine the path of motion and the speed of small polished bodies (*petits appareils planeurs*) which move freely in the air, and which the eye has not time to follow in their rapid motions. Studies like these, undertaken and methodically carried out, will certainly lead to a comprehension of the still obscure mechanism of the hovering of birds.

TECHNICAL EDUCATION.

WHEN the time comes for the discussion of the new Technical Instruction Bill, attention will no doubt be given to an important series of resolutions (printed on the next page) which have just been passed by the Executive Committee of the North of England Branch of the National Association for the Promotion of Technical Education. The first six of these resolutions were unanimously adopted by the Committee, and the seventh was, on the motion of Mr. T. Burt, M.P., seconded by Mr. J. H. Girling (President of the Trades Council), adopted with one dissentient. The following are the advantages which the Committee desire to secure:—(1) For primary and secondary education a greater freedom of instruction under the existing code preparatory to technical education in the higher schools. (2) A direct or indirect pecuniary aid for superior education in science and art schools and in Colleges which afford technical education. (3) For all apprenticeship schools or trade classes a supervision by members of the trade, but no Government grant, thus to avoid any objections which might be raised by Trades Unions, or any jealousy arising from an apparent protection of one

or more particular trades. (4) For University Colleges a grant similar to that made to training Colleges for education afforded to persons intending to become teachers.

The resolutions are as follow:—

1. That public funds (rates and taxes) should not be employed to meet the current expenses of teaching specific trades.

2. That it is undesirable that instruction in the use of tools should be introduced into primary schools as a grant-earning subject.

3. That with a view to preparing pupils for technical education later on—

(*a*) The grant to day-schools should depend, to a much less extent than at present, on the results of the examination of individual pupils in reading, writing, and arithmetic, and should be largely dependent on the inspector's report of the general character of the teaching and the equipment of the school.

(*b*) There should be greater liberty in the choice of subjects in primary schools, and the same class subject should not necessarily be taken throughout the school.

(*c*) The grant to evening continuation schools should be regulated by the report of the inspector on the character of the teaching, and on the attendance list, and not upon the result of the examination of individual pupils.

4. That when a technical school is combined with a science and art school, the contribution to the building fund, through the Science and Art Department, should exceed £1000, if, in the opinion of the Department, the requirements of the locality demand it.

5. That it is desirable that, when specific trades are taught in technical schools, the practical teaching of each trade should be under the general direction of a committee, consisting mainly of members of that trade; that the teaching should be given in the evening, and be restricted to pupils actually engaged in the respective trades, and that, when specific trades are taught, any deficiency in current expenses should be guaranteed by the trade of the district.

6. That a certain percentage of persons preparing for appointments as teachers in elementary schools should be allowed to attend lectures and laboratory work at Universities and University Colleges, where a curriculum satisfactory to the Education Department is provided, and that the same grant should be made on account of such students as in the case of ordinary training Colleges.

7. That it is desirable that University Colleges in which higher scientific and technological training are combined should be assisted by a Government grant, provided that evening instruction is given in all the subjects taught, at fees which shall bring the advantages of the College within the reach of all classes. The due administration of the grant should be secured by the appointment of certain nominees of the Government on the Executive Council of the College.

THREATENED SCARCITY OF WATER.

THE appendices to the Weekly Weather Reports for the year 1887, recently published by the Meteorological Office, contain some interesting details relative to the rainfall. It is shown that the mean rainfall for the whole of the British Islands during 1887 was only 25·8 inches, whereas the mean for the twenty-two years 1866 to 1887 was 35·3 inches, so that there is a deficiency of nearly 10 inches over the whole area of the British Islands, or 27 per cent. less than usual. In the wheat-producing districts, which comprise the east of England and Scotland, the south of England, and the Midland Counties, the fall during 1887 was 21 inches, and the average value for twenty-two years is 28·5 inches, showing a deficiency in these parts of the Kingdom of 7·5 inches, or 26 per cent. less than usual. In the principal grazing districts, which comprise the west of England and Scotland, as well as Ireland, the fall in 1887 was 30·5 inches, and the value for the twenty-two years is 42·0 inches, showing a deficiency of 11·5 inches, or 27 per cent. less than the average. In the north-west of England the rainfall for 1887 was only 24·9 inches, which is 15·7 inches or 39 per cent. less than the average, and in the south-west of England the fall was 28·3 inches, which is 16·6 inches or 37 per cent. less than usual. Last year was the driest of any year since 1866, and this feature was common to all parts of the United Kingdom; the amount of rain measured was only about one-half of that recorded in 1872, which was the wettest year of the period. If the comparison is confined to the last ten years, the deficiency is nearly as marked, and 1887 is still found to be about 25 per cent. below the average, but the greatest deficiency in this case occurs in the Midland Counties, where it amounts to 36 per cent. of the average. The reports issued by the Meteorological Office for the first five or six weeks of the present year show the deficiency of rainfall still to be augmenting, and even more quickly than in any period last year. In the Midland Counties the rainfall to February 6 was only 0·6 inch instead of 2·9 inches, so that the deficiency from January 3 is as much as 79 per cent. of the average fall; and at Hereford, where the total fall is only 0·29 inch, the deficiency is 90 per cent. of the average. In the east of England the deficiency is 64 per cent., in the south-west of England 61 per cent., and in the north-west of England 58 per cent. There has been a deficiency of rain in all districts of England each week for seven consecutive weeks since December 19, with the exception of a single district (England N.E.) in one week, and since the beginning of October there have been but four weeks in which the excess of rain was at all general. Out of fifty-seven weeks since the commencement of 1887 there have been but ten in the south-west and east of England with an excess of rainfall, and only eleven in the north-west of England. With these facts to hand, there seems reasonable ground for alarm being felt in some localities at the threatened scarcity of water.

CHARLES HARDING.

PROFESSOR ASA GRAY.

WHEN the history of the progress of botany during the nineteenth century shall be written, two names will hold high positions: those of Prof. Augustin Pyrame De Candolle and of Prof. Asa Gray. In many respects the careers of these men were very similar, though they were neither fellow-countrymen nor were they contemporaries, for the one sank to his rest in the Old World as the other rose to eminence in the New. They were great teachers in great schools, prolific writers, and authors of the best elementary works on botany of their day. Each devoted half a century of unremitting labour to the investigation and description of the plants of continental areas, and they founded herbaria and libraries, each in his own country, which have become permanent and quasi-national institutions. Nor were they unlike in personal qualities, for they were social and genial men, as active in aiding others as they were indefatigable in their own researches; and both were admirable correspondents. Lastly, there is much in their lives and works that recalls the career of Linnæus, of whom they were worthy disciples, in the comprehensiveness of their labour, the excellence of their methods, their judicious conception of the limits of genera and species, the terseness and accuracy of their descriptions, and the clearness of their scientific language.

Asa Gray was born in Paris, Massachusetts, on November 18, 1810, and took his M.D. degree when twenty, at the Medical College of Fairfield, Oneida County. His proclivities were all scientific from a very early age, and he is said to have, whilst still a student, delivered lectures on chemistry, geology, and botany, in private establishments of that county. The two former subjects were at first his favourites—indeed, his earliest

contribution to science is a paper, by G. B. Crawe and himself, on the mineralogy of Jefferson and St. Lawrence Counties (N.Y.), in *Silliman's Journal* (1834, 346)—but they soon gave place to botany, owing to his having attracted the attention of Dr. John Torrey, State Botanist for New York, and Professor of Chemistry and Botany, but practically of botany only, in the New York Medical College. In 1833, Dr. Torrey made Gray his laboratory assistant, a post he held for some months, during which he presented what was his first botanical paper to the Annals of the New York Lyceum. This, which was on a very intricate and much misunderstood group of American sedges (*Rhynchospora*) showed Gray's acuteness as an observer, and skill in systematizing, as clearly as anything he has since written. In the following year he was appointed Curator of the New York Lyceum, where he extended his studies to the North American grasses and Cyperaceæ, and prepared his first botanical text-book, which was published in 1836, under the title of "Elements of Botany." The "Elements" is a noteworthy book; it was at once accepted as the best that had appeared in the States, and as second to none in the English language; its only rival was Lindley's "Introduction to the Natural System of Botany," the first edition of which had (in 1831) been reprinted under Dr. Torrey's supervision for the use of the American schools.

Whilst still attached to the New York Lyceum, Gray accepted the appointment of naturalist to Capt. Wilke's South Pacific Exploring Expedition, which was then being fitted out; but after two years' delay, and the curtailment of the opportunities for research that were to have been afforded him on the voyage, he threw up the appointment. This result is much to be deplored, for no young naturalist was ever better fitted by education, and by training as an observer and collector, to have taken advantage of the splendid opportunities which that expedition afforded.

Having relinquished the prospect of Pacific exploration, Dr. Gray was invited by his friend Dr. Torrey to co-operate with him in the preparation of a flora of the North American Continent; and into this work, which became the leading object of his scientific life, he eagerly entered. At the same time he accepted the Chair of Botany in the University of Michigan, subject to the condition of being allowed a year's leave to be passed in Europe for the purpose of verifying the nomenclature of the American flora by a study of the species of which the types existed only in European herbaria. This was in 1838, and his first visit was to Glasgow, where the then Professor of Botany (Sir W. Hooker) was engaged on a flora of British North America, under the auspices of the Secretary of State for the Colonies. After a long sojourn in Glasgow, Dr. Gray visited the principal herbaria in London, France, Switzerland, Italy, Austria, and Prussia, making life-long friendships with scientific men of all pursuits wherever he went; his letters of introduction, coupled with his bright intelligence, genial disposition, and charming personality, giving him the *entrée* to *salons* as well as to the museums of every capital. This was the first of seven visits that Dr. Gray paid to Europe, and of which the last was concluded a very few weeks before his fatal illness.

On his return to America in 1839, Dr. Gray resided at New York, when the first volume of the flora of North America was completed, in conjunction with Dr. Torrey, and the second, elaborated wholly by himself, was begun, but not completed till 1843. In the meantime (in 1842) he had been appointed by the Fellows of Harvard College, Cambridge, Fisher Professor of Natural History, the duties of which Chair were restricted to an annual course of lectures on botany, and the charge of the College Botanical Gardens, to which an official residence is attached. This was his home for the rest of his life, and here, with funds partly derived from the College, and partly from private sources, largely supplemented by interchanges of specimens and books, he founded the Harvard Herbarium and Library.

The great desideratum for the conduct of Dr. Gray's new duties was a much fuller class-book of botany than the "Elements" of 1836, and in the same year he completed the first edition of his "Botanical Text-book." In this the subject-matter is divided into two parts, one devoted to structural and physiological botany, the other to the principles of systematic botany, including chapters upon plants useful to man. This was the first of a series of editions of a work that has been for nearly half a century the text-book of schools and colleges throughout the United States, and the latter issues of which have been generally recommended by the botanical professors of the United Kingdom as the best of its class. In 1880 the first volume of the sixth edition appeared, but the advances in botanical science made since the fifth was published, quite a quarter of a century before, had been so many and great that the amount of matter which this sixth will contain is quadruple that of the fifth. It will be when complete a co-operative work in four volumes. The first is by Gray himself, and is devoted to morphology, taxonomy, and phytography; the second, by Prof. Goodale, Gray's able successor in the Fisher Professorship, includes vegetable histology and physiology; the third, by Prof. Farlow, will treat on Cryptogams; and the fourth, which Dr. Gray reserved for himself, was intended to be occupied by the classification of Phænogams, their special morphology, distribution, and products. Gray's other educational works are: "Lessons in Botany and Vegetable Physiology," somewhat on the plan of Lindley's "School Botany," but much fuller; also two smaller works, that for charm of matter and style have no equal in botanical literature—"How Plants Grow," and "How Plants Behave"—they rival chapters in Kirby and Spence's introduction to entomology in instruction and interest; and lastly, "Field, Forest, and Garden Botany."

The great outcomes of Gray's labours in systematic botany are his works on the flora of North America, from the Arctic islands to Mexico, and from the Atlantic to the Pacific Ocean. In one form or another these embrace a great proportion of the 10,000 or 12,000 species which that continent is supposed to contain. More than half are included in the two volumes published in conjunction with Torrey, and in his "Synoptical Flora," of which two parts are published, and in his "Manual of the Botany of the Northern States." The remainder are described or mentioned in more or less detail in multitudes of detached papers, and especially in memoirs upon collections made by naturalists attached to the many Expeditions organized by the Government for the exploration of railway routes across the continent, and by collectors and private individuals in previously unexplored regions. It was the hope of their author that the publication of these collections would have accelerated the completion of the general flora, and such would have been the case had their author lived; but as it is, the stars have in great measure obscured the planet, for one of the greatest obstacles to the study of North American plants is the multitude of these detached memoirs, with complicated titles, in which so many genera and species are to this day buried. If the great work cannot be continued, as it is to be hoped it may be, by Dr. Gray's most competent herbarium keeper, Sereno Watson, it is most desirable that the contents of these memoirs should be reduced to a systematic form with the least possible delay.

Next to the synoptical flora, Dr. Gray's most original work is his "Genera Floræ Boreali-Americana Orientalis," which was intended to contain descriptions, with figures, of every genus of the Eastern States, with discussions upon their affinities, morphology, and distribution. Only two volumes had appeared when want of funds decreed its end. As a fragment it is unique, and had it but been

completed it would have been of great morphological value. To have done this would, however, have required more than the ten volumes that were regarded when the work was commenced as sufficient to complete it, and this independently of the Cryptogams.

Nor was Dr. Gray's all closet work: he diligently collected and observed over a considerable area of his native continent; along the Altantic coast from Canada to Florida; in the prairie and Rocky Mountain regions from Wyoming to the borders of New Mexico; in the great basin of Utah and Nevada; and along the Pacific coast from Oregon to St. Barbara.

With two notable exceptions, Dr. Gray confined his descriptive work to North American botany. These exceptions were: one, the fragmentary botany of Wilkes's South Pacific Exploring Expedition, with the execution of which he was intrusted, but which came to an end before it was half finished, for want of funds it is believed, after the publication of one quarto volume with a superb atlas of plates; the other is a memoir on the flora of Japan, founded chiefly on the collections made in that country by the United States North Pacific Exploring Expedition, which in point of originality and far-reaching results was its author's *opus magnum*. By a comparison of the floras of Japan with those of Eastern and Western America, and of these with one another, and all with the Tertiary floras of the Northern States, he drew in outline the history of the vegetation of the north temperate hemisphere in relation to its geography, from the Cretaceous period to the present time. It is a brilliant generalization, bearing the unmistakable stamp of genius.

It remains to allude to Gray's admirable defence of the doctrine of "the origin of species by natural selection," of which he, as one of a favoured few, had been fully informed by Darwin himself in 1857 ("Life and Letters," ii. 120), before it appeared in the Linnean Journal. His opinion, which was, from the first, cautiously favourable, but with reserve, soon ripened into a conviction of the truth of the principles involved. He alludes to it first in the concluding remarks to his essay on the flora of Japan, cited above, published in 1859, wherein he says that he is "disposed to admit that closely related species may, in many cases, be lineal descendants from a pristine stock." Again, in a letter to Mr. Darwin, dated early in July 1860, speaking in terms of highest praise of the "Origin," the following passages occur:—"The moment I understood your premisses, I felt sure that you had a real foundation to hold on. Well, if one admits your premisses, I do not see how he is to stop short of your conclusions, as a probable hypothesis at least." And, referring to his own review of it in *Silliman's Journal* (March 1860), he says:—"It naturally happens that my review of your book does not exhibit anything like the full force of the impression the book has made upon me. Under the circumstances, I suppose I do your theory more good here by bespeaking for it a fair and favourable consideration, and by standing non-committed as to its full conclusions, than I should if I announced myself a convert; nor could I say the latter with truth." It may be remarked here that just at this time a battle over species was raging in America, of which but faint echoes reached our shores. This was over the question of the single or multiple origin of species by creation. Gray was the champion of single creations, and, believing himself strongly supported by theological considerations, may well have felt that the further leap to evolution was one into the dark. Be this as it may, for the five years following the publication of the "Origin," Gray devoted himself to impressing upon the American public his opinion of its extraordinary merits by reviews in weekly and monthly periodicals, by lectures, and by discourses at scientific Academies. Latterly (in 1876) he collected many of these into a single volume which he entitled "Darwiniana." In it he defines his own position "as one who is scientifically, and in his own fashion, a Darwinian, philosophically a convinced theist, and religiously an acceptor of the 'creed commonly called the Nicene,' as the exponent of the Christian faith." From this position he never moved, and he subsequently delivered two lectures in further exposition of these views, at the Divinity School of Yale College. These were published in 1880, under the title of "Science and Religion." Finally, Mr. Darwin, whilst fully recognizing the different stand-points from which he and Gray took their departures, and their divergence of opinion in some important matters, regarded him as the naturalist who has most thoroughly gauged his work, and as a tower of strength to himself and his cause.

As a reviewer and bibliographer, Gray's labours must have been Herculean, and they were uninterrupted for nearly half a century. Even when on his travels in Europe, he was in the habit of contributing scientific notices to periodicals in the States. In 1836 he commenced writing reviews of botanical works, and notices of botanists, travellers, and collectors for *Silliman's Journal of Science and Arts*; and this function he continued to perform without intermission (latterly as a co-editor of that important periodical) till within a few days of his last illness. The number of these articles is truly astonishing, as is the knowledge they display of all branches of botany, Phænogamic and Cryptogamic. They are without exception just, sober, and discriminating, critical rather than laudatory, and eminently considerate in tone where censure is necessary. A selection from these, many being discussions full of original matter and suggestive observations, would be an instructive and acceptable contribution to the botanical literature of the century, and a meet tribute to their author's merits and memory.

Dr. Gray's figure and features were familiar in the scientific circles of this country; but for the information of others it may be stated that he was of spare, wiry figure, rather below the average height, his expression was keen and vivacious, and his movements, like his intellect, alert. He was a Foreign Fellow of the Royal and Linnean Societies, a correspondent of the Institute of France, and of the other Continental Academies, a Doctor of Laws of Oxford, Cambridge, and Edinburgh, and had served as President of the American Academy of Arts and Science, of the American Association for the Advancement of Science, and as a Regent of the Smithsonian Institution. Accompanied by Mrs. Gray he spent the summer of 1887 in Europe, chiefly in England, returning to Cambridge in September. In October he went to Washington on the affairs of the Smithsonian Institute. Soon after his return, on the 28th of November, he was struck with paralysis, from which he never rallied, and he died at the end of the following January. It is characteristic of him that his last letter, written in pencil immediately before his seizure to the contributor of these lines, was on the subject of a review for *Silliman's Journal* of Planchon's "Review of the Vines." Dr. Gray married in 1848, Jane, daughter of Judge Charles G. Loring, of Boston, who survives him. He left no family. An excellent medallion likeness of him in bronze was, on his seventy-fifth birthday, presented by his friends to Harvard College, Cambridge, U.S.

J. D. H.

NOTES.

On Tuesday evening a question was asked in the House of Commons, by Mr. Howorth, about the new regulations for the entrance examination at Woolwich. Mr. Howorth inquired whether these regulations were final and permanent, or only temporary. Mr. Stanhope, we regret to say, replied that the regulations are intended to be of permanent application. If that be so, it is the more necessary that a vigorous protest against the scheme should be made by those who have any

true appreciation of the place which properly belongs to the study of science in education.

On Tuesday the Committee of the Athenæum Club elected three new members in accordance with the rule which empowers the election of nine persons annually "of distinguished eminence in science, literature, or the arts, or for public services." The names of two of the new members are familiar to students of science—Major-General Donnelly, R.E., C.B., Secretary to the Department of Science and Art; and Prof. G. Carey Foster, F.R.S.

One of the leading native residents of Bombay, Sir Dinshaw Petit, has just given the Bombay Government a property valued at 300,000 rupees for the establishment of the proposed Technical Institute of Bombay.

We regret to announce the death of Dr. Maximilian Schmidt, an eminent geologist and Director of the Zoological Gardens at Berlin. He was born at Frankfurt in 1834, and died at Berlin.

Emile Rousseau, the well-known French chemist, died on the 4th inst., at the age of seventy-three.

The annual general meeting of the Fellows of the Royal Horticultural Society was held on Tuesday, Sir Trevor Lawrence, President of the Society, in the chair. The special Committee appointed to inquire into the working of the Society recommended that premises in No. 111 Victoria Street should be secured, and that for shows and meetings the Society should hire the drill-hall of the London Scottish Rifle Volunteers. The Committee also reported that they had under consideration "the construction of new by-laws intended to facilitate the carrying out of as complete a horticultural policy as possible—one in which all aspects and departments should be considered to the undue preponderance of none; but to the general advantage of all." After some discussion the Committee's recommendations were adopted. Several members of the Council having placed their resignation in the hands of the Fellows, it was resolved on the motion of Mr. Wilks, seconded by Mr. Veitch, to decline to accept their resignation, and they were then all formally re-elected, including Sir Trevor Lawrence, who was re-appointed President.

The Calendar and General Directory of the Science and Art Department for 1888 has been issued.

The curious fact was some time ago brought to light by Nahrwold that solid particles are ejected from a platinum wire glowing under the influence of an electric current, and form a metallic incrustation upon the walls of a glass tube by which the wire is surrounded. The cause of the emission of these solid particles of platinum has, however, until recently, remained a complete mystery. In the number of the *Annalen der Physik und Chemie* just received will be found an interesting paper by Dr. Alfred Berliner, who, in the course of a series of experiments upon the occlusion of gases by platinum and palladium, has discovered the source of this singular phenomenon. Thin strips of platinum, before being charged with the gas under experiment, were inclosed in a narrow glass tube, and freed from all occluded gas by being heated to redness, *in vacuo*, by the passage of a constant electric current for several hours. At the expiration of this time the metallic incrustation was invariably found when occluded gas had been evolved. On charging the strips with various quantities of any particular gas, the amount of incrustation formed after the complete expulsion of the gas in each experiment was found to vary in the same proportion. Hence it appears pretty clear that the evolution of gas is necessary for the emission of solid particles. This result is strongly confirmed by the fact that palladium, which has such a remarkable power of occluding gases, produces a similar incrustation much more readily and at a lower temperature. It appears probable that the action is merely mechanical; that we have, in fact, an immense number of microscopic volcanoes or solfataras, evolving the occluded gases with such energy that portions of the crater walls are detached and carried away by main force, like their brethren on the large scale, the scoriæ and lapilli, to distances very considerable in comparison with the size of the vents.

The next meeting of the French Association for the Advancement of Science will be held in Oran from March 29 to April 3. Interesting excursions will be made to Biskra and other places.

At the meeting of the Meteorological Society of France, on December 20, M. E. Lemoine was elected President for the ensuing year. M. Renou made a communication on the relations which exist between the annual number of solar spots and thunder-storms in various places, and concluded that the works hitherto published were far from sufficing to show any direct dependence between the two phenomena. At the meeting of January 11, M. Janssen, the retiring President, expressed his opinion of the necessity of organizing meteorological stations on a uniform plan at a certain number of stations, under the superintendence of professional and paid observers on whom a definite programme could be imposed, instead of having volunteer observers; this view was also supported by M. Renou. The latter gentleman also spoke of the importance of adopting a uniform cloud nomenclature, and announced that he would shortly present to the Society a work upon this subject. The general secretary presented a note from M. Garrigou-Lagrange on a new electrical anemometer giving the direction of the wind, and the horizontal and vertical components of its force (see Nature, November 3, 1887, p. 18), and recommended its adoption at some coast stations.

The Council of the Royal Meteorological Society, 30 Great George Street, Westminster, S.W., have appointed a Committee to collect observations on British hail- and thunder-storms from volunteer observers. The objects which they hope to attain thereby are:—(1) A knowledge of the nature and causes of the different kinds of thunder-storms, their attention having been specially called to the subject by the great loss of life and property during the past summer. (2) A discovery of the localities where hail and thunder are most frequent and destructive. (3) If possible, to obtain an increased power of forecasting hail and thunder, whereby they hope that eventually damage to persons, stock, and property might be lessened. Forms and instructions will be sent to intending observers.

We have received a "Brief Sketch of the Meteorology of the Bombay Presidency in 1886-87." It is by Mr. F. Chambers, Meteorological Reporter for Western India. Mr. Chambers points out that the meteorology of the year 1886-87 in the Bombay Presidency presents several features of special interest. There was a decided reappearance, for some time, of almost exactly the same unfavourable meteorological conditions which characterized the year 1877, when the rainfall in many parts of the Presidency was disastrously deficient. Fortunately, these unfavourable conditions did not last long enough to produce distress, for although a prolonged break in the rains caused considerable anxiety for a time, an excessive fall of rain late in the season brought relief, and on the whole the year was a favourable one.

A severe earthquake occurred in Grenada on January 10. A rumbling noise was immediately followed by a slight shock and gentle lateral oscillations. Then came a very violent shock and vertical undulating oscillations. These were succeeded by gentle oscillations. The shock is supposed to have lasted from twenty to thirty seconds. Several houses in the town of

St. George's were so much damaged that they cannot be safely occupied. The walls of the St. David's Roman Catholic Church are so seriously injured that they will have to be taken down in some places and rebuilt. The sacristy was all but demolished; the basement wall of the presbytery was thrown down, and the building itself had to be propped up with posts. The Court House in the same parish sustained considerable injury. The tower of the Anglican Church in Grenville was cracked. During the succeeding week several mild shocks of earthquake were experienced in the island, the strongest of which occurred between 7 and 8 o'clock on the night of Sunday, January 15.

DR. FORBES WATSON'S collection of commercial products, which was lately offered to the University of Aberdeen at the comparatively small price of £250, has been bought by Dr. Carnelley and his father, and presented to University College, Dundee. Prof. D'Arcy W. Thompson, at whose suggestion the purchase was made, writes to the *Dundee Advertiser*: "This excellent gift puts us at once in possession of a museum which is first-class of its kind, and of which town and College should be proud for ever. Dr. Forbes Watson is well known to many of the older men in Dundee for his knowledge of jute and all other commercial fibres. His works are standard on the subject. His collection was amassed with unrivalled opportunities and the highest technical skill. Great part of it was brought together as an official duty for the India Museum, and was presented by the Department to Dr. Forbes Watson when that Museum was broken up. It contains nearly 7500 samples. Between 700 and 800 of these are fibres, including textiles and paper-making materials. There are over 500 dyes and dye-stuffs, 500 oils and oil-seeds, 600 or 700 gums, resins, and guttas, nearly 2000 medicinal substances (may they be useful to us in the future), and more than as many samples of food-stuffs. The bulk of the collection is stored in bottles, filling fourteen cabinets, and there are also stands and cases for the display of specimens. Altogether the cases and bottles in which this great collection is stored represent a cost greater than the price which Dr. Forbes Watson now asks and receives."

THE Batavia *Niewsblad* announces that the Government has decided upon establishing a bacteriological laboratory in that town. An institution for the pursuit of that special branch of study will be built immediately the funds for the purpose become available. The existing laboratory arrangements will be improved and extended, so as to admit of pathological and bacteriological investigations.

WE are glad to learn from the *American Naturalist* that the project of a Marine Biological Laboratory on the New England coast is not languishing. Several thousand dollars have already been subscribed towards the erection of the necessary building and its equipment and maintenance. The Committee on the Laboratory have arranged a course of eight lectures, the proceeds of which are to be added to the fund.

LIEUT. NIBLACK, U.S.N., has returned to Washington from a three-years' voyage to Southern Alaska, where he has been engaged on coast-survey duty. He has brought with him many photographs and objects which will be of interest to students of ethnology and anthropology. He devoted special attention to the totem posts of Southern Alaska. He says that in that country winter is the best season for ethnological studies. The natives are then at home, whereas in the summer they are often far inland.

ASSISTANT CHARLES A. SCHOTT, assistant in charge of the Computing Division of the United States Coast and Geodetic Survey, has addressed a letter to the Superintendent of his Bureau about the recent discovery, by Assistant G. Davidson, of records of the magnetic declination, A.D. 1714. He says that these records greatly increase our knowledge of the secular variation of the declination. *Science* gives the following account of the substance of M. Schott's letter:—"By means of these observations we are able to improve materially the expressions for San Blas and Magdalena Bay, to add the new station Cape San Lucas, and to make their influence felt as far north as San Diego and Santa Barbara. It is the range which is greatly improved; besides, the epoch of maximum declination is shifted in the right direction. Apart from the fact that a region of west declination is here for the first time observationally indicated on the Pacific coast, the power of the newly recovered declinations is due to the circumstance, that, as far as known, they cover a time when the needle was in or near a phase the opposite of the present one. For want of early observations, those previously collected for San Diego and Santa Barbara, Cal., were extremely difficult to handle; and, while it was not an easy matter to establish new expressions for these stations, their correctness, or rather applicability over the whole period of time the observations cover, is quite reassuring. He points out the desirability of new observations (either using funds yet available before July next, or providing funds to be used after that date) at San Diego, Santa Barbara, and Monterey, and states that these stations have received no attention for seven years. These observations are demanded to give greater precision to the computed variations on our charts."

A NUMBER of American geographers, all belonging to Washington, have incorporated the American National Geographical Society for a term of 100 years. The principal objects of the Society are to increase and diffuse geographical knowledge, to publish the Transactions of the Society, to publish a periodical magazine and other works relating to the science of geography, to dispose of such publications by sale or otherwise, and to acquire a library under the restrictions and regulations to be established by its by-laws.

THE Commissioners of Public Schools of Baltimore, Md., deserve much credit for the efforts they are making to secure for the schools under their care important reforms which have always been advocated by students of sanitary laws. They lately resolved that the Mayor and City Council of Baltimore should be requested to authorize them to appoint an officer, to be known as the Sanitary Superintendent of Public Schools, whose duty would be: (1) to carefully examine all plans submitted for the construction of new school-houses, and suggest such modifications as may be necessary from a sanitary point of view; (2) to advise with the Commissioners with reference to necessary alterations in school-buildings to improve their hygienic condition; (3) to examine all text-books before adoption, in order that type, printing, or paper injurious to the eyesight of pupils may be avoided in selecting such books; (4) to satisfy himself, by personal examination if necessary, that all pupils admitted to the schools have been properly vaccinated, or are otherwise protected against small-pox; (5) to take such other measures, in conjunction with the Health Commissioner of the city, as may be necessary to prevent the spread of contagious diseases in, or through the medium of, the public schools; (6) to examine annually the eyesight of all children attending the public schools, and keep an accurate record of such examinations; (7) to report annually, or as often as may be required by the Commissioners, upon the sanitary condition of the schools, and of the pupils attending them, and to advise the Commissioners upon sanitary questions connected with schools whenever required; (8) to give instruction, by lectures or otherwise, to the teachers in the schools upon the elementary principles of school hygiene.

WE have received the second volume of the Transactions of the Meriden (Conn., U.S.A.) Scientific Association. It contains, among other things, a valuable list, drawn up by Mr. Franklin Platt, of the birds of Meriden.

A THIRD edition of Mr. John Venn's "Logic of Chance" (Macmillan) has just been issued. The work has been re-written, but the author explains that the alterations he has made do not imply any appreciable change of view on his part as to the foundations and province of probability. In the preface Mr. Venn mentions that he is engaged in preparing a work on inductive logic.

THE scientific writings of Jean Méry (1645–1722) have been brought together in a work edited by M. L. H. Petit, Assistant Librarian to the Medical Faculty of Paris. The work contains many contributions to biology which have not hitherto been generally known.

TOME III., Cahier I, of the "Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux," is devoted to a full bibliography of the Γ function.

WE have received the *Annuaire de l'Observatoire Royal de Bruxelles* for 1888, this being the fifty-fifth year of its publication. It contains the usual astronomical tables and data for the current year, and a mass of meteorological, geographical, financial, and other statistics. There is a complete list of the asteroids and comets discovered in the past year, with the elements of their orbits, and there is also an account of the state of solar activity in 1886. The tables of units and physical constants have been considerably extended, and a detailed account of electrical and magnetic measurements has been added. In addition there are, as usual, several scientific papers by the officials of the Observatory. M. Folie gives an account of his further investigations into the movements of the earth's axis, and in a subsequent article M. Niesten applies the correction for diurnal nutation to the various and widely differing determinations of the annual parallax of γ Draconis; the value obtained is $+0''\cdot086$. The important series of barometric observations, extending over a period of fifty years, are discussed at great length, and illustrated by diagrams.

MR. JOHN HEYWOOD, of Manchester and London, has issued a little book called "Flower-Land," by the Rev. R. Fisher. It is written in a simple style, and will no doubt be useful as an introduction to botany for children.

THE Perthshire Society of Natural Science has begun to issue Transactions and Proceedings. We have received the first part of the first volume. It contains notes on some rare birds lately placed in the Society's Museum, by Colonel H. M. Drummond Hay; mnium riparium, by R. H. Meldrum; some localities for Perthshire plants, by R. H. Meldrum; origin of the interbedded and intrusive volcanic rocks of Kinnoull Hill, by H. Coates; and the flora of the Woody Island, by W. Barclay.

MESSRS. KEGAN PAUL, TRENCH, AND CO. will publish immediately, in the "International Scientific Series," Sir J. William Dawson's new book entitled "The Geological History of Plants."

"A HISTORY OF PHOTOGRAPHY," by Mr. W. J. Harrison, will shortly be published. It is intended to serve as a practical guide to photography, and as an introduction to its latest developments.

A WORK containing a full account of the volcanic eruptions for the last sixty-four years on the island of Hawaii has been printed and will shortly be published in the city of Honolulu. The author is Mr. William Lowthian Green, at present Prime Minister of the kingdom of Hawaii, whose work on "The Vestiges of the Molten Globe" appeared in England some years ago, and has since attracted the attention of M. Lapparent and other Continental geologists. Mr. Green's new work will contain a complete tabular statement of the eruptions, and a map of the island of Hawaii.

MR. EDGAR THURSTON, Superintendent of the Government Central Museum, Madras, has printed a list of fishes obtained during a residence of three weeks at Râméswaram Island, which is separated on the one hand from the Indian continent, and on the other from the Island of Manaar, by an interrupted ridge of rocks known as Adam's Bridge. The fish-fauna of the coral reefs of this island stands out in striking contrast with that of other places on the Madras coast. "Coral Fishes," *i.e.* brightly coloured fishes—*Chætodon*, *Platyglossus*, *Heniochus*, *Pseudoscarus*, &c.—abound round the reefs, and feed either on the small delicate marine Invertebrata which swarm on the living corals, or, if their teeth are adapted for the purpose, on the hard calcareous substance of the corals. The bright colouring of the fishes is explained by Mr. Thurston on the well-known principle that "the less the predominant colouring of any creature varies from that of its surroundings, the less will it be seen by its foes, the more easily can it steal upon its prey, and the more it is fitted for the struggle for existence." Conspicuous by their abundance are several species belonging to the family Sclerodermi, including *Balistes* (file-fish), whose jaws are armed with teeth well suited for breaking off pieces of hard coral, or boring holes into the shells of the Mollusca, on the soft parts of which they feed. The file-fishes are said to destroy an immense number of mollusks, thus becoming most injurious to the pearl-fisheries. Present, too, in great numbers are several species of the family Gymnodontes: *Tetrodons* (globe fishes), including the beautifully marked little *Tetrodon margaritiferus*, and *Diodons*, which have a very bad reputation among the natives as being very poisonous.

IT is generally supposed that the Ainos of Yezo are amongst the disappearing races of the earth, and that they are "fast dying out," as the phrase usually runs. This appears to be an error, for according to a communication on the subject in the *Japan Weekly Mail*, from Mr. Bachelor, during the past fifteen years there has been little, if any, diminution in their number, which he puts down, so far as the Island of Yezo is concerned, at from 1300 to 1600 souls. Actual detailed statistics respecting the numbers of the Ainos do not appear to be given in the Japanese censuses, but official statistics do exist for certain Aino settlements since 1871, which may be taken as an index. These show an increase of 129 persons in sixteen years, although, by a careful examination of the data, it appears that one village not included in the earlier was given in the later years. In 1871, there were 665 males, 639 females, and 260 huts; in 1886, the numbers were 691, 742, and 318 respectively. These figures, making every reasonable allowance, show at least that there is good ground for doubting whether the Ainos are dying out, in Yezo at least, as rapidly as it is the fashion to assume that they are.

THE seventh annual meeting of the members of the Sanitary Assurance Association was held at their offices, 5 Argyll Place, Regent Street, on Monday. Prof. Roger Smith presided, and expressed his satisfaction at the continued prosperity of the Association.

IN the footnote in NATURE, December 15, 1887, p. 152, second column, line 5 from foot, *for* Careton *read* Cureton.

THE additions to the Zoological Society's Gardens during the past week include a Common Boa (*Boa constrictor*) from South America, a Royal Python (*Python regius*), two West African Pythons (*Python sebæ*) from West Africa, an Indian Python (*Python molurus*) from India, presented by Mr. Leopold Field; a Griffith's Fox (*Canis griffithi*) from Persia, two Cockateels (*Calopsitta novæ-hollandiæ*) from Australia, deposited; a Pluto Monkey (*Cercopithecus pluto*) from West Africa, an Antarctic Skua (*Stercorarius antarcticus*) from the Antarctic Seas, received in exchange.

OUR ASTRONOMICAL COLUMN.

MELBOURNE OBSERVATORY.—The Annual Report of this Observatory, dated August 14, 1887, states that the buildings and equipment of the Observatory were in good condition with the exception of the mirrors of the great Cassegrain reflector, which had become so dull as materially to interfere with the observation of the fainter nebulæ. It was proposed to substitute mirror A, the less tarnished of the two, for mirror B, now in the telescope, and either to have B repolished on the spot or to send it to Dublin to be re-polished under the care of Sir H. Grubb. The new transit circle was in excellent order, and 2487 right ascensions and 1301 polar distances had been observed during the year. Eighty-seven southern nebulæ had been examined with the great reflector, and four searched for, but not found. The use of the photo-heliograph, which had been altered in July 1886, so as to take pictures on a scale of 8 inches to the solar diameter, had been much interfered with by bad weather, and only 121 photographs had been secured. The principal fresh work proposed for the Observatory was the co-operation in the photographic survey of the heavens; the Victorian Government having consented to the Observatory joining in that undertaking, and having placed £1000 on the estimates of the current year towards the necessary expenditure.

THE AMERICAN NAUTICAL ALMANAC OFFICE.—The Report of Prof. Newcomb, Superintendent of the Office, for the year ending 1887 June 30 has recently appeared. From this we learn that the printing of the several Nautical Almanacs published by the Office fell a little into arrear in 1887, the printing of the American Ephemeris for 1890, which should, according to custom, have appeared in June, not being quite ready in October. The computations for the following years were in their usual state of forwardness. The principal part of the Report deals with the new tables of the planets on which Prof. Newcomb and his assistants are engaged. The work is divided into four sections—viz.: (I.) The computation of the general perturbations of the planets, the work now in hand relating to those of the four inner planets; on twelve of the fourteen pairs of planets which come into play in this part of the undertaking, the work has already been completed. The incomplete perturbations are those of Venus and Mars by Jupiter. (II.) The re-reduction of the older observations, and discussion of the later ones, with a view of reducing them all to a uniform system. In this section Maskelyne's Greenwich observations from 1765 to 1811, and Bradley's, 1750 to 1762, have been already reduced, the latter by Dr. Auwers. Airy's Greenwich observations, the Paris observations from 1800 as reduced by Leverrier, and Bessel's Königsberg observations, will need no discussion except that necessary to reduce them to the adopted standard system. The re-reduction of Piazzi's Palermo observations, 1791–1813, is in hand, but it is not yet decided as to whether Taylor's Madras observations should be included. (III.) The computation of tabular places of the planets from Leverrier's tables up to the year 1864—the most laborious and difficult part of the work—is in a fairly advanced state. (IV.) The final discussion of the results. Prof. Newcomb estimates that the equations of condition for correcting the elements of the four inner planets will be ready for solution towards the end of 1889, but they will involve extended discussion and comparison in order to get the results in the final form for publication. Of the work on the four outer planets, Uranus and Neptune are yet untouched; but Mr. Hill's new theory of Jupiter and Saturn is in the hands of the printer, and Mr. Hill is now engaged in the construction of the tables and ephemerides for finally correcting their elements. In connection with the lunar theory, the principal work on hand is the comparison of Hansen's tables with observed occultations since 1750. Another branch of the planetary work is the determination of the mass of Jupiter from the motions of Polyhymnia: the perturbations of the planet have been computed from its discovery in 1850 to October 1888, and the work awaits the observations during the approaching opposition to be brought to a final discussion.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 FEBRUARY 19–25.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 19

Sun rises, 7h. 9m.; souths, 12h. 14m. 6·2s.; sets, 17h. 19m.: right asc. on meridian, 22h. 9·7m.; decl. 11° 22′ S. Sidereal Time at Sunset, 3h. 15m.

Moon (at First Quarter February 20, 2h.) rises, 10h. 25m.; souths, 17h. 46m.; sets, 1h. 18m.*: right asc. on meridian, 3h. 42·8m.; decl. 14° 34′ N.

GEOGRAPHICAL NOTES.

AT Monday's meeting of the Royal Geographical Society, the paper read was by Mr. Randle F. Holme, on Labrador, which he visited in July–October of last year. Mr. Holme succeeded in penetrating into the heart of Southern Labrador, as far as Lake Waminikapou, and not far from the Grand Falls, which Mr. Holme believes will turn out to be the greatest falls in the world; but, as General Strachey pointed out in the discussion, Mr. Holme's conception of the height is probably exaggerated. Mr. Holme went from Newfoundland to Bonne Espérance on the south-east coast of Labrador, and sailing northwards touched at several points, proceeding up Hamilton Inlet and the Grand River, to the point mentioned above. Mr. Holme found many difficulties in the way, and much of the country he visited was virtually unexplored. With regard to the height of the Grand Falls, Mr. Holme states that the centre of Labrador, as is generally known, is a vast tableland, the limits of which are clearly defined, though

of course the country intervening between this limit and the coast always consists, more or less, of a slope. Roughly speaking, it may be said that in the south and north there is a more or less gradual slope from the height of land to the coast, while in the south-east the descent is sudden, and almost immediately after leaving the tableland there is reached a level which is but little above that of the sea. In the north-east portion the edge of the tableland approaches nearest to the coast, while it trends considerably to the west in the rear of Hamilton Inlet. The most fertile part of the country is that which lies between the tableland and the sterile belt on the coast, though the height of land itself is by no means a desert. On the height of land there is found a succession of great lakes joined together by broad placid streams. When the streams of water reach the edge of the tableland, they of course commence a wild career down towards the sea. In the case of the Grand River this rapid descent commences with the Grand Falls, and almost the whole of the great drop to the sea-level is effected in the one waterfall. The elevation of the Labrador tableland is given by Prof. Hind as 2240 feet. From this height the Moisie and Cold Water Rivers descend to the sea by means of a considerable number of falls. But in the Grand River below Lake Waminikapou there is only one fall, viz. that which occurs 25 miles from the river-mouth. This fall is 70 feet. It is true that the whole of the river from Lake Waminikapou to the First Falls is rapid, but there is no place where there is any considerable drop, and indeed no place where it is necessary to take the boat out of the water. Now the lake first above the Grand Falls is on the height of land. In the channels joining the various lakes above the falls there are no rapids and there is scarcely any stream. It therefore follows, assuming the elevation of the tableland on the east to be approximate to that on the south, that in the 30 miles beginning with the Grand Falls and ending with Lake Waminikapou, there is a drop of about 2000 feet. Some of this drop is probably effected by the rapids immediately below the falls, but the greater part is no doubt made by the fall itself. The river is said by Maclean to be 500 yards broad above the falls, contracting to 50 yards at the falls themselves. The interior of the country Mr. Holme found was richly wooded, and the climate mild, though the plague of flies and mosquitoes was almost intolerable. The few Indians who inhabit Labrador belong mostly to the Cree nation, and according to Mr. Holme are probably perfectly unmixed with either whites or Eskimo. As an agricultural or pastoral country Mr. Holme thinks Labrador has no future, though something may be made of its iron, of the existence of which strong indications exist. Mr. Holme's observations have enabled us greatly to improve our maps of Labrador, and the photographs he brought home give an excellent idea of the general character of the country.

OUR ELECTRICAL COLUMN.

SOME very interesting and remarkable trials of the transmission of energy were recently made between Kriegstetten and Solothurn in Switzerland, by Prof. H. F. Weber and others, when it was found that 30 horse-power put in at the first place delivered 23 horse-power at the other, 8 kilometres away—showing an efficiency of 75 per cent. The current, 11 amperes, driven under an E.M.F. of 2000 volts, showed absolutely no loss whatever, owing to the use of Johnson and Phillips' "oil" insulators. This mode of insulation proved absolutely perfect.

THE distribution of electricity for lighting purposes by means of secondary generators, is now being discussed at the Society of Electrical Engineers. This mode of working seems to have solved the question of the economical erection of conductors. Alternate currents of high tension in the main conductors allow wires of small diameter to be used, and a special form of induction coil transforms these currents of high tension, 2000 volts, to currents of low tension, 100 volts and under, for use in private houses. The system, due to Messrs. Gaulard and Gibbs, is in use at the Grosvenor Gallery installation, as well as at Eastbourne and Brighton, and is probably going to be largely used. Mr. Kapp's paper "On Alternate Current Transformers, with Special Reference to the Best Proportion between Iron and Copper," will lead to an interesting discussion. All induction coils, when used as transformers, are simply a magnetic circuit or closed iron core interlaced with an electric circuit or a closed copper core, and constructed so that the electric circuit shall embrace as many as possible of the lines of force of the magnetic circuit. Mr. Kapp divides transformers into two classes—one in which the copper coils are spread over the surface of the iron core as in a Gramme armature, and the other in which the iron core is spread over the surface of the copper coil. The former he calls "core transformers," and the latter "shell transformers." He advocates working transformers at low inductions—that is, far below the point of saturation of iron—because it increases the plant-efficiency, reduces the heat or energy lost in the iron core through hysteresis, and prevents the production of sound. The plant-efficiency of transformers sometimes reaches as high as 99 per cent., and they are perfectly self-regulating. There is very little choice between core- and shell-transformers, but the former have the advantage. Economy in construction and facility in manufacture and repair seem to be principal points of advantage to reach. It is amusing to find how, now that the system has proved to be practical, every man is devising his own transformer, and labouring to show that Gaulard and Gibbs were not the inventors of the system, and that their transformers are not the best.

PROF. EWING'S discovery of hysteresis in iron has been shown, both by Kapp and Ferrari, to play a very significant figure in the efficiency of transformers.

GUGLIELMO, of Turin, has shown that no loss of electricity takes place through moist air surrounding an aërial wire unless the E.M.F. exceeds 600 volts, after which the leakage increases with the E.M.F. and the saturation of the air.

IN Boston an electric lamp has recently been used to search for a body drowned in the harbour. The U.S. steamship *Albatross* is furnished with a full complement of lamps for fishing. The glow-lamp is encased in a wire netting, which acts as a trap. The fish, being attracted by the light, swarm into the net, which is then closed and pulled in.

THE new number just issued (No. 201) of the Proceedings of the Royal Society contains the following electrical papers: "On the Photometry of the Glow-lamp," by Captain Abney and General Festing; "On the Development of Feeble Currents," by Dr. Alder Wright and Mr. C. Thompson; and "On the Heating-Effects of Electric Currents," by Mr. Preece.

MAKING GLASS SPECULA BY HAND.[1]

THE author of this paper gives a very interesting account of the construction of glass specula, discusses the actual difference in form between a spherical and a parabolic mirror, and gives an account of some experiments to determine the thickness of the silver film. In making the specula Mr. Madsen used glass for the grinding tool in place of metal, as he considered that the coefficient of expansion of iron and glass being different, greater truth would be obtained by the use of the same material for the tool, thus following the practice of Foucault and of the French opticians of the present day. When a true spherical surface was thus obtained the polish was given by rouge on pitch with a tool the same size as the mirror, and the correction of the spherical curve was obtained by a very ingenious plan of graduating the polisher in such a way that the greatest action would be on the required part of the mirror, the arrangement of the squares of pitch being such as to prevent the occurrence of rings of unequal polish. In this Mr. Madsen seems to have been most successful.

In working, the mirror was uppermost, and this is a very important point in many respects. There is no doubt that in working this way the mirror is in the condition of least strain, and if it were possible this plan should always be followed, but it is absolutely impossible to do this with a mirror much larger than the size he worked, which might almost be taken as the limiting size of mirror possible with this method of working. Short, Mudge, Herschel, and all the early workers used this plan in making their comparatively small mirrors; but since, with larger sizes, the mirrors have been worked face upwards as the only possible way, and it is to be regretted that this plan was not followed.

In discussing the actual amount of the glass to be abraded to obtain the correction, the author finds that for telescopes where the focal length exceeds twentytimes their diameter this amount is

[1] "Notes on the Process of polishing and figuring 18-inch Glass Specula by Hand, and Experiments with Flat Surfaces," by H. F. Madsen. (Journal and Proceedings of the Royal Society of New South Wales, vol. xx., 1886, pp. 79-91).

so small that it can be neglected, and that a spherical form is as good if not better than any other; and there is no doubt, for telescopes of about this ratio, Sir John Herschel is quite right when he makes the statement in "The Telescope," p. 81, "that is a good form that gives a good image; and that the geometrical distinctions between the parabola, sphere, and hyperbola, become mere theoretical abstractions in the figuring and polishing of specula." But in the case where the aperture of the mirror is about one-sixth of the focal length the distinction between the sphere and the parabola does exist and becomes a large quantity, which only the Foucault method of working allows to be dealt with properly. In enumerating the different plans used by opticians in getting the parabolic curve, the author is in error in stating that Lassell adopted the method of local polishing, as he always used a large tool, and got the figure by alterations of the stroke. Foucault was the inventor of the system of local polishing, and this was afterwards used by Draper, who finally rested on that as the best method of working.

The author considers that when the focal length exceeds 40 feet even with a theoretically perfect mirror the slightest touch or variation in temperature will be sufficient to destroy good definition with high powers, irrespective of the disturbing effects of the atmosphere, and he comes to the remarkable conclusion that "by decreasing the focal length the rays cross at a less acute angle, and small variations in the reflecting surface have not so detrimental an effect"—a statement that is entirely unsupported.

No actual tests of the work that the 18-inch mirrors will do are given. The experiments on the thickness of silver-on-glass films are interesting, as are also those on the effect of pressure or heat in altering the colours or colour-bands seen between two plane surfaces almost in contact. Dr. Draper, by actually weighing the amount of silver deposited on a large surface, came to the conclusion that it was about 1/200,000 of an inch thick; and the author, by comparing its thickness with the length of a wave of light, comes to about the same conclusion, and considers that by ordinary care in polishing no optical change will be produced in the reflecting surface by the film of silver deposited upon it.

The roads to success in making the mirrors of a reflecting telescope are many and various. Almost every maker in this fascinating pursuit had his own that gave to him best results. This was more particularly the case before Foucault published his most admirable memoir on the construction of silver-on-glass telescopes. In this memoir Foucault describes his method of local polishing, and the tests that can be applied to the concave surface, and a method of obtaining the true parabolic surface with absolute certainty, bringing the art of specula-making at once to a system of working by measurements in place of the old empirical process that had up to that time been in use; and everyone now uses Foucault's method of *testing* concave surfaces, and nearly everyone his plan of figuring by local polishing. Mr. Madsen gives a very interesting account of the road he took, an account that would have been much more valuable if the details of the processes used in making both the concave and the flat mirrors had been fully given, as it is now more in the improvements in these details that gain is to be looked for than in any of the main lines already known.

A. AINSLIE COMMON.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 2.—"On the Spectrum of the Oxyhydrogen Flame." By Profs. G. D. Liveing and J. Dewar.

In a former communication the authors described simultaneously with Dr. Huggins the strongest portion of the spectrum of water; subsequently they described a second less strong but more refrangible section of the same spectrum. M. Deslandres has noticed a third still more refrangible section. The authors now find that the spectrum extends, with diminishing intensity, into the visible region on the one hand, and far into the ultra-violet on the other. These faint parts of the spectrum they have photographed, using the dispersion of a single calcite prism and a lengthened exposure; and in the present communication they give a map of the whole extent observed, and a list of wave-lengths of upwards of 780 lines.

The spectrum exhibits the appearance of a series of rhythmical groups more or less overlapping one another, and the arrangement of the lines in these groups is shown to follow, in many cases, the law that the distances between the lines, as measured in wave-lengths, are in an arithmetic progression. M. Deslandres had previously announced that the succession of lines in several spectra, as well as in the telluric groups A, B and α of the solar spectrum, follow this law when their distances are measured in reciprocals of wave-lengths, and he has stated that the groups A, B and α have counterparts in the spectrum of water. The authors find a striking resemblance between those groups and certain parts of the water spectrum, but no exact correspondence.

Dr. Grünwald, of Prague, predicted on theoretical grounds that certain lines would appear in the spectrum of water, and the authors have found a considerable number of lines which tally closely with Dr. Grünwald's predictions, some of them, in the extremities of the spectrum, being the strongest lines observed in those regions.

February 9.—"True Teeth in the Young *Ornithorhynchus paradoxus*." By Edward B. Poulton, M.A., F.L.S., of Keble and Jesus Colleges, Oxford. Communicated by W. K. Parker, F.R.S.

This paper was a preliminary account of typical mammalian teeth developing beneath the site of the horny plates, which subserve mastication in the adult animal. In the upper jaw there are three teeth on each side: in the lower jaw two teeth, corresponding to the two posterior teeth of the upper jaw, were proved to exist, but the anterior one may be also present, for the jaws examined were not complete. The animal in which the teeth were found was about 8·3 decimetres long in the curled up attitude in which it had been received, and the larger hairs had alone appeared above the skin.

The anterior tooth of the upper jaw was long, narrow, and simple, as compared with the others; it was very fully developed, containing completely formed dentine and enamel, and its apex was nearly in contact with the lower surface of the oral epithelium. All the other teeth were broad and large, those of the upper jaw possessing two chief cusps on the inner side of the crown, and three or four small cusps on the outer side, while this arrangement was reversed in the lower jaw. Dentine was only formed upon the large cusps, and was not present upon all of these. The histological details and the manner of development appear to be precisely as in the higher Mammalia, a fact which strongly supports the identification of teeth with the placoid scales of Elasmobranchs. If teeth are so extremely ancient, then we should expect them to be unmodified in the ancestral Mammalia, although the other more recently specialized characters in the higher mammals are found in a more primitive condition in the former.

The teeth were found in some sections of the skull prepared for Dr. Parker by his son, Prof. W. Newton Parker. These sections, which had not been examined by Dr. Parker, were lent to the author, and Dr. Parker most generously encouraged the publication of the discovery, and assisted the investigation with other material.

Mathematical Society, February 9.—Sir J. Cockle, F.R.S., President, in the chair.—Messrs. A. E. H. Love and G. G. Morrice were admitted into the Society.—The following communications were made:—Further remarks on the theory of distributions, by Capt. Macmahon, R.A.—The free and forced vibrations of an elastic spherical shell containing a given mass of liquid, by A. E. H. Love.—On the volume generated by a congruency of lines, by R. A. Roberts.—Isoscelians, by R. Tucker.

EDINBURGH.

Royal Society, January 16.—Prof. Chrystal, Vice-President, in the chair.—Obituary notices of some former Vice-Presidents of the Society were read.—Prof. Tait communicated a paper by Prof. A. Macfarlane, on a problem in relationship.—Mr. W. Peddie read a paper on transition-resistance and polarization at platinum surfaces. He showed that transition-resistance increases greatly while polarization is proceeding. The ratio of the final to the initial resistance is in some cases as 2 to 1, when the electromotive force of polarization is equal to that of a Daniell cell. From his results regarding the time-rate of increase of polarization he deduced (10^{-9}) cm. as the value of the distance between the platinum and the layer of gas

condensed upon it.—Mr. Peddie also read a note showing that the phenomenon of "electric-absorption" must be exhibited if a dielectric has a film of gas condensed on its surface.—Prof. Tait communicated a paper by Mr. Albert Campbell on the change in the thermo-electric properties of tin at its melting-point. While the tin is solid its line on the thermo-electric diagram is inclined upwards. Liquefaction occurs before the line reaches that of iron. At this point the direction of the line changes and becomes nearly identical with that of iron. Thus the "specific heat of electricity" in tin changes sign at the melting-point. This shows that the loosening of molecular attraction, which occurs at the melting-point, produces the same effect in tin as is produced in iron, while still solid, at the higher of the two temperatures at which its magnetic and other properties suddenly alter.—Prof. Tait read a paper on the thermo-electric properties of Signor Battelli's iron; and showed from Mr. Omond's Ben Nevis observations that ice-crystals may, in the greater number of cases, have at least a share in the production of the observed phenomena.

PARIS.

Academy of Sciences, February 6.—M. Janssen in the chair.—Second note on the law of probabilities as applied to target-firing, by M. J. Bertrand. The paper deals specially with the objections urged by General Putz in the *Revue d'Artillerie* against the principle admitted by Poisson, and against the law of probability now generally adopted in schools of gunnery. Reference was also made by General Menabrea to the important researches of M. Siacci in this field of inquiry.—Remarks in reply to an objection raised by M. Khandrikoff to the theory of solar spots and protuberances, by M. H. Faye. During his observation of the recent lunar eclipse Prof. Khandrikoff noted some protuberances, the presence of which in the absence of spots for some days before the eclipse seemed to militate against M. Faye's well-known theory. To this objection M. Faye replied at some length, pointing out that it is partly based on a misunderstanding of the true character and bearing of his views.—On perfect numbers, by Prof. Sylvester. Recently M. Servais stated that a perfect number (if such exist) containing only three distinct prime factors is necessarily divisible by 3 and 5. It is here shown that no such number exists, the line of argument employed at the same time demonstrating the theorem that there exists no perfect number containing less than six distinct prime factors.—Observations made at the Observatory of Algiers during the total lunar eclipse of January 28, by M. Ch. Trépied. These observations comprise, among other matters, a study of the colours assumed by the lunar disk; a spectroscopic examination of the eclipsed portion of the disk; and the occultations of the stars contained in the list prepared by the Observatory of Pulkowa for the purpose of obtaining an exact determination of the apparent diameter of the moon. Communications were also received from the Observatories of Bordeaux and Nice on various phases of the same occurrence.—Ephemeris of the planet 252 for the opposition of the year 1888, by M. Charlois. The true positions, right ascension and declination, are given for the period from March 5 to March 19. At opposition (March 12) the magnitude will be 13·4.—Note on permanent deformations and thermodynamics, by M. Marcel Brillouin. Two propositions are established: (1) that for most elastics solids there exists no finite relation between the temperature t, the mechanic variable X, and the geometric variable x; (2) that for most solid bodies there exists a linear equation with total differentials between t, X, and x; or, more correctly, there exist as many equations of this class as there are independent geometric variables. In a future communication the theoretic results of this study will be announced.—Influence of diet in determining the fixation and elimination of carbon in man, by MM. Hanriot and Ch. Richet. The results are tabulated of mixed nitrogenous, fat, and feculent diets, including beef, bread, potatoes, butter, cheese, sugar, wine, and coffee, continued for a period of fifteen days.—On the presence of striated muscles in mollusks, by M. Raphael Blanchard. M. Hermann Fol's recent statement that true transversal striation of the muscular fibre is found in no mollusk, is shown to be erroneous and based on defective observation of these organisms, in some of which true transversal striation certainly occurs.—On the endomorphic modifications of the granulitic systems in Morbihan, Brittany, by M. Charles Barrois. This paper is devoted to a careful study of the remarkable endomorphic modifications and mechanical transformations of the Guéméné, Saint-Jean Brevelay, and Grandchamp granulitic formations, which traverse the Department of Morbihan in its entire length, and the typical constituents of which are: (1) zircon, apatite, black mica, oligoclase, orthose, and quartz; (2) orthose, microcline, quartz, tourmaline, and white mica.—On the Senonian and Danian systems of South-East Spain, by M. René Nicklès. Without attempting accurately to determine the respective limits of these formations, the author indicates the presence of extensive marine deposits in the Devonian containing fossiliferous limestones with several species of Hemipneustes associated with large banks of Hippurites and Pironea.—General Menabrea presented to the Academy the prospectus of a new edition of the works of Galileo, in about twenty-five volumes, which is about to be issued at the expense of the Italian Government, and copies presented to all the more important public libraries.—The Administrative Commission of the Academy announces that it has decided to supply Corresponding Members with the *Comptes rendus* free of charge from January 1, 1888. Correspondents are requested to acknowledge receipt of the first number, and notify their change of address to Messrs. Gauthier-Villars et Fils, publishers, Paris.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Treatise on Photography, 5th edition: Capt. Abney (Longmans).—The Story of Creation: E. Clodd (Longmans).—British Dogs, parts 15 and 16: H. Dalziel (U. Gill).—Beobachtungen der Russischen Polarstation an der Lenamündung, ii. Thiel, Meteorologische Beobachtungen: A. Eigner; II. Liefg. Beobachtungen vom Jahre 1883-84: R. THURSDAY, FEBRUARY 23, 1888.

PHYSICAL SCIENCE AND THE WOOLWICH EXAMINATIONS.

SINCE the appearance of our article of January 26 considerable interest has been manifested in this question, and during the past week important communications on the subject have come from the Secretary of State for War, and from the head master of Clifton College. We learn from Mr. Wilson's letter to the *Times* that the new regulations are not only calculated to do harm by the discouragement of science, but that they are also retrograde in another very important particular. By increasing the range of the obligatory examination in mathematics, though they will not very greatly affect the selection of candidates, yet, in the case of very many of them, by compelling wider and less thorough study, they will damage the training in that subject.

In answer to a question put by Mr. Howorth, in the House of Commons on February 15, the Secretary of State for War is reported to have said that the new regulations are intended to encourage those subjects which it is believed can be least easily crammed; to give a preponderance to those subjects which are to the majority of officers of greatest practical importance; and that the new regulations are to be of permanent application.

Are the regulations calculated to achieve these purposes? We think it can be shown very clearly that they are not. It is therefore with renewed hope that discussion will lead to their amendment that we enter upon the following examination of them.

(1) The new regulations are intended to encourage subjects which it is believed can be least easily crammed. Mr. Wilson, as we have already pointed out, has indicated that in the case of mathematics they will distinctly tend to encourage quantity at the expense of quality. With regard to science subjects, the examination statistics which we published in 1884 clearly proved that experimental science was not then chosen by candidates on account of susceptibility to cram, for it was at that time less frequently selected than any other subject by successful candidates. During the three or four years that preceded 1884, a branch of experimental science was offered by only 22 per cent. of the successful candidates; since that date the numbers have risen, notwithstanding the increased thoroughness of some parts of the examination; and in 1887 about 38 per cent. of the successful candidates offered a branch of experimental science. This development is noteworthy, and may be considered to indicate an increased appreciation of the value of such work by teachers and students, since it has taken place in spite of the subject being rather a bad than a good one from the mark-winning point of view, and also during a period notable for improvement in some parts of the examination. Geography and geology, which may be, as some hold, more susceptible of cramming than chemistry and physics, show no corresponding tendency. In 1887 this subject was taken up by a distinctly smaller proportion of successful candidates than in the years that preceded 1884.

There does not appear, then, to be any justification for treating science as a subject more easy to cram than others that are more favourably treated. Had it been true that it is so, it would have been selected by a greater proportion of candidates formerly, and it would certainly have been discouraged by the nature of the examination during the last few years.

(2) Are the subjects selected those most calculated to be of practical importance to a majority of officers in the Engineers and Artillery? A flood of light is thrown upon this point by the course of instruction given to the cadets in the Royal Military Academy.

During the first year of training at Woolwich, cadets will study in the compulsory courses the following subjects:—

Mathematics,	for which	3000	marks are given.
Field Fortification,	,,	2000	,, ,,
Military Topography,	,,	2000	,, ,,
French or German,	,,	1000	,, ,,
Chemistry and Physics,	,,	1000	,, ,,
Model Drawing,	,,	300	,, ,,

During the second year of training, the cadets are divided into two classes. Those who are selected for the Engineers will then study, in addition to purely professional subjects—

Mathematics,	for which	2000	marks are given.
Chemistry and Physics,	,,	1000	,, ,,
Freehand Drawing,	,,	1000	,, ,,

In the case of the Artillery cadets during their second year, chemistry and physics alone of the ten or eleven subjects examined in the entrance competition are considered to be of sufficient practical importance to be retained.

Thus it stands admitted by the military authorities, according to their own regulations for the education of cadets, that, of the subjects examined in the competition for Woolwich, experimental science stands next to mathematics as a subject of practical importance in the training of officers for the scientific branches of the army.

That very great weight should be given to mathematics and modern languages in the examinations for Woolwich cadetships is obviously proper; but since it is admitted, by the courses of instruction in the Royal Military Academy, that capacity for and extensive training in experimental science form part of the necessary equipment of an officer of Engineers or Artillery, a system of selection which includes no means whatever of securing youths capable of such studies in the preliminary examination, and which places youths of scientific power at such considerable disadvantages in the competitive part of the examination, plainly needs to be amended, in the interest both of the service and of the candidates. We do not doubt that those who get into the Academy will be excellently taught there, but under these regulations many will be rejected who are eminently fitted to do well, in favour of others who are less gifted with the qualities that are admittedly most valuable.

The Committee who framed these regulations has, we fear, forgotten that the Professors at Woolwich will not create a capacity for science work by the mere teaching of science to the successful cadets, and that the utmost they can do in the case of those whose talents are linguistic rather than scientific,[1] will be to compel them to acquire by hard, uncongenial labour the necessary minimum of knowledge that is required in the subsequent examinations. It is abundantly

[1] The enormous value to be given to modern languages is likely to result in many such winning admission to Woolwich in future.

evident that the War Office Committee has made a serious mistake. The new regulations, so far as experimental science is concerned, are needless as precautions against cramming; they will not give due weight to the subjects which are, by their own showing, of most practical importance to officers; and they will influence most unfairly the selection of candidates by giving no chance for scientific power to tell in the results of the examinations.

There is another side of this question which is of very great public importance, viz. the influence of these and other examinations on school work in general. Regulations such as those now in force at Sandhurst, and those about to come into operation at Woolwich, make it increasingly difficult for science subjects to maintain their proper place in schools where they are already adopted, and hinder their adoption elsewhere. Many of the ablest youths in our public schools enter as competitors in these and other examinations, and as they must offer the subjects that pay best, such regulations as those under discussion lower the general standard of school work by constantly withdrawing from the science classes a large proportion of the best students. At present good work in science pays less well very often than mediocrity in other subjects. This, as was pointed out by Sir Lyon Playfair in his Presidential Address to the British Association in 1885, helps to arrest progress in science teaching. We do not, of course, claim that the interests of science in schools should be allowed to outweigh the manifest needs of the public services. But the fact that public examinations exercise a potent influence, not only on the education of the candidates, but also on the general tendency of school work, throws great responsibility on those who control them, and makes it our duty to urge that this influence shall not be lost sight of, especially when, as in the case of Woolwich cadets, an aptitude for experimental science is admittedly a quality that will be of great practical value in the professional work of the successful competitors.

THE MOTHS OF INDIA.

A Catalogue of the Moths of India. Compiled by E. C. Cotes, First Assistant to the Superintendent, Indian Museum, and Colonel C. Swinhoe, F.L.S., F.Z.S., &c. Part I. Sphinges. Part II. Bombyces. (Calcutta: Printed by the Superintendent of Government Printing, 1887.)

IT is not too much to say that the task of writing a catalogue of the moths of India is one which might appal an entomologist of far longer experience than either of the authors of this work. For when we consider that no general catalogue or revision of the Heterocera exists more recent than that of Guénée, that almost the whole of the types of the described species are in England, whilst both the authors of this book are in India, and that the number of Indian moths is so great that in the two first families alone upwards of 1600 species or supposed species are catalogued, it is evident that the difficulty of such a work is enormous; and as the authors are not known as lepidopterists of long standing, and are resident on opposite sides of India, no one would expect too much from the first attempt at what has long been very much wanted—namely, some work which would enable the rapidly-growing circle of working naturalists in India to know what has already been described and where the descriptions have appeared.

I think, therefore, that the cordial thanks of all will be given to Colonel Swinhoe and Mr. Cotes for their bold attempt to fill this blank, and that no one will be too critical as to how their task has been done when the great difficulties under which they labour are remembered. There is not a word of introduction to say to what extent either of the authors is responsible for the work, but I believe that Mr. Cotes is really the compiler, and that Colonel Swinhoe, whose collection is much richer than that of the Indian Museum in the species which occur in Western India, has added such additional species and notes as he possesses.

The plan of the work is nothing more than a bare catalogue of names and references, with localities so far as known to the compilers or to the authors of these names; and, as we see that in some genera almost all the species are unknown to either of the authors except from the descriptions or plates, it is evident that a large proportion of the names are names and nothing more.

In the genus Syntomis, for instance, we find forty-two supposed species catalogued, of which fifteen are described by Moore, nine by Walker, and ten by Butler; of all these only eleven are in Colonel Swinhoe's collection, and thirteen in that of the Indian Museum, and we do not find that a single attempt has been made to discover how many of these forty-two names represent distinct species.

As long as authors continue to do as Messrs. Moore, Butler, and the late Mr. Walker have so freely done—namely, to describe anything they do not personally know, with little regard to what has already been described—it is evident that, when their views as to variation are also extremely narrow, a great many synonyms must result, and we think a little genuine work would tend to show that of the forty-two supposed species of Syntomis not more than perhaps twenty really exist in nature. It is, however, quite as probable that while not more than twenty distinct species are described from India, at least twenty more remain undiscovered, for it is hardly possible for anyone who does not know India personally to understand how infinitesimal our knowledge of the moths is, except in some half-dozen localities like Bombay, Calcutta, and Sikkim; and even in such places as these what we know is but little compared to what we do not know. Surely here is a field for study and amusement which must attract many who will, sooner or later, provide the materials and collect the knowledge necessary for a "Catalogue *raisonné*," but the sooner a good example is set, by the careful and scientific description of the genera and species which are known, with due regard to distribution and variation, the more and better will be the work done.

A book is projected by Mr. F. Moore, whose knowledge of Indian moths is certainly greater than that of all other entomologists combined; but it is sincerely to be hoped that he will not adopt such a plan or style of work as his recently published "Lepidoptera of Ceylon." The bulk and cost of such a work on the Lepidoptera of India would quite prevent its use by those most likely to use it to advantage, and even if it was completed in

his lifetime the earlier parts would be out of date before the last were published.

What is wanted is something like Stainton's "Manual of British Lepidoptera," together with a serial publication which would give such a medium to entomologists for publishing their discoveries as *Stray Feathers* gave to Indian ornithologists. When such a journal has been going on for twenty years or so, it will be time to think of a Catalogue of the moths of India really worthy of the name. At present such an ambitious scheme as that proposed by Mr. Moore seems to me only likely to stand in the way of something better hereafter.

It is a great pity that no references are given in this Catalogue to the descriptions of the very numerous genera, so many of which are the creation of Mr. Moore. How many of them will eventually stand, time alone can show, but certainly many of them will merge in genera known in other parts of the world besides India.

I think also that if the authorities for the localities given for the various species were stated, as has been done in the case of specimens in the Calcutta Museum, this would be a great addition to the Catalogue. It is quite as important to know who collected a particular species as to know in whose collection it exists; and many localities are given without any good authority.

Another improvement in the form of the work would be an abbreviation of the references, in the same way as is done in Standinger's "Catalogue of European Lepidoptera"; a short bibliography of works cited, and their abbreviated citations, will take away any possibility of doubt, and save innumerable repetitions of such references as

"Walker, Cat. Lep. Het. B. M.,"
"Moore, Proc. Zool. Soc. Lond.,"
"Felder, Reise Novara Lep.,"
"Butler, Ill. Typ. Lep. Het. B. M.,"

which might be reduced with advantage to

"Walk., B.M.,"
"Moore, P.Z.S.,"
"Feld., Nov.,"
"Butl., B.M."

But notwithstanding the imperfections of this Catalogue, its publication will be a real blessing to naturalists, if only by saving them an immense deal of the most tedious, troublesome, and unsatisfactory work—the hunting up of descriptions and references. How far these are correct, I have not as yet been able to prove; but the few omissions which I have discovered may easily be forgiven.

H. J. ELWES.

PROLEGOMENA TO THE STATISTICS OF THOUGHT.

Die Welt in ihren Spiegelungen unter dem Wandel des Völkergedankens. Prolegomena zu einer Gedankenstatistik. ("The Universe as reflected in the Movement of Thought among the Races of Mankind. Prolegomena to the Statistics of Thought.") By A. Bastian. One-vol. in 8vo, with an Atlas or Ethnographical Picture-book in oblong folio. (Berlin: E.S.Mittler, 1887.)

DR. BASTIAN'S idea is that the new science of ethnology supplies materials from which it is possible to construct a system of psychology on the inductive methods of natural science. The inductive study of the material universe has given us our modern science, and with it modern materialism. But materialism, says Dr. Bastian, is but a one-sided expression of the legitimate tendency of the age towards induction and natural science. It overlooks the fact that the world of ideas offers as legitimate a field for the application of scientific method as the world of material phenomena. Ethnology, which considers man not as an individual, but in his social aspects, teaches us that the universe of thought also obeys laws, and can be studied by the genetic method. And therefore Dr. Bastian desires to see the statistics of thought put together in a way that will exhibit the whole range of ideas about the universe and its contents which have been prevalent among the various races of men. These statistics will form the basis for a psychology constructed on inductive principles.

The description of a science which has still to be created must necessarily be vague and hazy, and in the present case the vagueness is increased by the fact that Dr. Bastian writes in a very involved and enigmatic style, so that his meaning cannot be read, but must be divined. But so far as we have been able to follow him we gather that in his "Prolegomena to the Statistics of Thought" he designs something different from what is given in ordinary Prolegomena, and that the volume should rather be called a provisional collection of materials for the comparative study of the ideas entertained by different races, or in different stages of culture, as to the universe and the leading matters of human interest that it contains. It would seem that Dr. Bastian, whose great range of knowlege in matters ethnological is well known, and who is also a voracious and somewhat undiscriminating reader of books on all possible subjects connected with the history of human thought, has accumulated huge commonplace-books to illustrate his favourite project. The small-type sections which make up a large part of the volume are simply chunks from these note-books, to all appearance entirely undigested. Commonplace-books have always a tendency to become chaotic, especially in the hands of a man who reads so widely and miscellaneously as Dr. Bastian has done; but we have never seen anything quite so formless as these pages. In themselves many of the extracts given are interesting or curious, but the disorder in which they stand is simply bewildering. Moreover, there are no exact references to chapter and verse of the authors quoted, and verbal excerpts stand side by side with brief jottings and condensed indications such as a man may make for his own use, but which are so many enigmas to the reader. There has evidently been no verification and no revision of the notes originally made by the author for himself, and many of them, therefore, are not only obscure, but not quite accurate; while others were not worth printing at all. The last remark is specially applicable to a vast number of quotations from ancient and modern metaphysicians, into whom Dr. Bastian has evidently dipped at hazard, without having any clear conception of the history of philosophy as a whole. On half a page we find Proclus, Anaximander, Philolaus, Aristotle, the Pythagoreans, F. A. Müller, Spencer, Schelling, Samuel ben Gebirol, and Anaxagoras. Who can hope to be instructed by such a

jumble? The large-type sections that connect these masses of confused notes are still more perplexing. Here, also, the commonplace-book predominates, but the extracts are worked up into some semblance of a continuous exposition. It is very seldom, however, that one can read a page on end without losing the thread. The reason soon becomes obvious. What is offered as a book is really nothing more than a transcript of rough jottings, in which Dr. Bastian had from time to time recorded his ideas in a form just sufficient to preserve a record for his own use. The sentences are often not even grammatical, and in brief the volume is only the roughest of rough note-books printed without revision. In spite, therefore, of the enormous labour and learning which it attests, the whole must be pronounced a failure, for the elementary reason that it is not a book. We trust that the publication may be useful to the author in helping him to get his superabundant material better under control, and so to produce hereafter something that is a book and can be read.

The ethnological picture-book is designed for young people, and its illustrations of cosmogonic and cosmographic ideas, of various conceptions of the future life and so forth, are well calculated to excite their curiosity and stimulate their interest in such things.

OUR BOOK SHELF.

Experimental Chemistry for Junior Students. By J. Emerson Reynolds, M.D., F.R.S. Part IV. Organic Chemistry. (London: Longmans, Green, and Co., 1887.)

THIS volume on organic completes the author's course of experimental chemistry. Whatever may be the opinions on the three previous volumes, there is no doubt this is the most rational attempt to treat organic chemistry practically—as a thing for students actually to do—that has as yet appeared. There is scarcely an experiment in the book that a student will be unable to do from the description given, and the order in which they are taken and general arrangement is the natural order of synthesis, proceeding from the less complex and easy to the most complex and least known.

The author begins with destructive distillation, and the production of alcohols, their salts, &c. The fourth chapter deals with metallic compounds or organo-metallic bodies. In the description of the manufacture of zinc ethide the method of making from zinc, C_2H_5I, and iodine might have been given, as the action is much quicker than with the Cu—Zn couple and the yield greater. The current of CO_2 can also be dispensed with advantageously. Two experiments here we must take exception to as being rather dangerous for beginners—sealing up sodium with zinc ethide, and in Experiment 691 making mercuric ethide as a sort of starting-point material. The author cautions against inhaling the vapour of this substance, as it is "supposed to be poisonous." We thought it was quite settled that it is about the most dangerous substance one has to deal with; and we certainly do not agree with the author that the method of employing mercuric ethide for making zinc ethide is the easiest of all methods for making the last-named substance.

In the remainder of the little book there is nothing either in arrangement or process to which objection can be taken, and undoubtedly it should be most useful to students attending a course of organic lectures. As a rule English students stop off with organic before they have really made its acquaintance; very few indeed continue its study long enough for it to be of any use to them. Most of the works in England where "organic chemistry" is the rule are obliged to obtain the services of German chemists; the English student's acquaintance with the subject generally stopping at the knowledge that there are such things as hydrocarbons, or "hydrocarbides," as the author of this book calls them.

Perhaps when such practical instruction is given in our schools as the course outlined by this book, we may begin to produce students who can go into "a works" and be trusted not only to follow a process but to originate new ones. W. R. H.

The Farmer's Friends and Foes. By Theodore Wood, F.E.S. (London: Swan Sonnenschein, Lowrey, and Co., 1888.)

THIS is a well-meant and well-put-together little volume, giving an account of the life-history of most of the animals which, for good or for evil, come across the path of the British agriculturist. Throughout, the attempt is made to prove that, when it is necessary for the saving of a crop to destroy any animal, it is far better to trust to Nature, as being more competent, than to man; but then this seems to beg the whole question, as it presumes that man has not already very much interfered with Nature's regulations.

The volume is, in part, the result of personal investigation, but the author quotes freely from all our best-known writers on the subjects of which he treats.

The figures are good. A table of contents would have added to the usefulness of the work, especially as the index is not very detailed. The volume may be safely placed in the hands of all interested in the subject.

The Story of Creation. By Edward Clodd. (London: Longmans, Green, and Co., 1888.)

THE author of this book does not pretend to make his readers acquainted with new facts and ideas. His object is to present a popular exposition of the theory of evolution, using the word evolution in its widest sense. The work is divided into two parts—one descriptive, the other explanatory. In the descriptive part he begins with a chapter on matter and power. He then considers the distribution of matter in space, and gives a general account of the sun and the planets, of the past life-history of the earth, and of present life-forms. In the explanatory part he discusses the questions relating to inorganic evolution and to the origin of life and life-forms, and sets forth in logical order the arguments which are held to establish the truth of Darwin's theory of the origin and development of species. A final chapter is devoted to social evolution, including the evolution of mind, society, language, art and science, morals, and theology. The book is vigorously written, and well illustrated; and readers who have had no special scientific training will find that it enables them to understand and appreciate some of the greatest and most fruitful generalizations of modern science.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Botanists and the Micromillimetre.

I NOTICE that in a review of a "Manual of British Discomycetes" which appeared in NATURE on February 9 (p. 340), and apparently also in that work itself, the word *micromillimetre* is used as equivalent to the thousandth of a millimetre.

I have made some inquiry, and am told that it is now commonly employed by biologists, and especially by botanists, with that meaning.

As it would be very unfortunate if the same word were habitually used in different senses by students of different branches of science, may I be allowed to point out that, according to the definitions of the C.G.S. system, a micromillimetre is the millionth of a millimetre.

In the well-known Report of the Committee of the British Association for the "Selection and Nomenclature of Dynamical and Electrical Units" it is laid down that the prefixes *mega* and *micro* are to be employed "for multiplication and division by a million."

This ruling has been generally accepted not only by scientific men, but also by those engaged in commerce. Megohm and microfarad are terms which are used in contracts, and are universally understood to mean a million ohms and a millionth of a farad respectively. It will be hopeless to try to introduce scientific systems of measurement into the affairs of daily life if scientific men themselves disregard the rules on which those systems are framed.

It would also be particularly confusing if the micromillimetre were wrongly used by microscopists. In its proper sense it is the most convenient unit in which to express molecular magnitudes. It has been employed for that purpose by Sir William Thomson and others in England, and also by physicists abroad. If the micromillimetre of the microscopist is 1000 times too large, all sorts of mistakes will be rife as to the relative dimensions of molecules and of the smallest objects visible with the microscope.

The proper name for the thousandth of a millimetre (μ) is the *micromētre*, and though the similarity of this word to *micromĕter* is no doubt a drawback, it is not likely that confusion could often arise between them.

If, therefore, I am rightly informed as to the custom of botanists in this matter, I beg respectfully to suggest that they should bring their nomenclature of units of length into conformity with the definitions of the C.G.S. system. Otherwise there will be a permanent confusion between the *micrometre* (μ) and the micromillimetre ($\mu\mu$). ARTHUR W. RÜCKER.

Science Schools, South Kensington, February 17.

"The Teaching of Elementary Chemistry."

ALLOW me to draw the attention of the chemical section of your readers to a few highly misleading passages in the two books reviewed under the above heading in NATURE of January 19 (p. 265).

On p. 65 of the "Elementary Chemistry" we read:—

"Hence when sodium and water interact, a portion of the hydrogen which was combined with oxygen is evolved as hydrogen gas, and another portion enters into combination with the sodium and the oxygen to produce caustic soda."

On pp. 116–17 is to be found the following astounding passage:—

"To prepare Cl_2O, mercuric oxide (HgO) is heated in a stream of dry chlorine. When mercuric oxide is heated it is decomposed into mercury and oxygen; therefore by passing chlorine over heated mercuric oxide we carry out a reaction in which oxygen is produced in presence of chlorine."

In the "Practical Chemistry," under Experiment 1, Chapter II. (p. 6), occurs the following warning to the student:—

"Do not remove the lid at any time for more than a second or so, else some of the magnesia will be volatilized and lost;" while on p. 285 of the "Elementary Chemistry" we read:—

"No compound of Mg has been gasified."

Even this contradiction is excelled by one on pp. 62 and 63 of the "Practical Chemistry," which is not so manifestly a slip. We read (p. 62):—

"The reactions between aqueous solutions of alkalies and the three elements, chlorine, bromine, and iodine, are similar; compounds of similar compositions and similar properties are produced under similar conditions."

Under Experiments 19 and 20, which follow, the student is told to treat cold solutions of potassium hydroxide with chlorine and bromine respectively. The well-known changes are described, and the bleaching properties of the solutions after addition of a little acid, are to be tried. Then follows (p. 63):—

"Exp. 21. Perform an experiment similar to 19 and 20, but use *iodine* in place of chlorine or bromine: the liquid which is produced does not bleach. No compound of iodine analogous to KClO and KBrO has been obtained."

Truly this is "seeing things as they are" with a vengeance.

Z.

Natural Science and the Woolwich Examinations.

MAY I be allowed, as one of the most experienced science masters in the public schools, to say a word in reply to Mr. Gurney's letter in NATURE of this week (February 16, p. 365)?

There seems to me a general fallacy running through that letter arising from "the absence (on the writer's part) of clear discrimination" between the nature and methods of mathematical science (which, as J. S. Mill taught us long ago, are mainly *deductive*) and experimental science (which proceeds by *inductive* methods). It is on this ground mainly, coupled with the extent to which it cultivates the faculty of *observation*, that we claim for it a special educational value.

After an educational experience at least as extensive as Mr. Gurney's, I join issue with him most distinctly on this point. I am afraid there lurks behind Mr. Gurney's depreciation of the educational value of science the disappointment which other mathematicians have experienced in finding that the man who takes to experimental science as a mere excursion-ground for the diversion of the mathematician is not infrequently brought to confusion by Nature. *Science is something more than measurement.* Mr. Gurney's notion that mathematics and a knowledge of French and German are a sufficient groundwork for true scientific knowledge is such a confession on his part of the small value he attaches to experimental demonstration and to laboratory training (or to field-work in the case of geology) as is sufficient to put him out of court as a witness on this question. Nor do I think that he is competent to speak with any authority on the work done in the public schools. If he fancies that the best boys of the public schools go to Powis Square to finish their education, he is labouring under a delusion.

The whole argument of the letter is retrogressive; nor is it strengthened by the writer's condemnation of a "smattering" of science, which is no discovery. But I maintain that a boy can, by the age of eighteen, get a sound groundwork in science laid, though not by the cramming system; and that to this the term does not apply at all. Again, he condemns premature specialization of a boy's studies in favour of science, while he inconsistently advocates a much narrower specialization in favour of mathematical studies.

How far Mr. Gurney is from being convinced by his own arguments is shown by the fact that in the concluding paragraph of his letter he practically surrenders the point on which the whole question turns.

In conclusion I would commend to his careful consideration the letter which appears in the *Times* to-day from the head master of Clifton College, whose competence to form a judgment on the educational aspect of this question I suppose no one doubts. A. IRVING.

Wellington College, Berks, February 17.

WITH your kind permission, and in consideration of the importance of the matter, I crave leave for space for a few remarks in addition to those contained in my reply to Mr. Gurney.

(1) Looking at the history of education in this country, we can account for, though we deplore the existence of, a prevalent notion, a sort of fashionable superstition, which regards scientific studies as outside the range of what is called "culture"; a superstition for which some of those who have spoken in the name of science are not altogether unanswerable, but which derives its chief strength from that profound ignorance of natural science—its nature, its methods, and its object—upon which so large a proportion of educated Englishmen seem rather to pride themselves than otherwise. There can be but little doubt that this has been turned to account as an influence in favour of the contemplated scheme.

(2) It is in no spirit of hostility to literary studies that one writes in these terms; on the contrary, it is as a lover of literature of the better sort that one would gladly see the literary spirit in this country, as in Germany, strengthened and braced by the strong atmosphere of scientific criticism, and a little more first-hand acquaintance with things as they are, which is the true

aim of science. It is impossible to estimate the good that might be done in this direction, if only the Universities had the wisdom and the courage to insist upon a knowledge of some one branch of science for all degrees, as was strenuously advocated years ago by Charles Kingsley.

(3) It seems a great pity that such a change as is contemplated should be adopted just now, since within the last three or four years some of us who are teachers of standing and experience have gladly recognized considerable improvement in the examinations in science as they are conducted by the Civil Service Commissioners. It would appear that the *cramming* of these subjects has been considerably handicapped, if one may judge from the considerable increase in the number of o's affixed to the names of candidates in the published lists *pari passu* with a considerable increase in the number of marks gained by one's own pupils, who have had the same teaching and laboratory training as those of previous years.

(4) It is surely fairly within the province of Parliament to consider the question whether it is expedient or conducive to the common weal, that science shall be placed at such a disadvantage that young men, who are candidates for the more scientific branches of the military service, shall be strongly tempted to eschew all preliminary training in science, as they certainly will be unless the regulations are somewhat modified.

Four years ago the action of a single Member of Parliament (Sir John Lubbock), backed up by the influence of the Councils of the Royal Society and the British Association, was effectual in securing a reconsideration of the provisional examination scheme for admission to Sandhurst; so that, although—as ultimately issued—the regulations contained an absurd anachronism in the proportion of marks assigned to scientific subjects, this was reduced to less startling proportions.

Can it be doubted, then, that if on the present occasion the three Members of Parliament who may be said to be the representatives *par excellence* of science in the Legislature (the President of the Royal Society, the President of the British Association, and the Member for the University of London), were to take united action in Parliament, the position of science (so far as the Army Entrance Examinations are concerned) might be changed from one of semi-strangulation to one of free and fair competition, which is all that its most ardent advocates can desire for it? This could be effected to the advantage of the studies of the cadet, by such a simple modification of the published regulations as would be involved in limiting the choice of optional subjects in Class I. to two, and allowing two subjects of Class II. to be taken up. A. IRVING.

Wellington College, Berks, February 20.

The Composition of Water.

PROF. THORPE, in his interesting article on the composition of water (p. 313), alludes to Dr. Scott's very valuable determinations of the ratio of the volumes of hydrogen and oxygen which combine to form water.

If we assume with Dr. Scott that the small amount of impurity present in his gases, and which he estimated in each case after the explosion, was evenly distributed between them, a curious relation may be observed between the amount of impurity present and the calculated ratio of the volumes.

This relation is apparent if we subtract the ratios calculated by Dr. Scott from some fixed number, say 2·000, and compare these differences with the relative amounts of impurity. It will be seen from the following table that the greater the amount of impurity present the greater is the difference of the ratio from the constant number, or, in other words, the lower is the ratio. The impurity is given in volumes per 100,000, and the differences are multiplied by 10,000.

Relative impurity.	Difference of ratio from constant.	Relative impurity.	Difference of ratio from constant.
35	83	102	125
36	55	105	133
41	66	106	140
47	44	146	154
52	32	162	106
56	90	167	224
66	72	188	118
72	46	254	187
75	80	495	540
78	120	498	506
98	73		

The relation is better seen, however, by mapping the results, taking the ratios as abscissæ, and the impurity in volumes per 100,000 as ordinates. The dotted straight line (Fig. 1) passes so well through the points that it leaves ten of them on the one side and eleven on the other.

It seems difficult to believe that this apparent relation can be merely a chance coincidence; the direction taken by the points is too definite. Nor can it well be due to any chemical action

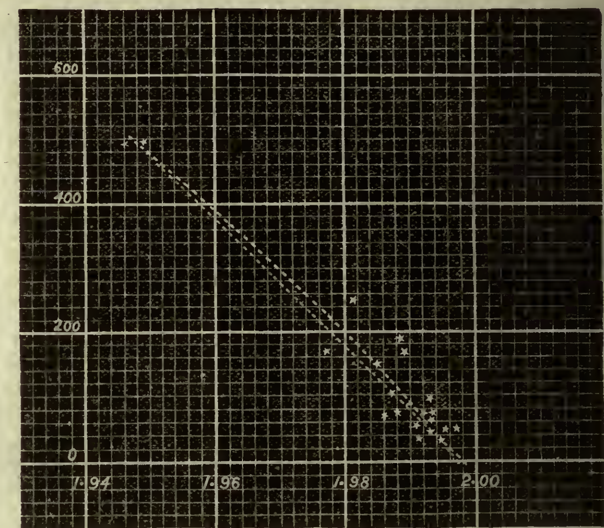

FIG. 1.

between oxygen and nitrogen, for Dr. Scott states that the water produced was free from any acid reaction, and that no trace of the oxides of nitrogen could be detected. The relation is even more marked if we assume that the whole of the impurity was in the hydrogen. This is shown in Fig. 2; the points obviously fall about a line which is nearly, if not quite, straight.

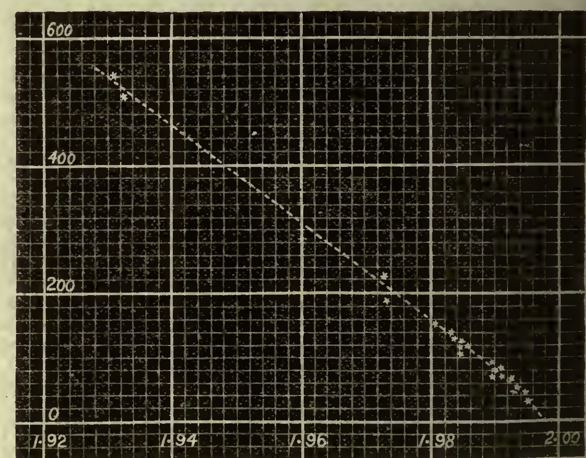

FIG. 2.

If, however, we assume that the whole of the impurity was in the oxygen, and if we neglect the two experiments with the excessive amount of impurity, no such relation is to be observed (see Fig. 3), but the ratios are distributed with fair regularity about a mean value of 1·9965 or 1·9970. The simplest explanation of the facts appears to be that the whole, or at least the greater part, of the impurity was really in the oxygen, and that the apparent relation of the amount of impurity to the ratio

is due to the error introduced into the calculations by referring the impurity to the hydrogen. But, whether this explanation be accepted or not, it is clear that the three lines drawn through the points representing the three series of ratios ought to meet at a point on the horizontal line of zero impurity, for the errors, whether due to chemical action or to calculation, would disappear with the cause that produced them. Hence, if no other source of error is present, the true ratio may be found by taking the most probable point of intersection of the three lines on the horizontal line of zero impurity. It is not easy to determine exactly the position of this point: it probably lies between the values 1·996

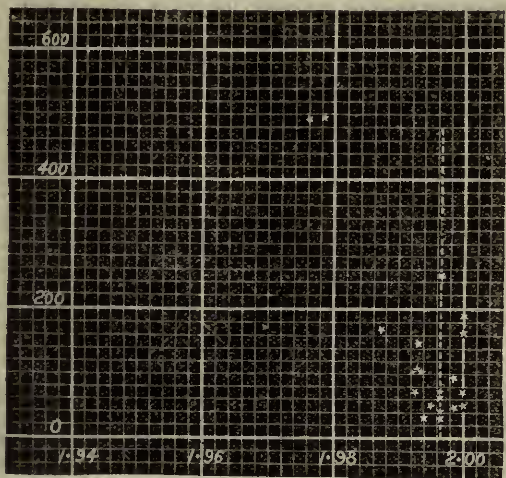

FIG. 3.

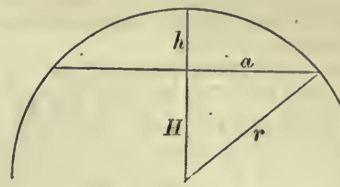
and 1·998, and the true ratio may perhaps be taken as 1·997 Dr. Scott adopts the ratio 1·994, but this appears to me to be certainly a little too low.

Prof. Thorpe shows that the atomic weight of oxygen, calculated from Regnault's densities of oxygen and hydrogen, corrected by Prof. Le Conte, and Dr. Scott's ratio (1·994) for the combining volumes, is 16·029. The ratio 1·997 would make the atomic weight O = 15 985. SYDNEY YOUNG.

University College, Bristol.

The Fog Bow and Ulloa's Ring.

IN the summer of 1875, I made a tour of inspection to our meteorological stations in the surveying-steamer *Hansteen*, Capt. M. Petersen, R.N. During the morning hours of August 7, I was on shore at Gandfjord, on the south side of the Varangerfjord, and measured the height of some terraces there. At 1h. 10m. p.m. we took serial temperatures in the Gandfjord with the deep-sea thermometer. The weather was calm, and a dense fog prevailed. The temperature of the air was 12° C. Leaving the Gandfjord we proceeded northwards. The dense fog continued. At once the fog began to be lighter and the sun to shine through, and a few minutes afterwards we were out of the fog, which was standing as a white wall in the south-west. In the moment the sun appeared, but before we were quite clear of the fog, I saw in the north-east a bow having the shape of a rainbow, but quite white, projected on the fog. With a sextant I measured its amplitude, or the chord along the horizon, and the height of the summit above the horizon—in both cases the middle between the outer and inner edge of the bow. The horizon not being distinctly visible, it is probable that the measures taken do not exactly refer to the true horizon, nor is it certain that the height of the summit was taken from the same horizontal plane in which the amplitude was measured. By the captain's reckoning, the apparent ship's time, at the moment of observation, was 2h. 40m., and the latitude 70° 1′. From these data, and the declination of the sun, I computed the azimuth of the sun at south 46° 5′ west, and its apparent altitude at 31° 12′. Supposing, as the results of the several computations tend to indicate, that the white bow is circular, and has its centre in the anthelic point, we may calculate the angular radius of the bow by three different methods.



Let h represent the height of the summit of the bow above the horizon, a half the amplitude or chord along the horizon, H the dip of the centre of the bow below the horizon, supposed to equal the altitude of the sun, and r the angular radius of the bow. Then we have—

$$r = H + h \quad \ldots\ldots\ldots \quad (1)$$

$$dr = dH + dh \quad \ldots\ldots\ldots \quad (1')$$

$$\cos r = \cos a \cos H \quad \ldots\ldots\ldots \quad (2)$$

$$dr = \frac{\tan a}{\tan r}\, da + \frac{\tan H}{\tan r}\, dH \quad \ldots\ldots \quad (2')$$

$$\cos r = \cos a \cos (r - h)$$

$$\tan r = \frac{1 - \cos a \cos h}{\cos a \sin h}, \text{ or putting}$$

$$\cos a \cos h = \sin^2 M$$

$$\tan r = \cot^2 M \cot h \quad \ldots\ldots\ldots \quad (3)$$

$$dr = \cos (r - h) \frac{\cos r}{\sin h} \tan a\, da - \sin (r - h) \frac{\cos r}{\sin h}\, dh \quad (3')$$

The observations gave $2a = 49°$, $a = 24° 30'$, and $h = 7°$ (or a little more).

From (1) we have $r = 31° 12' + 7° = 38° 12'$.

Putting $dH = \pm 2'$, $dh = \pm 15'$, we have by (1′)

$$dr = \pm \sqrt{2^2 + 15^2} = \pm 15'{\cdot}1 = \pm 0°{\cdot}25.$$

From (2) we have $r = 38° 53'{\cdot}5$,

and by (2′) $dr = 0{\cdot}577\, da + 0{\cdot}770\, dH$, dH being the error in the altitude of the measured chord, or the chord's altitude or depression, reckoned from the horizon.

Putting $da = dH = \pm 15' = \pm 0°{\cdot}25$, we get—

$$dr = \pm 0°{\cdot}24.$$

From (3) we have $r = 41° 8'$,

and by (3′) $dr = 2{\cdot}315\, da - 3{\cdot}074\, dh$.

Putting $da = dh = \pm 0°{\cdot}25$, we get—

$$dr = \pm 0°{\cdot}97.$$

Taking the weights inversely as the squares of the probable errors, we find that the results from (1) and (2) have a weight of 15 times that found by (3), and the mean will be—

$$r = 38° 38' \pm 6'{\cdot}4.$$

From this mean we find that h should have been 38° 38′ − 31° 12′, or 7° 26′ instead of 7°, or somewhat greater than measured, as supposed in my note-book. Computing from (2) we find that we should have calculated with H = 30° 51′ instead of 31° 12′, or the chord has been measured in a level 21′ lower than the horizon, which is highly probable with the fog spreading over the surface of the sea. The measured chord being too great, and the measured height too small, it follows from (3′) that (3) must give the radius by far too large.

The next occasion I had to observe the fog bow was in 1878, on the North Atlantic Expedition, when returning from Spitzbergen. During August 30, our ship, the *Vöringen*, had a rather tedious work in advancing southwards, on account of the foggy weather prevailing the whole day. In the afternoon we had advanced so far south of Bodö as to approach the Sandhorn, a mountain about 3000 feet high, lying to the east of the route.

At 5h. 20m. p.m. I saw an anthelic fog bow, white, with the outer edge reddish, the inner edge bluish. I measured, with the sextant, the amplitude along the horizon at 76°, the sun's altitude at 12°, and the breadth of the bow at 2°. The temperature of the air was about 14° C. The latitude was about 67° 10′.

Assuming the measured chord to lie in the true horizon, we get by (2) from $a = 38°$, H = 12°, $r = 39° 35'{\cdot}5$. But it is highly probable, that the measured chord lay deeper than the

fog-veiled horizon, perhaps some degrees deeper, and it may be quite as possible that I have measured the diameter as a chord. This supposition gives $r = \frac{1}{2}\, 76°$ or $38°$. The mean of these two determinations is $38° \, 48'$, with a probable error surely not less than $\pm 48'$, or half the difference.

At 6h. 1m. p.m., the circumstances were more favourable. I measured $2a = 76° \, 11'$, $H = 8° \, 11'$, the breadth of the bow 2°. The latitude was 67° 7′. From these data we have, by (2) $r = 38° \, 50'$. Assuming the observed amplitude to have been the diameter, which is very probable, we have $r = 38° \, 5''.5$. The mean value is $38° \, 28' \pm 22'$.

If the fog bow, like the rainbow, has always the same diameter, we can join the three values thus found for the radius into a mean result. We have thus, giving the single determinations a weight inversely as the squares of their probable errors—

1875 August 7,	2h. 46m.	$r = 38° \, 38' \pm 6'$
1878 August 30,	5h. 20m.	$r = 38° \, 48' \pm 48'$
1878 August 30,	6h. 1m.	$r = 38° \, 28' \pm 22'$
Mean		$r = 38° \, 38' \pm 1'.4$

The breadth of the bow being 2°, with a probable error of $\frac{1}{10}$ or $\pm 6'$, we get—

for the outermost red ring $r = 39° \, 38' \pm 6'.2$
for the innermost blue ring $r = 37° \, 38' \pm 6'.2$.

At 7h. p.m. the bow stood white against the blue sky, the Sandhorn below it. At 6h. 40m. p.m., and sometimes before, I remarked that my own shadow was visible on the fog wall. In order to get a wider view of the phenomenon, I went up upon the roof of the chart-house, where my eye was 27·5 feet (8·4m.) above the surface of the sea. From here I saw how my shadow distinctly imitated all my movements. The shadow of my head appeared dark on a lighter white ground, and from a certain distance surrounded by a concentric coloured glory, in which the colours were arranged in the order of the spectrum, so that the outermost circumference was red, the middle yellow, and the innermost blue. There was no white band in the glory. With the sextant I measured the radius of the yellow ring, which was the most intense, at 1° 31′. The intensity of the other coloured rings was too feeble to allow their radius to be measured with the sextant. From a comparison with the radius of the yellow ring I judged that of the blue at 1° 15′, and that of the red at 1° 45′, with a possible error on both sides of ± 5′. This phenomenon is Ulloa's Ring.

Taking all my results together, we have the following synoptical table :—

Ulloa's Ring.	Radius of inner	blue	1° 15′ ± 5.
,, ,,	,, ,,	yellow	1° 31′ ± 2′.
,, ,,	,, ,,	outer red	1° 45′ ± 5′.
Fog Bow	,, ,,	inner blue	37° 38′ ± 6′.
,, ,,	,, ,,	middle	38° 38′ ± 1′.
,, ,,	,, ,,	outer red	39° 38′ ± 6′.

The fog bow cannot be the rainbow with three or four inner reflections, as these rainbows, if visible, would not be anthelic, but have, for the red rays, distances from the sun of 42° and 43°. Moreover, the intensity of the fog bow is too considerable to be the result of so many reflections in drops of rain. The ordinary or first rainbow, with one inner reflection, has a radius or distance from the anthelic point of 42° 30′ for the red, and 40° 30′ for the violet rays, which gives, the sun's radius being 16′, its innermost radius like 40° 14′. The outermost red ring of the fog bow has a radius of 39° 38′. Its distance from the ordinary rainbow is consequently only 36′. This space we see sometimes covered by the supernumerary rainbows, caused, as Sir G. B. Airy's investigations have shown, by the interference of the rays leaving the raindrop.

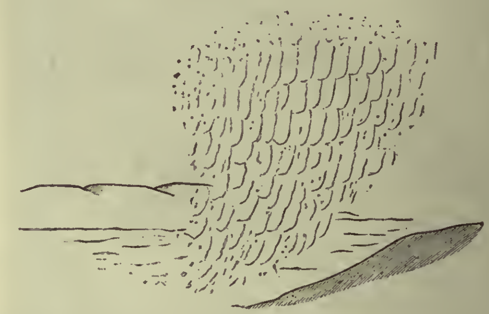
It seems probable that the smallness of the fog globules, as contrasted by the larger size of the raindrops, must enter as an essential part in the explication of the fog bow. In Günther's "Lehrbuch der Geophysik und physikalischen Geographie," ii. p. 151, he speaks of white rainbows, the description of which agrees with the aspect and position of my fog bows, and for which Bravais has given an explanation ("Sur le Phénomène de l'Arc-en-ciel blanc," *Ann. de Chim et Phys.* [3], vol. xxi. p. 348). Not having Bravais' memoir at hand, I may only remark that, as far as I can see from Günther, he assumes the fog drops to be hollow, a supposition which is hardly in accordance with modern investigations.

When I saw the fog bow, I had, I am sorry to say, no polariscope, so that I was unable to investigate the polarization of its light, so characteristic for the rainbow. H. MOHN.

Christiania, January 31.

The Shadow of a Mist.

THE reticulated rippling shadow of the mist described in Mr. Fawcett's letter (NATURE, January 5, p. 224) reminds me of a somewhat parallel phenomenon seen by me a few years ago. I saw a snow-storm some miles away crossing the valley between the Mendips and the Quantocks. It hung like a long, heavy curtain partially obscuring the *bright* western sky. The



light shining through the shower showed a fairly regular pattern. On a reddish-brown ground the darker, because denser, parts of the shower took the form indicated roughly by the accompanying diagram. Was the snow falling in spiral streams, and would a similar explanation apply to the shadow of the mist seen by Mr. Fawcett? HENRY BERNARD.

The English Church, Moscow, January 31.

Instability of Freshly Magnetized Needles.

I MADE no attempt to investigate the fluctuations of the dipping needle. They seemed to me to pass away after a few minutes, and I therefore took that method to get rid of them, supposing that the phenomenon was well known to other observers. The variations that I observed amounted to three or four minutes, I should think. It is true that the dip circle which I used was of an ancient pattern ; as Prof. Rücker says, hardly up to modern requirements. I did not send it back to the maker for adjustment, as Mr. Whipple says he would have done, because it was lent to me, and it was the best I was able to get.

Recognizing the fact that we could not expect to get the best results from our outfit, it was deemed best to make only one set of observations at each station, and multiply the number of stations as greatly as possible. This made it necessary to do the work quickly at some stations in order to adapt our time to that of trains, or in order to get the drudgery involved in camp-life done within the twenty-four hours. It is probable that at some stations we overdid the matter, and that the observations would have been better if more time had been taken. The dip observations I always regarded as least satisfactory. But all of the work has been published in such a way that its value can be estimated by anyone interested, and everyone is welcome to place whatever value he pleases upon it. We did the best we could under the circumstances, and the expense was met by private means.

The dip circle was returned to Washington when we were done with it, so that I am not now in a position to throw any light upon the subject under discussion. For most of the stations at which observations were made, I think the magnetic elements were determined with as great precision as a single observation would give them, and they seem to me to be as valuable as they profess to be, and not very much more. The fact that so little magnetic work had been done in the central part of the United States seemed to me to justify the plan of making the number of stations large, rather than of trying to attain the precision of observatory methods in field work at a few stations.

FRANCIS E. NIPHER.

Microsauria and Dendrerpeton.

In the notice in NATURE of January 12 (p. 244) of Fritsch's new number of his excellent work on the Permian fauna of Bohemia, which has not yet reached me, I observe a reference to *Microsauria*, which would seem to imply that I had included *Dendrerpeton* in that group. Possibly this was not intended by the reviewer, as it certainly could not have been intended by Fritsch, who knows my views quite well; but in case it should be misunderstood I beg to say that I have not held this view, but on the contrary have confined the name Microsauria to species with simple teeth, and have placed *Dendrerpeton* with Labyrinthodonts, though by no means as a typical genus of that group. In my last paper on this subject (Trans. Royal Society, 1882), I expressly exclude the two species of *Dendrerpeton* referred to from Microsauria, and define the latter as having non-plicated teeth (pp. 634-35). I may add, however, that I have always held and now hold that the Microsauria, though in some respects inferior to Labyrinthodonts, embrace in their structures premonitions of the true reptiles not found in the latter.

The study of these creatures was one of those bye-efforts thrust on me by circumstances, and which I have closed up so far as I am concerned in the paper referred to; but I have learned to love the little Microsaurs and to regard them as a hopeful and prophetic group. J. WM. DAWSON.

McGill College, January 26.

A New Historic Comet?

PERMIT me to inform Mr. Knott that the "new historic comet" is not a new comet at all. He will find it as No. 154 in Mr. Chambers's Catalogue No. II. in his well-known "Handbook of Descriptive Astronomy." It is there described, 302 A.D. "in May–June a comet was visible in the morning—(Ma-tuoan-lin: Williams 26)." W. H. S. MONCK.

Dublin, February 10.

The Proposed Teaching University for London.

No one, I am sure, who has carefully read my letters in the *Times* on this subject could agree with the writer of your article that I appear "to consider the dispute as one between the efficiency of 'lectures' on the one hand, and of 'reading' on the other."

The writer of the article has certainly misunderstood my views "upon the matters in dispute," as well as my object in quoting Darwin's dictum on the advantages of "reading" as compared with "lectures." PHILIP MAGNUS.

Exhibition Road, London, S.W., February 10.

Institute of Chemistry.

WITH reference to a circular letter dated the 12th inst., and bearing the signature of Mr. W. Thomson, which has been sent to the Fellows of the Institute of Chemistry, we beg that you will be so good as to allow us to inform the Fellows, through your columns, that we have not been consulted in regard to the action taken by Mr. Thomson, and that we decline to offer ourselves as candidates for election in opposition to the nominations of the Council. BOVERTON REDWOOD.

London, February 20. ALFRED GORDON SALAMON.

CORAL FORMATIONS.

I DESIRE to call attention to a condition of reef that I think has been very little studied, but that may contain a clue to a solution of some of the difficulties that still surround the subject of coral formations generally.

I may as well at once avow myself to be one of those who, on reviewing the later evidence on coral growth, have come to the conclusion that it is sufficient to justify an abandonment of the supposition that subsidence plays a principal part in the production of barrier reefs and atolls, but are at the same time not satisfied with one part of the explanation offered by Mr. J. Murray.

I refer to the great effects attributed by him to the disintegration and solution of dead coral by the chemical action of sea-water, in hollowing out and deepening the large and deep lagoons inside both these classes of reefs.

Mr. Murray's theory on this point, as summarized by himself, is that—

"(1) When coral plantations build up on submarine banks, they assume an atoll form, owing to the more abundant supply of food to the outer margins, *and the removal of dead coral rock from the interior portions by currents and by the action of the carbonic acid dissolved in sea-water.* (2) That barrier reefs have built out from the shore on a foundation of volcanic debris, or a talus of coral blocks, coral sediment, or pelagic shells, and *the lagoon channel is formed in the same way as a lagoon.*"

The italics are mine, and indicate the part of his theory to which from my view, and, I believe, that of others, there are objections, but to which Mr. Murray attaches considerable weight.

Is it necessary thus to invoke the aid of dissolution of the dead coral by chemical action as an important agent in the formation of these deep lagoons and channels? I think not.

An examination of the forms of, and depths on, well-surveyed submerged banks in different regions reveals a considerable number of reefs, which, if their development continues on the same lines as apparently heretofore, must, in the course of time necessary to bring them to the surface, form perfect atolls of large size, inclosing deep lagoons, without any further scooping out by solution.

Many instances occur in the China Sea. The Tizard Bank, in lat. 10° 20′ N., and long. 114° 25′ E., is 32 nautical miles in length, with an extreme breadth of 10 miles, and was well surveyed in 1867. The central portion is very flat and almost void of patches. Its depth is from 30 to 47 fathoms. Its edge is crowned with a coral rim varying from 4 to 10 fathoms in depth, broken here and there by openings, in some cases over 30 fathoms deep. The bank rises steeply from deep water, but, as no sectional soundings were taken, the precise angle of slope is unknown. The rim is composed of coral in luxuriant growth, and it can scarcely be doubted that in time it will reach the surface. In fact, on its periphery of 100 miles, in eight places small patches of reef, three of which bear islets, have already done so.

When the remaining portions of the rim are also awash, the reef will be in all respects an atoll similar to the great Maldive atolls, without any necessity for solvent action enlarging or deepening it.

Eight other banks of similar character, and in various stages, occur not far from this reef.

The great Macclesfield Bank, farther north, over 70 miles in length, and 40 miles in width, is of precisely the same nature, but its development is not so far advanced; the rim being in no spot nearer the surface than 10 fathoms, the water on it varying from that amount to 19 fathoms, while the depth of the inclosed area is from 40 to 60 fathoms. The survey of this bank is not so complete as in the case of some others, but enough has been done to show its character very plainly.

The Prince Consort Shoal (300 miles S.W. of the Tizard Bank) is apparently at a still earlier stage, a few patches of 17 fathoms and a considerable area of 30 fathoms partly inclosing a central area of 40 fathoms depth. The great Seychelles Bank in the Indian Ocean, 200 miles by 100, is very imperfectly known, but in most places the lines of soundings over its edge exhibit this tendency to form a rim. Here, however, the general depth on the bank is not over 30 fathoms. The Amirante Bank is a similar example.

The evidence afforded by these reefs has probably escaped notice from the fact that as published in charts for the purpose of navigation they are mostly shown on a very small scale, in which their character is scarcely apparent. The original manuscript surveys in the records of the Hydro-

graphic Department being not generally available, no opportunity has been afforded for their examination, but on these their form is highly suggestive. It should also be remembered that few submerged banks have yet been surveyed on a sufficiently large scale and in sufficient detail to show their characteristics.

I may, however, add that it is well known to seamen experienced in navigation in coral waters that shallower soundings are frequently found on the edges of banks.

How precisely it comes about that coral is growing on the yet deep rims of these large banks, and that little or none is flourishing in the interior, evidence is yet wanting to show. These, however, are the facts, and the result, so far as the necessity for future scooping out is concerned, seems indisputable. I may nevertheless offer a suggestion.

This condition of reef is apparently only to be accounted for in two ways. Either by subsidence; or by assuming that the animals, be they corals or other lime-secreting organisms, that settle on the bank, do, when it gets, by their accumulation, within a certain distance of the

surface, and under certain conditions of currents and food supply, intercept so much of the food borne in by the currents, that similar life, suitable to that depth zone, cannot be supported in the central area. Thenceforward, the rim alone will grow, and the organisms fitted to live in the successively shallower zones to the surface will only find on it foothold.

This would be the perfect atoll, but, with less nicely balanced conditions, growth would also take place in patches in the central area, as is so often the case.

It is to be observed that the depths on the more or less level tops of these large banks, as also in many perfect atolls, is frequently between 30 and 50 fathoms.

The smaller the bank, the less would be its general depth when the rim is formed, owing to the different proportions in which an area and its periphery, over which the non-consumed food must pass, relatively increase, and assuming that the animals that live nearer the surface consume more than those at greater depths.

I am fully aware that this view of the growth of an

atoll is not new. Darwin says, "A bank at the proper depth beneath the surface would give rise to a reef which could not be distinguished from an atoll formed during subsidence." Murray says, "Very early in the history of such an atoll, and while yet several fathoms submerged, the corals situated in the central parts would be placed at a disadvantage." It does not, however, appear to have been contemplated that the inclosed lagoon would, under any circumstances, without some further agency than the simple growth of the rim, be so deep as it appears to me, from the cases above cited, that it can be ; nor, so far as I can find, have any such instances been before remarked.

Darwin notices the case of the Chagos Bank, but, on the authority of Captain Moresby, he states that the rim is dead, and concludes that life was killed by subsidence, and he apparently also infers that it will not grow to the surface.

I can find no fresh evidence on this particular reef, but for some of the banks in the China Sea I have the independent testimony of two of the officers employed in their survey, Staff-Commanders Tizard and Petley, R.N., that the coral growth is most luxuriant.

Touching for a moment on the point of the formation of banks at a proper distance below the surface ; the investigation of banks in the Atlantic, recently described by Mr. J. Buchanan, shows that banks with almost wall-like slopes are growing up by the accumulation of organisms.

Turning to barrier reefs, similar instances can be found. Off the coast of the island of Palawan, a shallow rim is forming on the edge of the bank which stretches from the island to a distance varying from 15 to 30 miles, having a general depth on it of 40 fathoms. The length of the rim is 250 miles, and it consists of streaks and patches of coral with from 4 to 30 fathoms on them.

On the south of the eastern end of New Guinea, a formation, known to navigators as the sunken barrier, lines the edge of a bank similar to the above, and is of precisely the same character. Its length is 140 miles, and the depth between it and the land varies from 30 to 60 fathoms.

Dr. Guppy has recently pointed out some smaller instances of the same tendency in the Solomon Islands, and has made some remarks on the formation of barrier reefs in the same sense as my suggestions. I am not therefore advancing anything novel, but simply pointing out evidence which tends to show that the principle may be carried further than has hitherto been supposed.

Looking now at the fringing class, how comes it that so many wide reefs of this character exist, which, if Mr. Murray's contention be correct, should surely show more signs of the formation of a lagoon channel than they do?

Take the case of Rodriguez, in the Indian Ocean, with which I am personally intimately acquainted. Here a fringing reef surrounds the western sides of the island for a width of 4½ miles. There are narrow channels it is true, but so shallow that in many places boats cannot pass at low water. The island is situated in the heart of the strong trade winds, and the reefs are exposed to a heavy sea, which, with a rise of tide of nearly 6 feet, gives every facility for scour and rapid change of water.

I am not disputing the fact that calcareous dead organisms are dissolved by carbonic acid. I am no chemist, and moreover the *Challenger* observations amply prove it, but I would ask Mr. Murray if there is not a great difference between the position of small shells falling in water which completely surrounds them whilst they are constantly coming in contact with fresh particles of it, and of the more or less solid mass of a coral reef, which can only be attacked on its upper side to advantage, and where the resultant fine mud covers and protects the remaining rock, especially in the case of lagoon channels, when the bottom is partly composed of detritus from the land.

At the bottom of a lagoon of any depth, moreover, the motion of the water must often be comparatively slight, and the action consequently extremely slow.

The rotten state of the surface of every coral reef awash with the water shows that this disintegration is going on, but the fact that for large areas it remains awash, and must have so remained for ages, seems to me to point to the supposition that the removal of matter is too insignificant to account for the formation of deep lagoon channels in this manner, though doubtless it may explain the shallow pools and creeks found in all fringing reefs.

I have addressed myself solely to one point in this many-sided question, but I may add my opinion that, before any explanation which will fully account for the almost infinite variety of coral formations, can be given, much more knowledge of details of the complex conditions under which they may grow is required.

Certain knowledge of the depths at which different corals and other lime-secreting animals live under varying circumstances ; of the amount of food carried in the different strata and in different waters ; of the effect of the velocity of the currents that bring the food to the banks ; and more accurate surveys on large scales, especially of the shapes and contours of coral reefs, and of their composition, are all wanting. These details must greatly affect coral growth, and the results must greatly vary. On the other hand, similar results may be brought about by different causes.

It may surprise some to learn how little in the preliminary matter of surveys alone has been done in the principal coral-reef regions, especially in the Pacific, which is generally quoted ; and consequently how very inexact our knowledge is of the depth both inside and outside of the majority of atolls in the world, and also of the state of the bottom of the sea, on which it is very possible that many elevations may be found in the condition of those to which I have called attention.

In the Pacific the vast majority of islands have been merely sketched without a single sounding having been taken, either inside or outside lagoons.

I append a few statistics relating to the larger coral groups to show our position in this respect ; merely remarking that the waters of the Fiji and the Society Islands are the only ones which can be said to be in any sense surveyed.

W. J. L. WHARTON.

THE AKKAS, A PYGMY RACE FROM CENTRAL AFRICA.

At the last meeting of the Anthropological Institute, Prof. Flower gave a description of two skeletons of Akkas, lately obtained in the Monbuttu country, Central Africa, by Emin Pasha, and by him presented to the British Museum. Since this diminutive tribe was discovered by Schweinfurth in 1870, they have received considerable attention from various travellers and anthropologists, and general descriptions and measurements of several living individuals have been published, but no account of their osteological characters has been given, and no specimens have been submitted to careful anatomical examination. The two skeletons are those of fully adult people, a male and a female, but unfortunately neither is quite complete. The evidence they afford entirely corroborates the view, previously derived from external measurements, that the Akkas

are among the smallest, if not actually the smallest, people upon the earth. There is no reason to suppose that these skeletons were selected in any way as exceptional specimens, yet they are both of them smaller than any other normal skeletons known, smaller certainly than the smallest Bushman skeleton in any Museum in this country, and smaller than any out of twenty-nine skeletons of the diminutive inhabitants of the Andaman Islands, of which the dimensions have been recorded by Prof. Flower in a previous paper communicated to the Institute. The most liberal calculation of the height of these two skeletons places that of the male at about an inch below 4 feet, and the female at less than an inch above. We may say 4 feet, or 1·219 metre, as the average height of the two, while a living female of whom Emin Pasha has sent careful measurements is but 1·164 metre, or barely 3 feet 10 inches. The results previously obtained from the measurements of about half-a-dozen living Akkas are not quite so low as these, varying from 1·216 to 1·420, and give a mean for both sexes of 1·356, or 4 feet 5½ inches. Schweinfurth's original measurements were unfortunately lost, and the numbers since obtained are quite insufficient for establishing the true average of the race, especially as it is not certain that they were all pure-bred specimens.

In the list given in the third edition of Topinard's "Anthropologie" (1879) only two races appear which have a mean height below 1·500 metres, viz. the Negritos of the Andaman Islands 1·478, and the Bushmen 1·404. Of the real height of the former we have abundant and exact evidence, both from the living individuals and from skeletons, which clearly proves that they considerably exceed the Akkas in stature. That this is also the case with the Bushmen there is little doubt, although the measurements of this diminutive race are less numerous and carefully made.

The point of comparative size being settled, it remains to consider to what races the Akkas are most nearly allied. That they belong in all their essential characteristics to the black or Negroid branch of the human species there can be no doubt, in fact they exhibit all the essential characteristics of that branch even to exaggeration. With regard to the somewhat more rounded form of head (the cephalic index in these examples being 74·4 and 77·9 respectively), Hamy has long since pointed out that in equatorial Africa, extending from the west coast far into the interior, are scattered tribes of Negroes, distinguished from the majority of the inhabitants of the continent by this special cranial character, as well as by their smaller stature. The Akkas are grouped by Hamy and Quatrefages as members of this race, to which the distinctive name of "Negrillo" has been applied. Their small size has naturally led some anthropologists, including Schweinfurth, to ally them to the diminutive African race inhabiting the southern part of the continent—the Bushmen; but beyond certain characters met with in the whole Negroid branch, including the frizzly hair, there is little in common between them. The Bushmen are a very strongly marked race, and both their external appearance and osteological characters are so exceptional that they can never be confounded with any other. The natives of the Andaman Islands have also very distinctive characters, which they do not share with the Akkas, whose position all recent investigations show to be that assigned to them by Hamy as members of the Negrillo division of the Negroid branch of mankind. It is possible that these people gave origin to the stories of pygmies so common in the writings of the Greek poets and historians, and whose habitations were often placed near the sources of the Nile. The name "Akka," by which, according to Schweinfurth, the tribe now call themselves, has, singularly enough, been read by Mariette Pasha by the side of a portrait of a dwarf on a monument of the ancient Egyptian empire.

REV. JOHN HEWITT JELLETT, D.D., D.C.L.

IT is with extreme regret that we announce the death of the Reverend the Provost of Trinity College, Dublin. He died last Sunday evening after a very short illness.

The Provost was present in his usual health at the Spring Commencements, which were held on the 14th inst. in the Hall of Trinity College; on the 16th he was not quite well; on the 18th some dangerous symptoms appeared; and the end came, painlessly and unexpectedly, on the 19th inst.

John Hewitt Jellett was born at Cashel in the county of Tipperary on December 25, 1817. He entered Trinity College, Dublin, when seventeen years of age. Obtaining a Scholarship in 1836, he graduated as a Senior Moderator and Gold Medallist in Mathematics in 1837, and three years afterwards he obtained a Fellowship.

In 1848, he was appointed to the Professorship of Natural Philosophy; in 1870, on the death of the Rev. Dr. Luby, he was co-opted a Senior Fellow of Trinity College, and on the death of the Rev. Dr. Lloyd, in 1881, he was nominated by the Crown to the Provostship.

Twenty years ago he was made one of the Commissioners of National Education in Ireland, and he was President of the Royal Irish Academy from 1869 to 1873.

In 1850, Jellett published his well-known "Treatise on the Calculus of Variations," a subject which had engaged the attention of some of the noblest mathematical intellects of the world. The volume contains improvements of previously existing methods, which, had they been given as so many separate treatises, would in themselves have formed no ordinary title to fame; but the author's aim was rather to compile a memoir which would enable the earnest student to be on a level with the knowledge he had himself attained to, however little that aim might be to his own glory.

For this work the Royal Irish Academy awarded Jellett in 1851 their Cunningham Gold Medal. In 1872 appeared the "Treatise on the Theory of Friction," a work well known and highly appreciated. In addition to these volumes a number of scientific memoirs were from time to time published by him in the Transactions of the Royal Irish Academy, and in Leonville's *Journal de Mathématique*, of which perhaps the more important were on the "Equilibrium and Motion of an Elastic Solid" and "On Researches in Chemical Optics."

Like other well-known mathematicians of the Dublin University, Jellett was as much thought of for his pulpit discourses as for his scientific memoirs. He was of good presence, had a clear articulation and a very persuasive style; and his appearance in the pulpit of the College chapel was always welcomed. When he dwelt on the moral difficulties of the Old Testament, none went their way without being impressed by the straightforward honesty of the man.

Occupying a very conspicuous position in a University city like Dublin, the Provost seemed to command the respect of all. Some perhaps there are who would have preferred that the head of so ancient a seat of learning should have taken no part in modern political strife; but, even amid the feverish excitement of party warfare, the Provost of Trinity College, though he often fearlessly and eloquently put forward his own views, did so without giving offence to any.

Intimately associated, from the year 1834, with the life of the College over which he at the last presided, the Provost knew much of, and was a prime mover in, many of the changes which have marked out a new life in the place. Within its walls he was known and respected, while the tribute to his memory paid by all classes of the Dublin citizens is a striking proof of how he was loved.

This is not the place to dwell on the intense loss his

death brings to those who had experienced the charm of that hidden inner life which was known to his friends as both kind and just, affectionate and sympathetic.

NOTES.

THE retirement of the veteran Prof. Prestwich from the Chair of Geology at Oxford is an event which cannot be chronicled without regret. But it is pleasant to know that he relinquishes the post which he has dignified for so many years to find in the quiet of his country home that leisure and rest to which his long devotion to the cause of science so justly entitles him. He has crowned his professorial career by the publication of the splendid volume which completes his great work on geology. On the very day after the appearance of that volume the electors met at Oxford to select from the numerous candidates a successor to fill his place. His University and the science of geology may both be congratulated on their choice. Prof. Green, whom they have chosen, is one of the most accomplished geologists in the country, one who has been trained in the practical school of the Geological Survey, who has done admirable original work, and who possesses in no common measure the power of luminous exposition. He is gifted, moreover, with a faculty in which geologists are often singularly defective, that of mathematical investigation, and we may hope that one of the results of his transference to Oxford will be to afford him an opportunity of devoting himself to the attack of many geological problems from the mathematical side. He carries with him to his new sphere of labour the best wishes of all to whom the progress of geology and the cultivation of science at the Universities are dear.

ON May 27 next Prof. F. C. Donders, of Utrecht, will be seventy years of age. The law requires that he shall then resign his duties as Professor at the University and as Director of the Physiological Laboratory, and it is thought that men of science in all parts of the world may be glad to take the opportunity of expressing their appreciation of the great services Prof. Donders has rendered to the study of physiology and physiological optics. An influential committee has been formed in Holland for the purpose of giving effect to this idea, and the proposal is that Prof. Donders' name should be connected in a permanent way with the spot where he has lived and worked for more than forty years, by the creation of a fund to be devoted to a scientific purpose, and to be known as the "Donders Memorial Fund." The uses to which the fund will be put, and the rules by which its administration will be governed, will of course be determined in accordance with the wishes of Prof. Donders. The Ophthalmological and Physiological Societies have taken the matter in hand in this country, and we have no doubt that the committees they have appointed will do their work satisfactorily. It ought not to be difficult for them to secure an adequate token of the respect felt in England for an illustrious man of science to whom the medical profession and the public are so deeply indebted. It is proposed that the amounts contributed by the several donors be not specified, but that they be grouped into a common sum for transmission to the Dutch Committee; and that the names of those contributing be inscribed in a suitable form for presentation to Prof. Donders. For this reason smaller as well as larger subscriptions will be acceptable. Subscriptions may be sent to Dr. Gerald F. Yeo, Secretary of the Committee of the Physiological Society (address—King's College, London, W.C.), or to Dr. W. A. Brailey, Secretary of the Committee of the Ophthalmological Society of the United Kingdom (address—11 Old Burlington Street, London, W.). Subscriptions may also be sent to the office of this journal.

AT a meeting of the Royal Society of Edinburgh, held on January 30, Profs. Clausius, Haeckel, and Mendeléeff were elected Honorary Fellows.

SIR JAMES PAGET, F.R.S., has consented to give the annual address to the students of the London Society for the Extension of University Teaching, at the Mansion House, on Saturday, March 3, at 3.30 p.m., under the presidency of the Lord Mayor. The subject of the address will be "Scientific Study."

A MARBLE medallion portrait of the distinguished palæontologist, Dr. Thomas Davidson, F.R.S., first chairman of the Brighton Museum Committee, was unveiled in the geological room of the Free Town Museum, Brighton, by the Mayor, Mr. E. Martin, on Friday, the 17th inst. The medallion, which is much admired, is the work of Mr. Brock, A.R.A. It was presented to the town on behalf of the subscribers by Mr. Edward Crane, chairman of the Museum Committee, who referred in detail to Dr. Davidson's services to science and to the Museum. Sir R. Owen sent a letter regretting that failing health prevented his paying the respect of personal attendance to the memory of his distinguished fellow-worker. Prof. Judd also wrote bearing cordial testimony to the skill and enthusiasm with which Dr. Davidson carried on his researches.

GENERAL PERRIER, the most eminent French authority on geodesy, died at Montpellier on Monday at the age of fifty-five. He had attained the rank of Brigadier-General in the French army, and was at the head of the Geodetic Department at the War Office. He was a member of the Academy of Sciences.

THE relations of science and religion do not form one of those topics which we permit ourselves to discuss in NATURE. At the same time we may call attention to a series of three remarkable articles on "Darwinism and the Christian Faith" recently published in the *Guardian* (January 18, January 25, and February 1, 1888), and now reprinted as a pamphlet. The author is anonymous, but is understood to be an Oxford College tutor, and Honorary Canon of Christ Church. The orthodoxy of the *Guardian* is, we believe, unimpeachable. We notice therefore with gratification that not only is Darwinism thoroughly accepted and lucidly expounded by the writer in the *Guardian*, but that he is an exceptionally well-informed and capable critic, whose scientific knowledge is varied and sound. The publication of these articles in the *Guardian* is a proof that the clergy as a body are not so unwilling to accept new scientific views as might be supposed were we to regard Dean Burgon as a fair sample of his class. The *Guardian's* contributor discusses the difficulty of reconciling the existence of a just, omnipotent, and omniscient God with the existence of pain and the ceaseless "struggle for existence," and *à propos* has a remark tinged with local colour which is worth reproducing. "And yet," he says, "man, who is so wise and good that he is always saying, with King Alphonso of Castile, 'If God had called me to His councils things would have been in better order,' has invented competitive examinations, which mean suffering and pain for all, without even a compensating 'survival of the fittest' or improvement of the race!" We believe that competitive examinations were invented by the Chinese, and introduced into Europe by Jesuit missionaries. The Chinese are celebrated among the nations of the world for the elaborate system of cruel tortures employed in their administration of justice. On the other hand, we owe tea and many other nice things to them.

THE annual winter meeting of the Department of Superintendence of the U.S. National Education Association was held lately at Washington. The most important topics treated were "How and to what extent can Manual Training be ingrafted on our System of Public Schools?" and "How can the Qualifications of Teachers be determined?"

THE Archæological Congress which is to be held at Moscow, in 1890, will have an international character, many German, French, Italian, and other men of science having already been invited to attend. The Congress will consider the following subjects: (1) prehistoric antiquities; (2) historical, geographical, and ethnographical questions; (3) Russian art monuments; (4) ecclesiastical monuments; (5) Slavo-Russian language and writing; (6) Slavo-Byzantine and West European antiquities; (7) Oriental and heathen antiquities; (8) latest progress of archæology.

MRS. ZELIA NUTTALL has been elected a Fellow of the American Association for the Advancement of Science in recognition of her researches in Mexican archæology.

A TRANSLATION of Dr. E. B. Tylor's hand-book of "Anthropology" into Spanish by D. Antonio Machado has just been published in Madrid. The author contributes a special preface drawing attention to the valuable anthropological material still to be found in Spanish America.

THE first number of what will no doubt prove to be an important and valuable periodical has just been issued. It is called *Internationales Archiv für Ethnographie*, and is edited by J. D. E. Schmeltz, of the Ethnographical Museum of Leyden, who has received promises of co-operation from many of the foremost ethnologists and anthropologists in Europe and America. The present number (which contains German, Dutch, and French contributions) opens with a striking article, in German, by Dr. L. Serrurier, Director of the Leyden Ethnographical Museum, on the arrows of New Guinea. Representations of the various types of New Guinea arrows, admirably printed in colours, illustrate this interesting paper.

WE have received the first number of *The American Anthropologist*. This new quarterly periodical is issued under the auspices of the Anthropological Society of Washington, and the editorial committee seek the co-operation of all who are interested in the advancement of anthropological science. In the first number there are papers on the law of Malthus, by Dr. James C. Walling; the development of time-keeping in Greece and Rome, by F. A. Seely; the human hand, by Dr. Frank Baker; and the Chane-abal (four-language) tribe and dialect of Chiapas, by Dr. D. G. Brinton.

THE *American Meteorological Journal* for January contains:—(1) An article by F. Waldo on instruments for measuring atmospheric pressure, showing the differences that exist in the standard barometers of different countries, and that the standards do not always remain constant for a number of years. (2) A paper by Prof. H. A. Hazen on the exposure of thermometers, with a discussion of a new plan proposed by Dr. R. Assmann. The latter paper was presented to the Berlin Academy in November last. (3) On a thirty-day period of the weather, by H. Helm Clayton. The writer considers that the period is strongly substantiated by facts, although at present they remain empirical facts.

THE Deutsche Seewarte has published the seventh volume of the results of meteorological observations for 1° squares of the North Atlantic Ocean. The object is to discuss the observations collected by German and Dutch vessels between latitude 50° and 20° N. in the North Atlantic, adjoining the district of the nine equatorial 10° squares between latitude 20° N. and 10° S., and longitude 10° and 40° W., the observations for which have been discussed by the Meteorological Council. The district now covered by the two institutions embraces 60° of latitude and 30° of longitude, with the exception of one 10° square, which will shortly be published. The German observations are published in a tabular form, showing for each degree the direction of the winds under sixteen points, the number of storms, the mean wind force, pressure, temperature of air and sea, rainfall, and other particulars. The number of observations for each subdivision is sometimes small, but always quoted, and in their present form the observations may be added to subsequently, or amalgamated with those of other countries. A small but important district south of 20° N. (the limit of the German investigation) and west of 40° W. (the limit of the English investigation), embracing the region of the origin of the West India cyclones, has yet to be undertaken by some body, to complete these important contributions to maritime meteorology.

A NEW chloride of gold, Au_2Cl_4, has been prepared by Prof. Julius Thomsen, of Copenhagen (*Journ. für Prakt. Chemie*, 1888, No. 2). The method of preparation is remarkably simple, gaseous chlorine being merely brought into contact with gold in a fine state of subdivision and at a moderately elevated temperature. About 50 grammes of finely divided gold, obtained by precipitating a solution of the trichloride with sulphurous acid, was thoroughly washed, partially dried to the consistency of a thick mud, and placed in a previously weighed glass tube. At its lower end the tube was drawn out and the delivery tube of a chlorine generator sealed on to it. A stopper and exit tube at the upper end completed the arrangement. A rapid stream of chlorine gas (half a litre per minute) was then passed through the apparatus, the lower end of the wider portion containing the gold being gently heated to start the reaction. The whole was then placed in a glass beaker surrounded by cotton-wool in order to prevent too rapid cooling, by which device the heat of the reaction itself was sufficient to complete the combination. At the commencement the absorption of chlorine was perfect, not a bubble escaping, but at the expiration of half an hour the point of saturation was reached. After expelling the uncombined chlorine the tube was again weighed, and the amount of chlorine thus taken up determined. In every experiment the proportion of chlorine to that of gold was found to be very slightly more than two to one, the average ratio being 2·09 to 1·0. The slight excess of chlorine was due to minute spangles of trichloride of gold sparsely disseminated throughout the mass. The simplicity of this mode of preparation and the constancy of the results may perhaps excite wonder that Au_2Cl_4 has not hitherto been as well known as AuCl and $AuCl_3$. As a matter of fact, Prof. Thomsen discovered it several years ago, and published his results, but owing to the adoption of different methods by later workers the conclusions of Prof. Thomsen were not considered confirmed. Now that the work has been repeated and completely verified there is no longer any reason why Au_2Cl_4 should remain in the background. It is interesting theoretically as being the aurous salt of chlor-auric acid, $HAuCl_4$.

FROM the Annual Report of the New York State Department of Public Instruction, it appears that during last year over 31,000 teachers were employed in the State of New York, and that of this number only 5821 were males. The number of children of school age was 1,763,115; the total enrolment, 1,037,812; the average attendance, 625,610. Mr. Draper, the Superintendent, the author of the Report, says that the attendance in the schools does not keep pace with the growth of the population, and that the uneducated class is increasing.

COLONEL LE MESSURIER has just brought out a third edition of his useful pocket hand-book on the "Game, Shore, and Water Birds of India." The utility of this unpretending little work has been vouched for by the call for its re-issue in an octavo form with the addition of many drawings made by the author during his recent furlough in England, and we are glad to see to what practical use he has turned some of Prof. Flower's exhibits at the Natural History Museum. Colonel Le Messurier writes as a field-naturalist for field-naturalists and sportsmen, without any

great pretensions to scientific knowledge, but there is no doubt that all naturalists will gain useful hints from this little volume, which is profusely illustrated with woodcuts, giving the characteristic features of most of the species.

"THE STATESMAN'S YEAR-BOOK" for 1888 has been published. It contains additions and alterations which largely increase the value of the work, and the statistical and other information has been brought up to the latest available date.

WE have received three issues of the "Annuario" published by the Imperial Observatory at Rio de Janeiro—the issues for 1885, 1886, and 1887. The work is well compiled, and the editor evidently takes great pains to secure that each issue shall be decidedly better than its predecessors. Besides the usual collection of astronomical facts, the work contains useful tables relating to meteorology, chemistry, physics, geography, and other sciences.

THE "Annuaire Géologique Universel" of Dr. Dagincourt, which has just been issued for the third time, has been much enlarged and improved. The new volume contains an exhaustive review of recent work in palæontology and geology.

A FOURTH edition of Prof. Nichol's "Tables of European History, Literature, Science, and Art, from A.D. 200 to 1888" (Maclehose) has been issued. The idea of the work is good, but we cannot say that the scientific tables are always quite satisfactory. In his lists of men of science the compiler includes the names of some writers who have a very inadequate claim to the place he accords to them.

THE Trustees of the Australian Museum have issued a descriptive catalogue, by Dr. R. von Lendenfeld, of the Medusæ of the Australian seas. Speaking of the Scyphomedusæ, Dr. von Lendenfeld says that he has observed three species in New Zealand, three species on the coast of Victoria, and five species in Port Jackson. Two of the latter are identical with the Victorian species. Of the nine species, six have been described by Dr. von Lendenfeld; his specimens of the remaining three were not sufficiently well preserved for description. The difficulty connected with the preservation of these beautiful animals has, he points out, been a great obstacle in the way of a thorough knowledge of them.

THE fifth volume of the collected works of Paul Broca has just been issued by M. Reinwald, in Paris. This volume, which, like the others, is sold separately, is particularly interesting to zoologists. It contains Broca's numerous and important memoirs on the brain of man and primates. It is well illustrated.

M. ZOGRAFF's new work on the structure of the *Acipenser ruthenus*, which appeared in the *Izvestia* of the Moscow Society of Amateurs of Natural Science (vol. lii. fasc. 3), will be most welcome to zoologists. Following the methods adopted by Günther, Johann Müller, and Pallas, and more especially by the Swedish ichthyologist, F. A. Smitt, who has applied the system of numerous measurements used in anthropology to the study of fishes, M. Zograff has undertaken to give anew a complete description of the Russian species of *Acipenser*, and the Central Asian species of *Scaphirhynchus*. He begins his work by a general description of the body of the Russian Acipenseridæ: the varying shapes of their heads; the indexes of length, width, and thickness of the body; the skin and spines; the teeth; the muscles; and the brain. The whole is accompanied by numerous engravings and coloured plates, great attention being given to the minute anatomy of all parts of the different species.

AMONGST the papers contained in the last issue of the Transactions of the Seismological Society of Japan (vol. xi.) is one on earth tremors in Central Japan, by Prof. Milne. The paper is a continuation of one on the same subject read before the same Society in 1883, which was referred to in these columns at the time. In the present paper the writer discusses recent investigations into earth tremors in Italy, describes tremor recorders, with special reference to an automatic tromometer, gives numerous tables of records of the latter instrument, and finally refers to the subject of earth tremors on mountains. The paper is one of great length, and is accompanied by numerous charts and tables, which make it a respectable volume in itself. The conclusions may, however, be given in a brief space. Prof. Milne says that his chief object has been to show the relationship which earth tremors hold to barometrical fluctuations, barometrical gradients, and the wind. He concludes that they are more frequent with a low than a high barometer, but even with the former they may often not be observed; that with a high gradient they are almost always observed, but with a small gradient only seldom: that the stronger the wind the more likely they are to be observed; when there has been a strong wind and no tremors it has often been a local wind, or one blowing inland from the Pacific Ocean; the recorded earthquakes do not appear to be connected with earth tremors, more than that both are more frequent at the same seasons; and tremors are as severe on the summit of a lofty mountain as on the plains. So far as his observations have hitherto gone in Japan, it appears that the majority of earth tremors are movements produced by the action of the wind upon the surface of the earth, and that these may often be propagated to distant places where wind disturbances have not occurred.

ON January 13, at 11.10 p.m., a faint shock of earthquake was felt in the district of Örebro, in Central Sweden. It was not accompanied by any subterranean noise.

AT five o'clock on Sunday afternoon a cyclone broke over Mount Vernon, a town in Illinois, sixty miles to the south-east of St. Louis. Many persons were killed or injured, and five hundred buildings were demolished in a few minutes. The cyclone is said to have come up from the south-west with a rotary whirling motion, sweeping a path five hundred yards wide and several miles long, within which everything was destroyed.

DURING last month the so-called "red after-glow" was observed at sunset in the vicinity of Stockholm. Varying in intensity the glare extended considerably towards the zenith.

THE Finnish Government is on the point of organizing a number of stations along the coast of Finland for the observation of the nature and peculiarities of the drift-ice during the winter months.

A LARGE block of stone with rude drawings and some Runic inscriptions has just been discovered in the island of Tjörn, on the south-west coast of Sweden. It is of particular interest as being the first of its kind found in the southern part of the province of Bohus.

A MEETING has just been held at Tönsberg, in Norway, of those interested in the Arctic seal fisheries in that country, for the purpose of considering the Scottish Fishery Board's proposals that the close time for seal should end on April 10 instead of as at present April 3, and begin on July 10 instead of July 15. Both proposals were unanimously rejected, the reason advanced being that their adoption would tend to ruin the industry, so far as Norway is concerned. The Scotch proposal that young and old seal should be treated alike during the open season was adopted. Finally, the following resolutions were passed: (1) that it was advisable that the close season should end at 6 a.m. on April 3 instead of at midnight; (2) that the law of preservation of seal should be altered so that the area covered by it should range from 60° to 70° N., and from 10° E. to the coast of Greenland. A report of the meeting will be forwarded to the Scottish Fishery Board for their consideration.

THE Norwegian Fishery Promotion Society of Bergen has petitioned the Government for a grant of £15,000 for the development of the deep-sea fisheries of Norway.

THE Merchant Taylors Company have recently voted ten guineas to the Parkes Museum to aid in its work of practical teaching and demonstrating sanitary science.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀), two Rhesus Monkeys (*Macacus rhesus* ♀ ♀) from India, an Alpine Marmot (*Arctomys marmotta* ♀), European, a Vulpine Phalanger (*Phalangista vulpina* ♂) from Australia, presented by Mr. H. Austin Clow, F.Z.S.; three Esquimaux Dogs (*Canis familiaris*) from Greenland, presented by Mr. W. T. Tournay, F.Z.S.; three Derbian Wallabys (*Halmaturus derbianus*) from Australia, presented by Lieut. C. M. Hepworth, R.N.R.; four Alpine Accentors (*Accentor alpinus*), European, presented by the Lord Lilford, F.Z.S.; a Cardinal Grosbeak (*Cardinalis virginianus*) from North America, presented by Mr. Ayerst; four Lion Marmosets (*Midas rosalia*), an Eyra (*Felis eyra*) from Brazil, four Parrot Finches (*Erythrura psittacea*) from New Caledonia, two Common Gulls (*Larus canus*), a Black-headed Gull (*Larus ridibundus*), British, purchased; four Cereopsis Geese (*Cereopsis novæ-hollandiæ*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

MR. TEBBUTT'S OBSERVATORY, WINDSOR, NEW SOUTH WALES.—Mr. John Tebbutt, the well-known and enthusiastic amateur astronomer of New South Wales, has just published a little pamphlet giving a history and description of his private observatory, the work of which, he remarks with justifiable pride, "has proved of sufficient importance to admit of Windsor being placed in the list of observatories in the British and American *Nautical Almanacs*, the *Connaissance des Temps*, and the *Berliner Astronomisches Jahrbuch*." And this distinction has been well earned, for the lists here given of observations made, and of papers contributed to various scientific publications, show the history of the little observatory to have been a most honourable one. Mr. Tebbutt has made all the observations himself, and until 1881 performed all the reductions; latterly he has received occasional assistance in the computations from his son or friends near. His instrumental equipment was for many years of the most modest description: for seven years it consisted principally of a sextant, and a telescope of 1⅝ inches aperture. In 1861 a refractor of 3¼ inches aperture, and in 1864 a transit instrument of 2 inches, were added. In 1872, Mr. Tebbutt became the possessor of an equatorial of 4½ inches, which was his chief instrument until about a year and a half ago, when he bought a fine 8-inch equatorial by Grubb, once the property of the late Dr. Bone, of Castlemaine. The observations made have been principally of comets, for a number of which Mr. Tebbutt has also computed orbits, but daily meteorological observations have been kept up for twenty-five years, the results of which have been published in five parts, and transit observations have been taken regularly for time. Mr. Tebbutt has also done good service to science by his papers on astronomical subjects in various organs of the colonial press, for hitherto the private pursuit of astronomy has been greatly neglected in the Australian colonies, and he has almost stood alone as an amateur observer. It is to be hoped that this record of his labours and his success may call forth many imitators.

PULKOWA OBSERVATORY.—The Report of this Observatory for the year ending May 31, 1887, refers to the heavy loss the institution sustained in the death of Dr. August Wagner. Owing to his death, the work of publication has been somewhat delayed; he had, indeed, finished a memoir on personal and instrumental errors for the introduction of vol. xii., but the materials he left for the stellar and planetary catalogues were not so readily dealt with. Still, it is expected that this volume, and the introduction to vol. xiv., may soon be ready for publication; vols. xv. and xvi., which will contain meridian observations for the period 1872–80, and the catalogue, are ready to follow vol. xiv. through the press. Of vol. viii., the catalogue, forming the first part—meridian observations 1840–69 of Bradley and other stars down to mag. 6—has already been distributed, and the remainder is in hand; vol. x., Prof. Struve's double-star observations, is still incomplete. The observational work of the Observatory has suffered no great change. The 30-inch refractor has been used by Dr. H. Struve for the measurement of the more difficult of Burnham's stars, the fainter satellites of Saturn, and the satellite of Neptune. The old 15-inch has been used by Drs. H. Struve and Hasselberg for photographic experiments, and by Prof. O. Struve for observations of Procyon, which has now been followed through nearly a complete period of its orbital motion.

WOLSINGHAM OBSERVATORY.—The Rev. T. E. Espin reports that during the last year he has continued his sweeping for red stars and stars with remarkable spectra, and that he has published spectra of 126 objects in the *Astronomische Nachrichten*, Nos. 2788 and 2825, of which eighty-six were found in the sweeps. Fifteen of the stars were of Secchi's type IV. Three new variables of long period have been discovered, and the usual observations of variables have been made and forwarded to Prof. E. C. Pickering. The Observatory has been enriched by the present from Canon Slatter of a fine 4·8-inch equatorial by Troughton and Simms. The new edition of Birmingham's Red Star Catalogue will be ready for the printer in a few weeks.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *FEBRUARY* 26—*MARCH* 3.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 26

Sun rises, 6h. 54m.; souths, 12h. 13m. 10·0s.; sets, 17h. 32m.: right asc. on meridian, 22h. 36·3m.; decl. 8° 48′ S. Sidereal Time at Sunset, 3h. 56m.

Moon (Full, February 27, 12h.) rises, 16h. 22m.; souths, 23h. 50m.; sets, 7h. 4m.*: right asc. on meridian, 10h. 15·3m.; decl. 12° 53′ N.

THE RELATIONS BETWEEN GEOLOGY AND THE BIOLOGICAL SCIENCES.[1]

IN the remarks which at our last anniversary I had the honour of offering from this chair, I congratulated the students of geology and mineralogy upon the new and intimate relations which, to their mutual advantage, are now growing up between those departments of science. It has, however, been suggested that, while geologists are thus being brought into closer alliance with mineralogists, the strong bonds of union which have so long united us with the biologists are becoming somewhat relaxed, and, indeed, stand in no small danger of actual dissolution.

Highly as I estimate the value of the *rapprochement* between the geological and mineralogical sciences, I for one should regard such a result as far too dearly purchased, if it necessarily involved any interruption of the close relations which have so long subsisted between geology and biology. But I cannot for one moment believe that such a grievous misfortune seriously threatens the cultivators of the two great departments of natural science.

Notwithstanding certain divergencies of opinion which have made themselves heard within an ancient University, and have awakened a faint echo in the halls of our National Museum, I cannot doubt that the teachers of geology and biology will easily discover a *modus vivendi* upon what is, after all, a subject of very secondary importance—the arrangement of natural-history collections.

No one can read recent declarations of the present Director of our National Museum without being impressed by his manifest desire to make the splendid collections under his care reflect, as completely as possible, the present condition of our knowledge of natural history. And if, on the other hand, we turn to the remarks made by the Keeper of the Zoological Department, at Swansea, in 1880, and to those of the Keeper of the Palæontological Department, at Manchester, last year, we shall find in those utterances ample guarantees that, in the arrangement of their collections, questions of practical convenience will not be lost sight of; we shall be satisfied that there is not the smallest danger of revolutionary ideas leading to the removal of "ancient landmarks," or of unattainable ideals being sought through the wholesale commingling of incongruous elements. The collections of our Universities are happily free from the conditions which must always hamper an institution where the interests of popular amusement have to be reconciled with those of scientific work; and it is for the teachers of natural science in those centres of thought to agree upon an arrangement which may best serve to illustrate their courses of instruction.

But while the discussion on museum-arrangement may be regarded as a purely academical one, which, after scintillating for a while in letters and pamphlets, died out in some not very formidable explosions at the recent meeting of the British Association, it may be wise on our part not to pass by quite unnoticed some indications of the attitude of the younger school of biologists towards palæontological science, this attitude having been very conspicuously manifested during the discussion in question.

If I rightly apprehend the views of some of my biological friends, as gathered not only from their published utterances, but also from private conversations, the position they are inclined to take up may be expressed somewhat as follows:—

"Palæontology has no right whatever to separate existence as a distinct branch of science. Fossils are simply portions of animals and plants, and ought to be dealt with as such; for all scientific purposes it is quite immaterial whether the organism which we are called upon to study expired only an hour since or died millions of years ago. Imperfect fragments can only be properly interpreted in the light afforded by the more complete structures found in recent organisms; and hence the naturalist who is engaged in studying a particular group of living organisms is the only person competent to deal with its fossil representatives. In our laboratories and our museums alike, therefore, fossil remains ought to be studied side by side with the living types which most nearly resemble them, and always by the same investigators. This being the case, it is neither necessary nor expedient that there should be a class of students whose chief concern is with extinct forms of life; and as for the geologists, they have really no farther concern with fossils than just to find them, attach a label indicating the period at which they must have lived, and hand them over to the biologist for study and incorporation in his collections. Any action beyond this can only be regarded, indeed, as an act of usurpation on the part of geologists, and must tend, not to the advancement, but to the injury of true science."

Such, so far as I have been able to gather them, are the extreme opinions which some biologists now entertain. It may, perhaps, seem presumptuous on my part to venture to offer a plea for palæontology, but there are considerations which may induce us to regard such a plea as coming better from one whose place in the ranks of the geological army lies nearer the centre than in the biological wing; from one who regards palæontology as the borderland of the geological and biological sciences—a borderland where the cultivators of both ought ever to meet, not for rivalry and aggression, but for the necessities of intellectual commerce and the advantages of mutual help.

The view of palæontology which I have ascribed, I believe not unjustly, to some biologists is one which has just such an amount of truth in it as to render it plausible, but at the same time, as I cannot but believe, is one of those half-truths which are proverbially more dangerous than downright errors. Palæontology is not, as has often been confidently asserted, simply a branch of biology; it is equally a part of geological science, and there are the strongest grounds, both of reason and expediency, for retaining it in that position. All geological science is based on the principle that the past can only be interpreted by the study of the present; Darwin was the intellectual child of Lyell, and the "Origin of Species" was the logical outcome of the "Principles of Geology." No palæontologist, worthy of the name, has ever dreamed of studying fossils except in the light afforded by the investigation of their recent analogues. Indeed, if we were to carry out the aggressive ideas of some biologists to their legitimate consequences, there would be left to us no science of geology at all; for why, it may be asked, should the study of physical processes in the past be carried on separately from the investigation of the same processes as exhibited at the present time? But then, by a strange Nemesis, I fear the same all-devouring physics, after swallowing up geology, would make very short work indeed with biology itself. And there is still in the background another claimant for universal empire in the realms of thought, for are there not some who dream of all sciences ultimately becoming the victims of that new portent of ambition—"geography"?

In considering the present position and future claims of palæontology, I may be permitted at the outset to offer a protest against a class of objections which has sometimes been very unfairly urged against the votaries of that branch of science. It has often been assumed that the students of fossils are contented with a lower standard of excellence than that which is aspired to by the cultivators of other branches of natural history. Now, setting aside for a moment the very important consideration that, owing to the imperfection of the remains which they are called upon to study, palæontologists are confronted by difficulties which do not beset the investigators of recent forms, I maintain that the charge is an altogether unjust one. Palæontologists are no more responsible for the unwise use made of fossils by incompetent persons than are zoologists for the vagaries of shell- and butterfly-hunters, or botanists for the absurdities of fern- and diatom-collectors.

Doubtless there has been much work done in connection with

[1] Address to the Geological Society by the President, Prof. John W. Judd, F.R.S., at the Anniversary Meeting, on February 17.

fossils, as well as with other natural history objects, of which we can only speak with shame and regret as having been undertaken unadvisedly and performed ignorantly,—work which, prompted by an unwise ambition, has been conceived in error and brought forth in presumption.

It would ill become anyone from this chair to speak lightly of the great, the inestimable services rendered to our science by the collectors of fossils. How many interesting and novel forms have been brought to light by their patient efforts! How often has the structure of ob cure types been rendered clear through their constant and persevering endeavours to obtain more perfect specimens! Yet sometimes the very zeal of collectors has led them astray. Despairing of finding systematic zoologists and botanists who could devote the necessary time and attention to the study of objects which they have obtained with so much trouble and pains, they have unwisely undertaken, without the necessary training and knowledge, the naming and description of forms of life which required for their proper interpretation all the skill and experience of the most able comparative anatomist or vegetable morphologist.

I feel sure that, if those who have thus erred, through acting with "a zeal which is not according to knowledge," could realize the injury done to science by such proceedings, they would pause before burdening scientific literature with premature names, imperfect diagnoses, and ill-digested materials. Fossils are, it is true, "the medals of creation," and for the purposes of the historian of past geological times, it may seem that any name, however bad, which can be employed for purposes of reference must be better than none at all. But fossils, it must be remembered, are much more than mere "medals." They are the precious relics of the faunas and floras of bygone times; landmarks—the only ones we can ever hope to discover—which may serve to guide us in tracing the wonderful story of the evolution of the existing forms of life. Reverently—as the mineralogist treats meteorites, those pocket-planets and errant members of the outer universe—should the biologist regard fossils, the fragments of an earlier life, the collateral, if not the direct, ancestors of living types.

So far I am from thinking that the study of fossils ought in all cases to be undertaken by those who are actually engaged in working out their recent representatives, that I believe such a practical abolition of palæontology as a distinct branch of science would tend, not to the advantage, but to the injury, of both biology and geology. And I will venture to set forth my grounds for this conclusion.

It may be remarked at the outset that at a time when all the tendencies of biological science appear to be towards an extreme specialization, it is strange to find that there are advocates for the suppression of what is now so well-developed a department of biological science as palæontology. When the work to be done has become so vast that some biologists feel themselves compelled to restrict their studies and labours to the morphological, or even to the histological department, others to the embryological, the physiological, the taxonomic, or the chorological branches of zoology or botany respectively, why should not some concentrate their efforts upon the elucidation of the ancient forms of life? When the study of a single group, often a very limited group, of animals or plants is sufficient to exhaust the energies of a particular naturalist, it is surely not unreasonable that forms which have become extinct and have left only very imperfect evidence of their structure and affinities, and these requiring peculiar methods for their study, should attract the attention of special investigators.

The study of fossils, we may remark, if it be undertaken by any biologists, must fall to systematic zoologists and botanists, and these have become somewhat rare and out of fashion in modern times; so few in numbers, indeed, do they seem as to be scarcely able to cope with the ever-increasing array of living forms; and it would be a hopeless task if upon them were also cast the overwhelming mass of fossil ones.

Imagine the embarrassment and dismay of a student of living sponges, whose favourite (possibly his only) method of research has consisted in studying with the microscope innumerable thin slices cut from tissues and embryos, if a cartload of chalk-flinks were thrown down at his door, and he were required to interpret the fragments of sponge-skeletons which they contained in every conceivable variety of disguise through peculiar processes of mineralization!

There are, indeed, a variety of special reasons why ordinary systematic zoologists and botanists become, by the very habits acquired in their daily pursuits, singularly ill fitted for dealing with fossil forms.

In studying recent forms the zoologist or botanist is bound to take into consideration, in fixing the systematic position of an organism, not only its skeleton, but all its soft parts, and even the structure and mode of development of its embryo; he may also be called upon to note physiological peculiarities, before he is in a position to arrive at a decision as to its place in the zoological or botanical series. But for the student of fossil forms none of these aids are available, he is compelled to do his best without them. Investigators of the recent Mollusca are, of course, "malacologists," but he who studies the extinct forms of the group must perforce labour under the stigma of being "a mere conchologist." In examining recent vertebrates it is allowable to make every possible use of the aid afforded by a study of the ligamental skeleton, in unravelling their affinities; but he who works on fossil vertebrates is and must remain a pure osteologist. Botanists have been led to the conclusion that for the classification of plants the reproductive organs always afford the safest guides; but palæontologists, alas! are frequently called upon to do their best in deciphering fragmentary remains of the vegetative organs.

It is not, as some biologists would almost seem to imagine, that palæontologists are led by any perversity of mind to reject the light which is afforded to them, or that they are not deeply sensible of the great value and importance of many recent researches in respect to living forms; but simply that they realize—often very sadly realize—the impossibility of availing themselves of the help afforded by such researches, in connection with the very imperfect material with which they are called upon to deal.

If we were to suppose that a surveying ship brought home from a newly-discovered island a heterogeneous mixture of isolated bones and teeth, of shells, bits of stick and fallen leaves, zoologists and botanists might be perfectly justified in refusing to waste their time upon such unsatisfactory materials. But if, subsequently, news arrived that after the departure of the ship the whole island had sunk beneath the ocean, then the circumstances would have completely changed, and no pains and care would be felt to be too great if expended in dealing with such a unique collection, however imperfect it might be. Or, to take a case which has actually occurred, the curators of the Ashmolean Museum were fully justified in ordering the destruction of the moth-eaten dodo skin, so long as they had no reason for doubting that other and better specimens were procurable; but now no labour and pains is considered too great in studying the most imperfect fragment of the bird.

And here I may perhaps be permitted to say a word in defence of what has been treated as an absurd practice on the part of palæontologists—that of giving names to small fragments of organisms. It must be admitted that when subsequent investigation proves that distinct generic and specific names have been given to the root, the stem, the outer and the inner bark, the pith, the foliage, and the fruit of the same plant, the absurdity does seem striking. But it is impossible to defer giving a name to a fossil until all doubts about its structure and affinities have been completely settled by the finding of exceptionally perfect specimens. Nevertheless, it ought certainly to be insisted on that names should be given to very fragmentary fossils only by a competent naturalist, and that he must accept the responsibility of his act. A single tooth of a mammal may afford good grounds for the establishment of a genus and species, while it might be utter folly to treat the tooth of a shark in the same manner.

The remains of many extinct forms are in such a peculiarly mineralized condition as to require special skill and training for their proper interpretation. Skeletal elements which were originally siliceous are now represented by pseudomorphs in calcite, and *vice versâ*. Characteristic structures in bones, shells, or wood may be wholly obliterated, and mineral structures of a strangely deceptive kind may be developed in their place. The curious story of *Eozoon canadense* and its supposed allies is surely a sufficient justification for the existence of palæontologists—that is, of specialists trained equally in the interpretation of biological and petrological structures. Dr. Sorby has shown that whole families of Mollusca may disappear from a fauna because of the unstable condition of the calcic carbonate which composes their shells, and his conclusions have been confirmed by Mr. Kendall.

Prof. Sollas has similarly shown that the absence of the por-

cellanous types of the Foraminifera from the Palæozoic rocks may be due, not to their non-existence when those rocks were formed, but to the fact of their shells being composed of the unstable aragonite.

Such facts as these must convince any unprejudiced person of the absolute necessity, to the naturalist who attempts to study extinct forms, of an acquaintance with the nature of the mineral changes which organic remains undergo. In his interesting memoir upon those curious and enigmatical fossils, the Receptaculitidæ, Dr. Hinde has admirably shown the advantages of this combination of biological and petrographical study.

In this connection I cannot avoid alluding to a very prevalent and, as I cannot help thinking, very erroneous notion, that an intermingled zoological and palæontological collection, however inconvenient, would certainly be very instructive. To this view I offer the strongest protest, for I believe that the mistakes which would arise from the examination of such a collection would far outweigh any instruction to be derived from it.

I fail to see what useful lesson would be taught by swamping a collection of the lizards, snakes, tortoises, and crocodiles living at the present day with the vast slabs containing the relics of Reptilia which have existed in periods ranging from the Permian to the Pliocene. Nor is it apparent to me why the precious remains of *Archæopteryx* should be hidden away among a wilderness of bird-skins.

Any arrangement which could lead to the idea that even the richest collection of fossils is in any way commensurable with the assemblages of specimens that in our museums represent the existing fauna is very greatly to be deprecated. So numerous are the gaps among fossil faunas, owing to the fact that only animals with hard parts, and, as a rule, only those that lived in the sea, had any chance of preservation, that the finest palæontological collections are, and must always remain, extremely fragmentary. We have, in the past, fallen into so many and such grievous errors, by ignoring the imperfection of the geological record, that we may well hesitate before doing anything that would confirm this mischievous delusion.

On the other hand, it may be pointed out that our acquaintance with extinct forms of life has increased to such an extent in recent years that a biologist may well be pardoned for not realizing the vastness and importance of the problems involved in the study of fossils. It can only be a very inadequate idea of the value of palæontological evidence which leads fossils to be regarded (like the fauna and flora of a newly-discovered territory) as simply supplying a few missing links required to fill up gaps in a natural-history classification, or as the appropriate ballast for a Noah's Ark on a scale of national grandeur. Small as may be the whole bulk of a palæontological collection in the eye of the student of recent forms, its great and transcendent value depends on the fact that the objects composing it belong to the faunas and floras of periods widely separated from the present and from one another. The discovery of a new type of reptiles in the Trias is a very different matter from the detection of an equally remarkable form living in New Zealand. The latter may, it is true, be a singular survival of some old type; but the former is an actual landmark in the course of reptilian development; and by the study of the fossil we are actually brought much nearer to the solution of the problems connected with the history of that development than is possible by the study of any recent form.

In pointing out how vast has been the progress of our knowledge in recent years concerning the ancient life of the globe, I may remind you of the estimates made by Prof. Huxley when speaking from this chair a little more than a quarter of a century ago. He then characterized "the positive change in passing from the recent to the ancient animal world" as "singularly small"; and he regarded the extinct orders of animals as not amounting "on the most liberal estimate" to more than one-tenth of the whole number known. The evidence which has been accumulated during the last twenty-five years, however, has modified this estimate in a remarkable manner, as no one would be more ready to admit than the author of it himself.

There is no little difficulty in making a calculation of the proportion of living to extinct orders, owing to the discrepancies in the opinions of zoologists and comparative anatomists as to what are the characters which ought to be considered as of ordinal rank. For my present purpose I very gladly avail myself of the useful "Synopsis of the Animal Kingdom" prepared by Mr. E. T. Newton, which is "founded on the classification proposed by Prof. Huxley, with such modifications as are rendered necessary by recent discoveries."

We may, I think, take the whole number of living orders of animals generally accepted by zoologists at about 108. But in any comparison of these with fossil forms, it is only fair to exclude from our consideration such as possess no hard parts and stand little or no chance of being preserved in a fossil state. Few would be bold enough to doubt that such soft-bodied forms must have existed in the past, or that they probably bore about the same proportion to the forms with hard skeletons as in the existing fauna; even the boldest sceptic on this subject would, I should think, be convinced by such singular accidents as that of the finding of the impression of *Rhizostomites*, one of the Discophoræ, preserved in the soft calcareous mud of the Solenhofen Slate.

Now among the 108 living orders of animals, at least 36 are totally destitute of any hard parts capable of being preserved in a fossil state, and we have thus left 72 living orders with which our comparison of the extinct orders must be made.

What is the number of orders which must be created to receive extinct forms, is a question that has given rise to wide diversities of opinion in recent years. While few naturalists would consider 18 as an excessive estimate, there are others who would probably double that number.

Taking the lower estimate and comparing the 18 extinct orders with the 72 living ones which contain animals with hard parts, we find the proportion of extinct orders to be 20 per cent. of the whole number known at the present time.

But in comparisons of this kind, it must be remembered that there is an unconscious tendency among the students of recent forms of life to *under-estimate* the differences between extinct and living forms. If we take such groups as the *Graptolitidæ*, the *Monticuliporidæ*, and the *Stromatoporidæ*, of the nature of the polyps of which we can know nothing, we can only place them in existing orders on the ground of some very general analogies in the skeleton. How little this may be worth, recent zoological researches, like those of Prof. Moseley on the *Milleporidæ* and the *Stylasteridæ* have amply shown.

The students of existing forms of life have arranged their pigeon-holes; and into those pigeon-holes our unfortunate fossils are too often *made* to go. If there were no other objection to the wholesale commingling of recent and fossil types in a museum, there would be the valid and insuperable one arising from the fact that there are very considerable and important groups of fossils which cannot, without violence, be made to find any place in our accepted classification of existing animals—and perhaps never will.

If, however, we consider the modifications which have been brought about in our views concerning the relations of extinct to living forms by the important discoveries that have been made since 1862, we shall be impressed by the conviction that no comparison of the numbers of living and extinct orders can give any adequate idea of the important influence of palæontological studies upon biological thought. The discovery of transitorial forms, like the *Archæopteryx*, the toothed birds of America, and the reptiles with avian affinities, together with the working out of the rich faunas of the Rocky Mountains, of Pikermi, Quercy, and the Siwaliks, of the Pampean formations of South America, the Karoo beds of South Africa, and the caves of Australia, have already done much towards revolutionizing the ideas held twenty-five years ago by biologists concerning the significance and value of fossil forms. While the recognition of the less specialized precursors of such types as the horse and the elephant have perhaps produced most effect in removing objections to evolutionary doctrines, the light thrown by the study of fossil forms on the manner in which individual structures have arisen, as has been so well shown by Prof. Alexander Agassiz, in the case of the Echinodermata, opens up to us a wide and perhaps far more hopeful field of inquiry. We are, however, only at the beginning of the great task of utilizing the grand palæontological collections of mammals, of reptiles, of fishes, and of the various groups of the invertebrates, for explaining the significance and tracing the origin of the structures found in living types.

While maintaining that studies of this kind demand and justify the concentration of the labours of a special class of investigators, I feel sure that no one will misinterpret my meaning as to the qualifications required by the students of fossil forms. Far from suggesting that the palæontologist may be one destitute of a proper biological training, or that he may be satisfied with an equipment of knowledge which would be insufficient for a systematic zoologist or botanist, I would maintain that no one

has a right to take up the study and description of any fossil group until he has made a very careful and exhaustive study of its nearest living allies; but, in addition to this, he ought also to have made himself acquainted with the peculiar mineral changes which organic remains are liable to undergo. He will, moreover, be far more likely to interpret aright and to make the best use of the materials that come to his hand, if he have at least a general knowledge of what others working on similar materials belonging to other departments of the animal or vegetable world have been able to accomplish, and of the methods which they have followed. Such palæontologists, I insist, have as much right to recognition as any other class of biological specialists.

Still less should I wish it to be implied that I think systematic biologists can afford to be ignorant of the results of palæontological studies, in their own particular fields of labour. One of the most mischievous weeds that have accompanied the evolutionist in his incursions into various parts of the biological field is the preposterous "genealogical tree." We can scarcely turn over the leaves of a modern systematic work without finding it flourishing in full luxuriance. No sooner has the student of a particular group arranged his families, genera, and species, than he thinks it incumbent upon him to show their genetic relations. Very admirably has Prof. Alexander Agassiz pointed out the utter fatuity of such a proceeding. As Lyell used to say, in speaking of such proceedings, the imagination of the systematist, untrammelled by an acquaintance with the past history of the group, "revels with all the freedom characteristic of motion *in vacuo*." If for no other reason, zoologists and botanists ought to study fossil forms in order that, by encountering a few hard facts in the shape of fossils, they may be saved from these unprofitable flights of the imagination.

(*To be continued.*)

SCIENTIFIC SERIALS.

Rendiconti del Reale Istituto Lombardo, December 1887.—On the Tertiary formations near Cape La Mortola, in Liguria, North Italy, by Prof. T. Taramelli. The paper deals specially with the abrupt interruption which occurs in the prevailing Eocene and Secondary systems about this part of the Ligurian coast. This interruption is brought into connection with the great development in Liguria of the marine Pliocene formation, which in the Varo basin and near Ventimiglia stands at a present altitude of over 550 metres above the sea, but which does not occur at all further east in Istria and Friuli, where it is represented by thick alluvial deposits of vast extent.—On the neutralizers of tubercular virus, by Prof. Giuseppe Sormani. In continuation of his previous studies, the author here deals with twenty-one additional substances, or chemical reagents, making eighty altogether. According to their different action on Koch's Bacillus these are grouped in three categories: those that have no effect; those that only attenuate, and those that entirely destroy, the virus. As many as twenty-two, including camphorated chloral, the bromide of ethyl, and the nitrite of ethyl, are found to be effective.—Meteorological observations made at the Brera Observatory during the month of November 1887.

Rivista Scientifico-Industriale, January 15.—The crepuscular tints in connection with the hygrometric state of the atmosphere, by Prof. Costantino Rovelli. Constant observation shows that red and orange tints prevail in a dry, yellow and green in a moist, state of the atmosphere. This suggests a threefold division of the solar spectrum into (1) the region of warm rays transmitted by the lower atmospheric strata, and corresponding to a dry condition of the air; (2) the region of middle rays, yellow and green, more easily diffused and partly transmitted by the air in moist weather; (3) the region of cold rays diffused by an atmosphere abounding in aëriform vapour. The terrestrial dust suspended in the air, by condensing the aqueous vapour, as is now generally accepted, may also tend to produce those occasional after-glows of intense brightness, which have been so often observed after violent volcanic eruptions. The various character and intensity of the tints may all be thus explained by the theory of the eclectic transmission of the coloured rays by the corresponding states of the atmosphere, and partly also by the particles of dust held in suspense.—On the constitution of fogs and clouds, by Prof. F. Palagi. These phenomena are attributed to the presence of minute drops of water with diameter of 1/10 to 1/20 mm. at a temperature above zero. The recent observations made by the author on Mount Titano show that when the temperature falls below zero these globules are converted into minute hexagonal needles and flakes of the same form, the former about 1/20 mm. thick, and from two to ten times longer, the latter from 1/10 to 1/4 mm. in diameter. In their passage from the higher regions through the lower and less cold strata, but still below zero, these simple crystalline forms appear to be transformed by the process of condensation and agglomeration into the stars and flakes of ordinary snow. But when the temperature rises above zero they are again changed to the minute liquid drops of clouds, fog, and rain according to the varying degrees of altitude and temperature.

Bulletin de l'Académie des Sciences de St. Pétersbourg, vol. xxxii. No. 1.—On the effects of the earthquake of February 23, 1887, at the Observatory of Pavlovsk, by Dr. Wild (in German). The effects of the catastrophe having been observed at the Observatories of England, France, Italy, Germany, and Austria, in trepidations of the magnetic instruments, it was interesting to see whether the earthquake was felt as far as St. Petersburg. The results indicate that it was not.—On the genus Hemiculter and a new species of Hemiculterella, by N. Warpachowski (in German).—Russian words used in the Sagai dialect, and their phonetic modifications, by N. Katunoff; and lists of Sagai names of rivers, villages, and tribes, by the same. This little dictionary is highly spoken of by M. Radlof.—Studies, by O. Backlund, about the Pulkowa catalogue of stars, "Positions moyennes de 3542 étoiles," published in 1886 (in German). A detailed comparison of the Pulkowa catalogue with the measurements by Herr Romberg at Pulkowa, as also with the catalogues of Becker, Respighi, and Boss.—Hydrological researches, by Dr. Carl Schmidt.—The temperature-maxima before midday in tropical seas, according to the observations of the corvette *Vityaz*, by M. Rykatcheff (in German). They show the existence of two separate maxima, one of which sets in half an hour before midday and the other half an hour later. More extensive observations are needed.—On the synthesis of albumen in chlorophyll-bearing plants, by Chrapowitzki (in German). The chlorophyll spots must be considered as places where synthesis of both carbohydrates and albumen is going on.—New additions to the Asiatic Museum, by C. Salemann. Summaries of two Persian and three Kagatai manuscripts brought in by M. Pantusoff from the Semiryetchensk province.

THE *Izvestia* of the Russian Geographical Society (1887, iv.), contains most valuable papers and maps. Dr. Junker contributes a report on his seven years' journeys in Equatorial Africa, and his paper is accompanied by a map, 53 miles to the inch, of the region extending for ten degrees on the north of the Equator, between the 22nd and 33rd degrees of longitude. Two papers, by M. Potanin, contain a summary of the information gathered from the natives as to Eastern Tibet (the regions of Amdo and Kam), and the region of Central Mongolia situated between the Nan-shan, the Khangai, Hami, and the Utai-shan. Both papers are accompanied by maps, on a scale of 100 miles to an inch, and the two maps complement one another, so as to give a very accurate idea of the upper Hoang-ho. Of the other papers, one by M. Krasnoff, on the manners of life of the Kirghizes in the Semiryetchensk province, will be welcome to ethnographers. The same number contains also a list of fifteen places in Laponia, the latitudes and longitudes of which have been measured in 1864 by Captain Ernefeld; and, in a separate appendix, tables, by Prof. Sharnhorst, for the calculation of heights from barometrical observations. It is self-evident, although it is too often lost of sight, that the calculation of heights upon observations of the barometer, when it is made by means of logarithms, means a much greater accuracy of results than anything that can be obtained from a few observations of atmospheric pressure during a journey, and that some plainer tables would give the results with an accuracy quite sufficient for the accuracy of the data themselves. M. Sharnhorst's tables are an improvement upon those formerly in use, and ought to be introduced into every manual for travellers, instead of the usual logarithmical tables.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 26.—"Report on Hygrometric Methods. First Part, including the Saturation Method and the Chemical Method, and Dew-point Instruments." By W. N.

Shaw, M.A. Communicated by R. H. Scott, F.R.S., Secretary to the Meteorological Council.

With the exception of certain "absolute hygrometers," the behaviour of which has not yet been sufficiently tested, the determination of the pressure of water-vapour in the air is indirect, and requires a formula of reduction. The formulæ in use are based upon assumptions which are at present not so completely verified by experiment that any hygrometric method can be relied upon to give measures of the pressure of aqueous vapour trustworthy to within 0·1 mm. of mercury. The authority for these statements is given in detail in an account of the hygrometric work done since 1830, appended to the report as Note A.

In the report, the chemical hygrometric method is provisionally regarded as a standard.

The assumptions upon which the formula of the method is based are (1) that it is possible to absorb the whole of the moisture from air by passing it over desiccating substances; and (2) that a numerical value can be assigned to *d*, the specific gravity of aqueous vapour referred to air at the same temperature and pressure. The first assumption is sufficiently nearly accurate for hygrometric observations. With regard to the second, Regnault's direct observations upon steam (free from air) and other evidence point to the value 0·622. The assumption can, moreover, be tested, by applying the chemical method to air saturated at a known temperature, assuming the value 0·622 for *d*, and comparing the results with the table of saturation pressures *in vacuo*. This, however, *assumes Dalton's law to be strictly accurate*, an open question upon which opinion is reserved until further experimental investigation is concluded. Regnault found that the value 0·622 gave results for saturated air which were less than the tabulated pressures, the errors being always of the same sign, but so small in amount that he neglected them in his subsequent work.

The ultimate object of the experiments described in the report was to examine the behaviour of dew-point instruments in air of known state, and for this purpose air was saturated at a known temperature and drawn by an aspirator through vessels in which the dew-point instruments could be placed when required, and subsequently through drying tubes of special pattern. The vapour-pressure was thus obtained at the two extremities of the train of apparatus and the results compared.

The following questions are raised and discussed:—

(1) Were the drying tubes used as efficient as Regnault's? (2) Does the pressure of vapour in the air become changed by passing through the apparatus designed to contain the dew-point instruments, or by the mere presence of those instruments themselves? (3) Do the results of the chemical method agree with the tabulated vapour-pressures *in vacuo* when the air is more or less heated after being saturated? (4) Can the observed differences between the results be obviated by assuming a value for *d* (other than 0·622), which is compatible with values obtained by other methods? (5) Can any reason be assigned for the differences observed by Regnault in the case of saturated air?

(1) The answer to the first question is given in an account of a series of twelve experiments practically repeating Regnault's observations with saturated air. The tabulated results show divergences in the same direction and of the same order of magnitude as those in Regnault's paper. Some incidental points are also discussed—namely, the comparative efficiency of phosphoric anhydride, sulphuric acid, and calcium chloride, and the effect of india-rubber and glass connections between drying tubes. It is shown that the sulphuric acid and phosphoric anhydride tubes are efficient, that as a rule one tube is all that is strictly necessary, but that two should be used to provide for the case of exhaustion of the first tube or too rapid flow of air, and further, that the glass-and-mercury connections between the tubes employed in the second series of experiments cannot be regarded as producing any effect.

(2 and 3) The answers to the second and third questions are furnished by the results of eighty-two experiments with the chemical method upon air saturated at known temperatures by a specially designed "saturater" in a water-bath. The temperatures of saturation lay between 1° C. and 21° C., and, with one exception, were below the temperature of the surrounding air. Each experiment involves upwards of thirty readings of weight, pressure, and temperature. The temperature readings are corrected by means of a special comparison at Kew. Of the eighty-two observations thirty-two are retained as being free from any known disturbing causes, and from them it appears that, with *d* equal to 0·622, the pressure deduced by the chemical method is on the average greater by 0·03 mm. than that given in Regnault's table of vacuum pressures, as recalculated in Landolt and Börnstein's tables. This difference is very small compared with the discrepancies from Dalton's Law observed by Regnault in the case of water vapour.

(4) With regard to the fourth question; if the observations be employed to determine the value which must be substituted for *d*, the value obtained is 0·6245, which agrees very closely with 0·6240, the mean value for the same range of temperature deduced from Clausius's calculations based on thermo-dynamical reasoning. The value 0·622 is probably correct if the air is not nearly saturated; in that case the measure of the pressure of vapour in the air is 2/622 greater than it would be if the same air were reduced in temperature (at constant pressure) until it was saturated.

(5) The one observation of the second series with saturated air gives a result 0·18 mm. smaller than the tabulated pressure, and thus with the twelve experiments of the first series confirms the results of Regnault's observations. To account for this it is suggested that air which is very nearly or quite saturated would deposit some of its moisture on the glass tubes used to conduct it from one vessel to another. This behaviour of nearly saturated air has been already noticed, and it is confirmed by the observations on dew-point instruments, and moreover, by experiments, directly designed for the purpose, quoted in a note.

Details are given of observations with Regnault's hygrometer and Dines's hygrometer when exposed in glass vessels between the saturater and the drying tubes. The two instruments are separately discussed. With Regnault's instrument, after some practice, two different observers obtained practically identical results. In ordinary observations, the observed temperatures of the dew-point were below the temperature of saturation, but seldom by more than 0°·1 C. A considerable amount of uncertainty was shown to be attached to the readings, and by very close inspection readings of the dew-point were obtained above the temperature of saturation, in one case by as much as 0°·7 C.

From the experiments with Dines's hygrometer, it appears that the instrument is likely to give very easy determinations of the dew-point that are within small limits of error; but that, if it be observed with the closest attention, the result will be considerably too high in consequence of the formation of a dew deposit at a temperature above the dew-point, and it may possibly be erroneous in consequence of variations in temperature of the different parts of the box containing the thermometer.

An account is given of Alluard's modification of Regnault's hygrometer, and of Bogen's hygrometer.

A second note, B, is appended to the report, showing the tables used in various countries for the reduction of wet and dry bulb observations.

Chemical Society, February 2.—Mr. W. Crookes, F.R.S., in the chair.—Profs. Geuther, Ladenburg, Landolt, Nilson, Van't Hoff, Wislicenus and M. Lecoq de Boisbaudran were elected foreign members of the Society.—The following lecture was delivered:—The range of molecular forces, by Prof. A. W. Rücker, F.R.S. In discussing the range of molecular forces it is convenient to adhere to the language of the theory of action at a distance, though with full expectation that it will ultimately be replaced by another, such as the vortex-atom theory of Sir W. Thomson, or the granular theory of Prof. Osborne Reynolds, which involves only action in proximity. If we do this, however, it must be admitted that the law of molecular action may be very complicated. It may be granted that we naturally look for simplicity in our fundamental assumptions, but it is certain that we have *a priori* no more right to expect simplicity in the results of the action of a medium than simplicity in its constitution, and that the two are not necessarily obtained together. The largest values of the magnitude of the radius of molecular action which have been published have been deduced from observations on the condensation of gases and vapours on the surfaces of solids. Estimates on this basis made by Müller-Erzbach (*Exner's Rep.*, 1885, xxi. 409) and Kayser (*Wied. Ann.*, 1881, xiv. 450) have ranged between 1500 and 3000 micromillimetres[1] ($\mu\mu$). Such observations are open to many

[1] The micromillimetre is the millionth of a millimetre.

objections. Bunsen (*Wied.*, 1885, xxiv. 335) has shown that CO_2 will not condense on glass unless a film of water be previously formed. Warburg and Ihmori (*Wied.*, 1886, xxvii. 481, and *Wied.*, 1887, xxxi. 1006) adduce reasons for believing that the water film is largely due to uncombined or loosely combined alkalies on the surface. On clean unvarnished metals, washed glass and quartz, the thickness of the water film which can be removed by dry air without heating does not exceed 12 $\mu\mu$. A striking exception is agate, on which films 1640 $\mu\mu$ thick are stated to have been formed. As this substance, however, is composed of alternate layers of quartz and a porous impure opal, the basis for an accurate calculation does not exist. On the whole, it seems that no definite conclusions as to the magnitude of the radius of molecular action (ρ) can at present be drawn from these experiments. Quincke (*Pogg. Ann.*, 1869, cxxxvii. 402), as is well known, by measuring the capillary elevation of liquids between glass plates coated with thin wedge-shaped films, found $\rho = 50\ \mu\mu$. Plateau ("Statique des Liquides," 1873, i. 210) showed that the surface-tension of a soap-bubble, which thinned until its thickness was 118 $\mu\mu$, was unaltered. He concluded that $\rho < 59\ \mu\mu$. Maxwell ("Ency. Brit.," 9th ed., Art. "Capillary Action"), however, though by a confessedly imperfect theory, shows that the surface-tension may not change until the thickness of the film $= \rho$. Hence Plateau's result may mean only that $\rho < 118\ \mu\mu$. Reinold and Rücker (Phil. Trans., clxxvii. Part ii. 1886, 627) have proved that the surface-tension does not alter by 0·5 per cent, when the film is so thin as to show the black of the first order of Newton's colours. This appears at first sight at variance with Quincke's result, but their observations are really in remarkable accord with his. The black and coloured parts of a film are separated by a sharp line, which proves a discontinuity in the thickness (Proc. Roy. Soc., 1887, No. 182, 340). The colours, which correspond to certain thicknesses, which may be called the unstable range of thickness, are always missing. The black part of the film has been proved by Reinold and Rücker (Phil. Trans., Part ii. 1883, 645) to be of a uniform thickness, which differs but little from 12 $\mu\mu$. Sir William Thomson (Proc. Royal Institution) and these observers independently arrived at the conclusion that these curious phenomena are due to the fact that the surface-tension diminishes to a minimum, and then increases again when the thickness is somewhat $>12\ \mu\mu$. The colours of the film prove that the upper limit of the range of unstable thickness is between 96 and 45 $\mu\mu$. Quincke's result indicates that it lies between 100 $\mu\mu$ and 50 $\mu\mu$, according as we adopt Plateau's or Maxwell's views. These calculations are therefore in complete accord. Quincke's result is not an isolated fact, but is supported by observations on soap films. The statement that 50 $\mu\mu$ and the radius of molecular action are of the same order of magnitude may now perhaps rank as an ascertained fact. Another method of investigating the radius of molecular action is based on the phenomena of electrolytic polarization, by observing the change in the difference of potential between a metal and a liquid in which it is immersed, when a gas or metal is deposited on it by electrolysis. In the former case we do not know the density of the gas, in the latter Oberbeck (*Wied.*, 1887, xxxi. 337) concludes that a plate of platinum is completely polarized by a film of another metal of from 3 to 1 $\mu\mu$ in thickness. The method of experiment is, however, open to objections, which are indicated by Oberbeck himself. Measurements of the thickness of the double electric layer of Helmholtz, which is closely related to the distance between two consecutive layers of molecules, have been made by Lippmann (*Compt. rend.*, 1882, xcv. 687), and by Oberbeck and Falck (*Wied.*, 1884, xxi. 157). The values they give vary between 1 and 0·02 $\mu\mu$. Wiener (*Wied.*, 1887, xxxi. 624) has studied the alteration in the phase of light reflected from very thin silver plates deposited on mica. He finds that the effect begins to alter when the thickness is reduced to 12 $\mu\mu$, and that it was possible to detect a silver film the thickness of which did not exceed 0·2 $\mu\mu$. The diameter of a molecule is a conventional term for the mean distance of the centres of two molecules during an encounter. It may therefore be different in the liquid and gaseous states. Sir William Thomson ("Natural Philosophy," Thomson and Tait, Part ii. 295, 1883), as the result of his celebrated discussion of this point, concludes that the mean distances between the centres of molecules in liquids (supposed arranged uniformly) is between 0·07 and 0·02 $\mu\mu$, and that the latter quantity is an inferior limit to the diameter of a gaseous molecule. The diameters of molecules (d) may be calculated if we know the mean free path (L), and the so-called condensation coefficient (v), which is the volume of the molecules contained in a unit volume of the gas. Loschmidt (*Sitzungsber. Wien. Akad. Math. Classe*, lii. abt. 2) and O. Meyer ("Die Kinetische Theorie der Gase," 225, 1887) have calculated d on the assumption that the molecules in a liquid practically fill the whole space it occupies. Exner (*Rep. der Physik*, xxi. 226, 1885), using a formula given by Clausius, $v = (K - 1)/(K + 2)$, where K is the specific inductive capacity, and can be replaced by $v = (n^2 - 1)(n^2 + 2)$, where n is the refractive index, finds values of d about five times smaller. Three independent methods of calculating the diameter of a gaseous hydrogen molecule lead to results between 0·14 and 0·11 $\mu\mu$. The most reliable conclusions which have been reached as to molecular magnitudes may be summed up in the following table, which is reproduced from a diagram exhibited during the lecture.

$\mu\mu$.		
118	Superior limit to ρ	Plateau (Maxwell)
96–45	Range of unstable thickness begins	Reinold and Rücker
59	Superior limit to ρ	Plateau
50	Magnitude of ρ	Quincke
12	Range of unstable thickness ends	Reinold and Rücker
12	Action of silver plate on phase of reflected light alters ...	Wiener
10·5	Thickness of permanent water film on glass at 23° C. ...	Bunsen
4·3	Mean distance between centres of molecules in gases at 760 mm. and 0° C.	O. Meyer
3–1	Thickness of metal films which polarize platinum	Oberbeck
1–0·02	Thickness of electric double layer	Lippmann and Oberbeck
0·2	Smallest appreciable thickness of silver film	Wiener
0·14–0·11	Diameter of gaseous hydrogen molecule	Exner O. Meyer Van der Waals
0·07–0·02	Mean distance between centres of liquid molecules	W. Thomson
0·02	Inferior limit to diameter of gaseous molecule	W. Thomson

—The following papers were read:—A new method of obtaining monohydrazides of α-diketones, by Prof. F. R. Japp, F.R.S., and Dr. F. Klingemann. The authors have prepared von Pechmann's monohydrazide of diacetyl by the action of diazobenzene chloride on sodium methacetate.—The formation of dihydrazides of α-diketones, by the same.—The action of phenylhydrazine on anhydracetophenonebenzil, by Prof. F. R. Japp, F.R.S., and Mr. G. N. Huntly.—The supposed identity of rutin and quercitrin, by Dr. E. Schunck, F.R.S. A comparative examination of rutin obtained from the leaves of *Polygonum fagopyrum* and of quercitrin shows that, though they are extremely similar, yet they differ in composition and in some of their properties. Rutin has the composition $C_{42}H_{50}O_{25}$, and yields, on hydrolysis, one molecule quercetin and three molecules isodulcite, whilst quercitrin $C_{36}H_{38}O_{20}$, as is known, yields, under like conditions, one molecule quercetin and two molecules isodulcite.—The composition of bird-lime, by Dr. E. Divers, F.R.S., and M. Kawakita. Japanese bird-lime prepared from *Ilex integra* contains, in addition to 6 per cent. of caoutchouc and minute quantities of oxalates, the ethereal salts of palmitic acid, and, in small quantity, of a semi-solid undetermined fatty acid. On hydrolysis these yield *ilicylic alcohol*, $C_{22}H_{38}O$, differing only slightly from Personne's ilicic alcohol, and *mochylic alcohol* $C_{26}H_{46}O$. A resinoid body, $C_{26}H_{44}O$, was also separated. When heated with palmitic acid, the two alcohols are converted into compounds just like purified bird-lime. The authors consider bird-lime to be closely allied to the *waxes* in chemical constitution.

ERRATA.—P. 335, line 15 (from top), *for* $3SOH_2SO_4$ *read* $3H_2SO_4$; line 19 (from top), *for* SO *read* SO_2.

Physical Society, January 28.—Prof. W. G. Adams, F.R.S., Vice-President, in the chair.—In opening the proceedings the Chairman referred to the great loss which the Society had sustained by the death of Dr. Balfour Stewart, their late President, and said that his loss would be deeply felt by the whole scientific world.—The following papers were read:—On the effect of magnetization on the thermo-electrical properties of bismuth, by Mr. Herbert Tomlinson.—On the influence of magnetism and temperature on the electrical resistance of bismuth and its alloys with lead and tin, by M. Ed. von Aubel.—On a water-dropping influence machine, by Prof. S. P. Thompson.—On the price of the factor of safety in lightning-rods, by the same. It is here shown, upon certain assumptions, that the safety against fusion varies as total cost $\times \frac{f s}{\rho d l^2 k}$, where f = temperature of fusion of material above atmosphere, s = specific thermal capacity, ρ = specific electric resistance, d = density, k = cost in pence per lb., and l = length of the conductor. If the total cost and length are supposed to be given, the factor of safety $= \frac{f s}{\rho d k}$. Of the common metals iron has the greatest factor of safety, being more than four times that of copper. Such being the case, the author thinks it desirable that the Report of the Lightning-Rod Conference be reconsidered.—On the optical demonstration of electrical stress, by Prof. A. W. Rücker, F.R.S., and Mr. C. V. Boys. A number of lecture experiments were shown illustrating that electrical stress exists in the dielectric separating two charged bodies. The bodies were placed in carbon bisulphide, between two crossed Nicols, and on electrifying them by means of a Holtz machine, light passed through the analyzer. Two concentric cylinders gave a black cross on the screen similar to those seen on interposing a plate of some uniaxial crystal, and a model illustrating a charged Leyden jar was shown.

February 11.—Annual General Meeting.—Dr. J. H. Gladstone, F.R.S., Vice-President, in the chair.—The Chairman read the Report of the Council for the past year, and expressed regret at the losses the Society had sustained by the deaths of Dr. Stewart (their late President), Prof. Kirchhoff, Mr. Coutts Trotter, and Prof. Humpidge. The Council regret that no increase of members has taken place during the past year, and hope that the advantages offered by the Society may be more fully appreciated in future. Obituary notices of Dr. B. Stewart, Mr. Coutts Trotter, and Prof. Humpidge were then read. The Treasurer's Report shows that the financial condition of the Society is very satisfactory. On the motion of Mr. Lant Carpenter, seconded by Mr. Inwards, the Reports were adopted.—The following gentlemen were elected members of Council for the present year:—President: Prof. A. W. Reinold, F.R.S. Vice-Presidents: Dr. E. Atkinson, Prof. W. E. Ayrton, F.R.S., Mr. Shelford Bidwell, F.R.S. and Prof. H. McLeod, F.R.S. Secretaries: Mr. Walter Baily, and Prof. J. Perry, F.R.S. Treasurer: Prof. A. W. Rücker, F.R.S. Demonstrator and Librarian: Mr. C. V. Boys. Other members of Council: Hon. R. Abercromby, R. H. M. Bosanquet, M.A., W. H. Coffin, Conrad W. Cooke, Prof. F. Fuller, W. N. Shaw, A. Stroh, Prof. S. P. Thompson, H. Tomlinson, G. M. Whipple. On taking the chair the new President expressed his sincere thanks for the great honour the Society had conferred upon him. Prof. Fuller proposed a vote of thanks to the Lords of Committee of Council on Education for the use of the rooms and apparatus of the Normal School of Science, which was seconded by Mr. Shaw, and passed unanimously. A cordial vote of thanks to the Council and officers of the past year, moved by Dr. Blaikley, and seconded by Prof. Ramsay, was duly acknowledged by the President. A similar vote, proposed by Mr. Bosanquet, and seconded by Mr. Hadden, to the auditors for the past year, was passed unanimously.—The meeting was then resolved into an ordinary science meeting, at which the following papers were read:—On the limit of refraction in relation to temperature and chemical composition, by Mr. T. Pelham Dale.—Note on the use of the term "resistance" in the description of physical phenomena, by Mr. R. H. M. Bosanquet.

PARIS.

Academy of Sciences, February 13.—M. Janssen in the chair.—On an ancient process for rendering gems and vitrifications phosphorescent, by M. Berthelot. The treatise in which this process is described occurs in the collection of Greek alchemists transcribed in certain manuscripts of the thirteenth and fifteenth centuries (Bibliothèque Nationale, Nos. 2325 and 2327). It contains a series of purely technical receipts analogous to those of the Leyden papyrus, some apparently of great antiquity, explaining certain methods of "colouring artificial precious stones, emeralds, carbuncles, hyacinths, according to the book taken from the shrine of the Temple." Several Egyptian alchemists are mentioned, such as Agathodemon, the pseudo-Moses, Ostanes, and Democritus, and the text leaves no doubt as to the ancient practice of rendering certain gems phosphorescent in the dark by means of surface colouring prepared from substances which are still known to possess such properties.—On the properties of a new hydraulic machine intended for irrigation purposes, by M. A. de Caligny. For this apparatus, which has been for some time in use both at Aubois and on the canal between Mons and La Louvière, the author claims the advantages of great simplicity of structure as well as economy on the first outlay. It may also be utilized for replenishing cattle-troughs, and other secondary uses, at a minimum cost. It was awarded a gold medal at the Antwerp Universal Exhibition.—On the part played by the absorbing power of the soil in the formation of the natural carbonates of soda, by M. Paul de Mondesir. The paper deals with Berthollet's well-known theory regarding the formation of Egyptian natron, and shows that Berthollet's explanation is so far true that the marine salt really furnishes the soda, and carbonate of lime, the carbonic acid. But the reaction is neither direct nor continuous, and is produced in two distinct phases. In the first, the soil reacts on the marine salt, transforming it into chloride of calcium while yielding lime and absorbing soda. In the second, which can set in only after removal of the chloride of calcium, the bicarbonate of lime and the carbonic acid extract the soda from the ground, replacing it with lime. Berthollet's theory is thus left fundamentally intact, but so modified as to become universally applicable. In fact, the carbonate of soda is produced in all permeable calcareous soils in proportion to the quantity of marine salt contained in them.—Observations of the new planet 272, discovered on February 4, at the Observatory of Nice, by M. Charlois. The observations, including right ascension, polar distance, and the positions of comparison stars, extend over the period from February 4 to February 9. When discovered the planet was of 13·5 magnitude.—New observations on the variability of Saturn's rings, by M. E. L. Trouvelot. It is pointed out that the observations made during the last few years by Perkins, Offord, Davis, Stanley Williams, Stroobant, and others, all tend definitely to establish the proposition announced by the author in 1884, that, so far from being stable, the rings of Saturn are on the contrary essentially variable, and subject to constant fluctuations. The same truth is confirmed by the author's own observations made in 1886 and 1887 at the Observatory of Meudon, and here communicated to the Academy.—Theorems on Campbell's algebraic equations and quadratic functions, by Father Aug. Poulain. Newton, or rather Campbell, formulated a very simple rule for determining the existence of the imaginary roots in algebraic equations. The author here proposes a few theorems, by means of which the application of this law may be extended and the accompanying calculations much simplified.—On chemical equilibria, by M. P. Duhem. In a recent note M. H. Le Chatelier announced that the numerical laws of chemical equilibrium, as deduced from the two principles of thermodynamics, may be expressed in a simple way by means of M. Massieu's characteristic function H'. Here it is shown that this law may be thus formulated: The variation imposed on M. Massieu's function H' by a virtual isothermic modification of the system is equivalent to zero. It is further pointed out that the results obtained by M. Le Chatelier are practically identical with those arrived at by the author during a series of investigations spread over several years.—On the mineralizing action of the alkaline sulphides: reproduction of chrysoberyl, by MM. P. Hautefeuille and A. Perrey. During a protracted series of researches on the mineralizing action of the sulphides, the authors have succeeded in obtaining the crystallization of glucine, the separation of alumina and glucine, or inversely the reproduction of the aluminate of glucine, a combination which occurs in nature, and which is known by the name of cymophane (chrysoberyl). A simple process is described by means of which from a combination of glucine and alumina extracted from the emerald the

glucine may be obtained with a loss of not more than 10 per cent., and in such a state of purity that its equivalent has been found equal to 12·58.—Influence of various diets on the interchange of the gases in respiration, by MM. Hanriot and Ch. Richet. Continuing their researches on the respiratory function, the authors find that respiration increases with the increase of food, but only when this consists of the hydrates of carbon; that the interchange of the gases is but slightly affected by a nitrogenous and fatty diet; that feculent substances increase the absorption of oxygen and especially the production of CO_2; that the centesimal proportions of the absorbed oxygen or of the generated carbonic acid varies little during muscular repose; that the proportion of absorbed oxygen averages about 4·2 per cent., and of generated CO_2 about 3·4 per cent. The subject is illustrated by a diagram showing by a graphic process the influence of a nitrogenous and feculent diet on the respiratory functions generally.—Discovery of a worked flint and a mammoth's tusk at Vitry-en-Artois, by M. Ladrière. The position in which these remains were found seems to confirm the author's view that towards the close of the early Quaternary epoch (Mousterian age) *Elephas primigenius* and other large mammals, as well as man, were already spread over the west of Europe.

BERLIN.

Physical Society, January 20.—Prof. von Helmholtz, President, in the chair.—Prof. Oettingen spoke on the interference of electrical vibrations which is produced by the electrical oscillations discovered by Feddersen, during the spark discharge. The discharge oscillations of two Leyden batteries, differing in frequency and amplitude, were allowed to produce an interference in the path of a third spark, and this led to a constant succession of alternatingly increased and diminished intensities of this spark. The phenomenon was analyzed by means of a rotating mirror, which resolved it into its several phases, and the events taking place in each spark were recorded by instantaneous photography. The speaker exhibited a large number of these photographs, both as negatives and as positive reproductions, and explained them fully. In these experiments, as in those described at the previous meeting of the Society on the explosion of an electrolytic mixture of oxygen and hydrogen, Prof. Oettingen had succeeded in obtaining accurate results only when he had replaced the concave rotating mirror by a plane one, whose action he then thoroughly discussed.—Prof. Börnstein exhibited a preparation which he had recently obtained quite by chance, during one of his lectures. When lecturing on the diffusion of liquids, he was in the habit of using a Traube artificial cell. On placing a blue crystal of sulphate of copper in a solution of soluble glass, a precipitate is formed as a film on the surface of the salt, when it comes in contact with the soluble glass. The water from the solution then diffuses through the film, dissolving the salt and stretching the film until it is ruptured at some one point. When this occurs the solution of the sulphate of copper comes again into contact with the soluble glass, a new film is formed at the surface of contact, closing up the aperture, and the diffusion begins again. The film thus grows continually in a tubular form, until it finally permeates the whole solution. When recently repeating this lecture experiment, the speaker noticed that the film did not grow in the usual tubular way, but took the form of flattened parallel membranes which advanced through the solution at right angles to their length. He was at present unable to offer any explanation of this latter phenomenon.—Dr. Budde had recently submitted Clausius's fundamental law of electro-dynamics to a recalculation, while taking into account a large series of special conditions; among these he allowed for the motion of translation of the earth, and found that it had no influence on the validity of the law. At that time he had not calculated the influence of the earth's rotation; he had however, since then, repeated his former work, and gave an account of the results of his calculation, which showed that the rotatory motion of the earth had also no influence on the law. The same speaker finally drew attention to an error which occurs in all text-books, in connection with the determination of the potential of a system of points, and showed how illogical is the usual definition and of deducing of potential energy. Prof. von Helmholtz then directed attention to the fact that he was in the habit of determining potential energy in a different way, and that its derivation from a system of points is fraught with great difficulties.

THURSDAY, MARCH 1, 1888.

PHYSICAL SCIENCE AND THE WOOLWICH EXAMINATIONS.

WE are glad to learn that several Members of Parliament are interesting themselves in this important matter, and that Sir John Lubbock and Sir Henry Roscoe have both put down notices of motion calling attention to the changes that it is proposed to make in the regulations for admission to Woolwich. We hope and believe that their efforts will result in a rectification of these ill-conceived regulations.

We have already shown in our previous articles on this subject how completely the new regulations fail to find any justification, so far as their treatment of experimental science is concerned. We have demonstrated, by an examination of the professional course of training which the successful cadets will go through when at the Royal Military Academy, that of the subjects of general education experimental science stands below mathematics alone in practical importance for Woolwich cadets; whilst even a cursory inspection of the results of past examinations is sufficient to reveal the hollowness of the suggestion that in scientific subjects marks may be easily obtained by superficial study or cram. When we consider that the results of applying similar regulations in the case of the Sandhurst examinations are, or ought to be, familiar to the War Office authorities, it is astonishing that their extension to the scientific branches of the army should ever have been seriously contemplated.

The deliberate adoption of this scheme for selecting young men for a highly scientific profession, after the experience of several years had so completely established that it is eminently calculated to reduce the chances of candidates of scientific power to a minimum, can only be regarded as a remarkable example of official blundering. The rectification of the mistake is the more imperatively required because the treatment of natural science—that is, of candidates whose abilities are rather scientific than linguistic or mathematical—in public examinations has hitherto been altogether unsuited to the real wants of the age. Science in examinations being to a great extent a non-paying subject, the quality or even the existence of science-teaching is regarded, at the best, as a matter of secondary importance in many or most of our schools. The question, therefore, deserves the closest attention from all who hold that it is absolutely essential that there shall be a steady and sure advance in the standard of elementary science teaching in this country.

In his reply to Mr. Howorth, the Secretary of State for War is stated to have said that these Woolwich regulations had been considered by a "strong Committee." It would be interesting to know of whom this Committee consisted, and whether it was strong from a military or an educational point of view. Such information as we have been able to obtain leads us to conclude that it was a military Committee, and that though, as such, it was no doubt eminently fitted to come to wise conclusions on military questions—such, for example, as the proper training to be given to successful cadets after their admission to the Royal Military Academy—it was by no means composed of men equally fitted by experience to deal with the other side of the question. It is surprising to find that this important change, which will profoundly affect much of the higher school work of the country, was apparently decided upon without, or almost without, consultation with those most experienced in such questions This helps us to understand how it has happened that regulations not altogether unsatisfactory, and to which many places of education had adapted themselves, often at considerable expense and trouble, are suddenly to be displaced by others that are open to the gravest objections.

The new regulations seem to have almost every order of fault. They will be unfair to the candidates, leading to the rejection of those best fitted for the work to be done. It is to be feared, too, that they will encourage residence and study abroad, with the consequent loss of the valuable moral and physical training that can be had only in England. They will also act prejudicially on the general tendency of school education. We hope we may soon hear that better counsels have prevailed, and that these unfortunate regulations are to be replaced by others more in accordance with modern needs and ideas.

TEA CULTIVATION IN INDIA.

Die Theekultur in Britisch-Ost-Indien, im fünfzigsten Jahre ihres Bestandes, Historisch, Naturwissenschaftlich, und Statistisch. Dr. Ottokar Feistmantel. (Prague: O. Beyer, 1888.)

THE subject of tea cultivation in India is one to which innumerable writers have devoted their attention, and not the least valuable portion of Dr. Feistmantel's work, "Die Theekultur in Britisch-Ost-Indien," is the bibliography of the subject with which, while recording his indebtedness for much of his information to many of the English and German authors enumerated, he commences his remarks. In his preface he explains that in the course of an address on the products and exports of British India, recently delivered by him in Prague, he alluded to the fact that on the Continent of Europe tea was generally known only as either Russian or Chinese, and that it was barely known that India produced a large and annually increasing quantity of high-class teas, which are largely used in London for mixing with and improving China tea. The correspondence which ensued when these remarks were reported by the local press induced him to publish the present work as the result of information he had the opportunity of collecting while serving in India for eight years as palæontologist to the Geological Survey.

It is Dr. Feistmantel's aim to place before the German-speaking peoples of the Continent as complete an exposition of the conditions of the tea industry in India as has already been laid before English-speaking people by other writers; and he therefore begins with an abstract of the early history of the tea-plant in India, the dates of its first discovery as an indigenous shrub, and its first introduction into the different districts in which it is now cultivated. He mentions the first export from India to England in 1838 of twelve chests of tea, which sold for 19*s.* 5*d.* per pound.

 T

He points out the differences between the indigenous, the "China," and the hybrid varieties of the plant which are cultivated in India, and enumerates the various pseudo-teas which are known either in the frontier countries of India or in other countries: such as *Osyris nepalensis* or *arborea*, in Kumaon, Garhwal, and lately in Kashmir; *Elæodendron persicum*, in Burmah, from which, when mixed with oil, salt, garlic, and assafœtida, is prepared the nauseous compound, to European taste, known as "pickled tea"; *Ilex paraguayensis*, the Paraguay tea, or "Mate," of South America; *Ledum palustre*, or Labrador tea; the Tasmanian tea, made from various varieties of *Melaleuca* and *Leptospermum*; and the Faham tea, *Angræcum fragrans* of Mauritius; and others.

The number of plantations in the various provinces, area under cultivation, and annual yield of tea for all India, are given in detail; and the differences between the various kinds of China and Indian tea, as proved by analysis, are very fully treated of. The principal black teas made in India are flowery pekoe, orange pekoe, souchong, pekoe souchong, congou, and bohea; as also the several varieties of broken leaf, such as broken pekoe, pekoe dust, &c. All these are not, as is commonly supposed, the produce of different plants, but are prepared from one and the same plant, the classification being caused by the difference of age and development of the leaves used for the several varieties. The principal kinds of green tea are gunpowder, hyson, and young hyson, and these are manufactured almost exclusively in the North-West Provinces and Kangra.

It may be accepted as a fact that Indian tea is very rarely adulterated, being packed on the plantation, and shipped direct from the planter to the market; but "China tea" passes through many hands before it is packed for shipment, and is frequently mixed with willow or other leaves, or with artificial colouring-matter. But the adulterated tea is not now readily saleable in London, and is therefore re-exported to the Continent. A direct importation of tea from India to the Continent would insure the purity of the supply.

In a lecture given before the Society of Arts, in May last, by Mr. J. Berry White, and quoted by Dr. Feistmantel, a table is given showing the steady rise of the Indian tea crop from 232,000 pounds in 1852 to 76,585,000 pounds in 1886; and Mr. White estimated that the crop for 1887 would not fall far short of 90,000,000 pounds. The amount of tea exported from India between October 1, 1885, and September 30, 1886, is officially returned as 68,784,249 pounds, of which 66,640,749 pounds went to England. Nearly the whole of this tea is consumed in Great Britain, a small quantity being sent to the Continent mixed with inferior China teas, and consequently sold as China tea. The percentage of Indian tea used in England has also been steadily rising, for whereas in 1865 China tea formed 97 per cent. of the entire consumption, in the first quarter of 1887 the proportion was 51 per cent. of Indian to 49 per cent. of China tea.

Notwithstanding the steadily increasing production in India, China tea is still imported into the country; in 1885–86 about four million pounds were imported, but mainly into Bombay, where none is grown, and much of it for re-export to the Persian Gulf, Afghanistan, and some to Trieste, where it arrives as Indian tea.

Statistics concerning the consumption of tea show that the greatest tea-drinkers are the Australians, who in 1881 consumed 81 ounces per head of the population. England ranked next with 73 ounces, while the United States of America came next with 21 ounces. Russia, Belgium, Holland, and Denmark rank highest among Continental nations as tea-drinkers, but they only consume from 7 to 8 ounces per head of the population.

Dr. Feistmantel fully indorses the prevalent English opinion as to the superiority of Indian to China tea, and attributes its being almost unknown on the Continent mainly to the fact that "China tea" is a much older, and therefore better known, product throughout Europe. Even in England Indian tea took years to establish its reputation. It will in the end be as much appreciated on the Continent as it is in this country if a few merchants and tradesmen in different Continental cities, whose commercial standing will be a guarantee for the purity of the goods they supply, are induced to keep it.

A special chapter is devoted to the cultivation of tea in Ceylon, and shows the marvellous progress made by this new industry in consequence of the coffee disease having caused the conversion of so many coffee plantations into tea plantations. In 1875 only 1080 acres were under tea, whereas in 1885 no less than 102,000 acres were occupied by it, and the exports rose from 282 pounds in 1875–76 to nearly four million pounds in 1884–85. The plantations are principally in the western and southern provinces of Ceylon.

Dr. Feistmantel's work concludes with an interesting chapter on caravan teas, compiled from an article by Herr Walter Japha, published in the *Revue Coloniale Internationale* for September–October 1887.

Some amongst us are apt to feel a certain amount of jealousy at the not infrequent employment of foreigners in Government appointments, and this feeling is perhaps intensified by the knowledge that in this matter, as in Free Trade, there is no apparent reciprocity—for we seldom hear of the employment of Englishmen by Continental Governments; but the present is an instance, and by no means a solitary one, of the great service done to us by foreigners who avail themselves of the information they have collected in the course of their employment by our Government to diffuse among their fellow-countrymen such an intelligent knowledge of the productions of our distant possessions as is calculated to largely benefit our commerce by leading to an extensive demand for the goods of which they write.

It would seem, however, scarcely just that the work of diffusing this knowledge should be left to other nations, seeing that the benefits are to be reaped by ourselves. It is hardly likely that in England it will be recognized, as it is in some other countries, to be part of the duties of any Government Department; but why should it not be part of the work of such a body as the London Chamber of Commerce, or the new Imperial Institute, to disseminate information regarding our Colonial and Indian products among Continental nations, and to translate and circulate any useful works on commercial and kindred subjects, published in foreign languages, among such classes of the community as they would be likely to interest?

J. R. ROYLE.

LIVING LIGHTS.

Living Lights: a Popular Account of Phosphorescent Animals and Vegetables. By C. F. Holder. (London: Sampson Low, Marston, Searle, and Rivington, 1887.)

THIS pleasant volume of 167 pages is intended for young students of science, "their unscientific elders, and the boys and girls in general who have not yet had their interest aroused in Nature's works." The field covered is very wide, and the book is truly Germanic in its meanderings. The author would appear to be under the spell of those who "not only know all that is known by other people, but also all that they themselves imagine, which nobody else can possibly know." When it is said that the results obtained by the expeditions of the *Challenger*, *Talisman*, *Albatross*, *Travailleur*, and *Magenta*, are incorporated, no one can raise the charge of antiquity. The author discusses all possible sides of his subject, from luminous man to cosmic dust in its relation to sun-glow and even luminous paint itself, which was, as is well known, anticipated by the Chinese (oh, Mr. Balmain!). It must not, however, be imagined that the volume is a mere compilation. Quite the reverse; for, while the author embodies much that is original, he incorporates manuscript notes, placed at his disposal by our veteran Gosse, and by luminologists such as Giglioli, Dubois, and others.

Technicalities are for the most part relegated to an appendix, with full references to authorities; the result being that while the book, as a whole, furnishes the specialist with a work of reference the body of it is rendered assimilable by the feeblest tyro. The subject is introduced by a consideration of the bottom of the ocean, which the author naïvely terms the "lower firmament"—an idea which he elaborates in the subsequent chapters, treating of "meteors" and "fixed luminaries" of the sea. We meet with many friends of our youth, such as, for example, M. de Tessan's well-worn picture of the phosphorescent sea at Simon's Town, with its accompanying description.

By way of relieving monotony, anecdotes and similes are freely intercalated with the text. Some of the latter are very happy, as, for example, the comparison drawn between the blind-man and the *Bathypterus* (p. 92). On p. 13 we read: "By having a companion to keep up a continuous motion of the (luminous) water, I have almost been able to read the print of a newspaper by the light of these disintegrated (animal) forms"—a literal stern reality this, sufficient to break the heart of a Ruskin.

The author appears to be suffering under a phosphorescence mania. He leads off with the rather extravagant statement, "Among the revelations of modern science none have a more absorbing interest than those relating to the illumination of the deep sea." He is, moreover, a genuine enthusiast, and, like all such, sees the salvation of his race in his own hobby, for he gives it as his opinion (p. 41) that "the discovery of the secret of phosphorescence, and its practical application to the wants of mankind, would result in revolutionizing present systems; a heatless, inexpensive, inextinguishable light being the perfection of possibilities in this direction." Similar sentiments are expressed in the peroration: these we commend to the physicist.

The book is exceedingly well got up, and illustrated by twenty-six plates, most of which have been especially designed for it. One of these, representing the now famous giant Pyrosoma of the *Challenger*, in size proportionate to that of a man, is especially striking, and the publishers have, very properly, reproduced it on the cover. We would, however, suggest that, in the case of sponges and corals more especially, the animals themselves, and not their mere skeletons, should be delineated; the course here adopted is too suggestive of a "matching" of ordinary museum specimens for the sake of effect. Here and there we note a looseness of style and expression such as is frequently met with in a first issue. The book—strictly a general treatise on luminosity—is a conscientious exposition of a fascinating subject, sound though superficial, and in no sense sensational. We wish it success.

OUR BOOK SHELF.

Food Adulteration and its Detection. By J. P. Battershall, Ph.D., F.C.S. (New York: Spon, 1887.)

THE most striking points of this book are the photographic reproductions of various food-stuffs: starch-grains, fat-crystals, also margarine, milk, tea-leaves, &c. In the introduction Dr. Battershall laments the general inefficient state of the law in America, which would apply very much more forcibly to us, regarding adulteration.

The author does very good service in his introduction, drawing attention to the statistics of recent adulteration. From one table, taken from the work of the Public Analysts' Society in England, it appears the percentage of adulteration has not decreased in any appreciable degree, having been 18·10 per cent. in 1875–76, and 17·47 in 1880, and 16·4 in 1883. The Annual Report of the New York City Board of Health for 1885 furnishes some statistics of adulteration which are by no means pleasant, and show a not very high commercial morality, although the majority are said not to be injurious adulterations—merely fraudulent. The author is quite right when he says "that attempts to awaken public interest in the subject are only of real service as they are conducive to the adoption of more advanced and improved measures for the suppression of the practice."

Generally, the subjects are treated in the book in a very practical manner, and a good deal of information is also contained under each heading. Regarding the adulteration of wines, for instance, a good many interesting receipts for making wines are given, and similarly in the case of spirits and liquors. The section on water is a good *résumé* of processes of water analysis. Prominence is rightly given to Prof. Mallet's very sensible conclusions as to the value of analytical methods in respect to the hygienic character. Dr. Koch's biological method, cultivation in prepared gelatine, is mentioned, and a plate showing the living forms in Croton water and Brooklyn water is given, but we are not frightened by any alarmist theories or statements as to the injurious nature of these organisms; indeed, we are told that the greater number are unobjectionable, and frequently even of service, which is doubtless the case. The really active Bacteria are much less impressive in appearance.

There is a pretty long chapter on legislation in the United States on adulteration, which is not of much use, but is still interesting, to an English reader. The bibliography is very useful. Altogether it is a readable and useful book, and will doubtless meet with a good reception.

W. R. H.

Dynamics and Hydrostatics. By R. H. Pinkerton, B.A. (London: Blackie and Son, 1888.)

THIS is a first course of dynamics intended for the use of science classes and colleges, and specially adapted to the requirements of the Science and Art Examinations in theoretical mechanics. The subject is treated mathematically, but the mathematical knowledge required for an intelligent perusal of the book is limited to elementary algebra and trigonometry. The fundamental units are thoroughly well explained, and, which is saying a great deal, they are used consistently throughout. Every important proposition is followed by a number of good examples fully worked out, and many others are given as exercises.

The book is excellently adapted to the Second Stage of the Science and Art Syllabus, and teachers will not have much difficulty in selecting the portions suitable for students working for the First Stage. It is also well adapted for the use of students working at the subject for the London Matriculation and other University Examinations. But, notwithstanding these qualifications, it is thoroughly conscientious. In fact, from a mathematical point of view, the book leaves nothing to be desired, but in this practical generation a greater number of illustrations from every-day life would not have been out of place. A. F.

Geography for Schools. By Alfred Hughes, M.A. Part I. Practical Geography. (Oxford: At the Clarendon Press, 1887.)

THERE are many signs that the study of geography will in future take a much more important place in the ordinary school course than has hitherto been assigned to it. Even from the point of view of those severely practical persons who care little about the purely intellectual aspects of education, there can be no doubt as to the value of the kind of geographical knowledge with which this book is chiefly concerned; and the subject, if properly treated, is one in which young scholars may easily be led to take genuine interest. The present volume will be of great service to schoolmasters who may wish to make a fresh start in geographical teaching. It is based, as Mr. Hughes explains, on the results of seven years' experience in the modern side at the Manchester Grammar School; and no one who examines the book will be surprised that he has found it possible, within the limits of an ordinary term's geographical course, to give instruction on many classes of problems which are not usually treated at school. He begins with the consideration of latitude and longitude, and with rules for the drawing of maps from the atlas and from memory. He then deals with the measurement of the distance between two places on the earth's surface, and explains the rotation of the earth, with the consequent difference in the time of day at two places on the earth. The remaining subjects are the apparent movements of the fixed stars; the Pole star; Polar distance; the apparent movements of the sun; the seasons; meridian altitude of the sun; declination; the length of day and night at any time and place; the sun's altitude; place of sunrise and sunset; the length of twilight; apparent and Greenwich mean time; movements of the earth; the length of shadows; the distance to be seen from mountain summits; the trade winds; and the calendar. The questions connected with these subjects are discussed in a way that secures the combination of geography, geometrical drawing, arithmetic, and the elementary ideas of geometry; and the author's aim is to induce the student to think for himself, rather than to burden his memory with disconnected facts. It is hardly necessary to say how much better this is than the learning of the names of capes, mountains, rivers, &c., by heart. With such a work in their hands, teachers should be able to make lessons in geography a most useful introduction to the study of some important branches of scientific method.

Key to Todhunter's Differential Calculus. By H. St. J. Hunter, M.A. (London: Macmillan and Co., 1888.)

THIS "Key" will be extremely useful to those who are teaching the subject, but more so to those who are getting it up by themselves. The examples are worked out in a clear and intelligible manner, the geometrical problems being so worded that the student can supply figures to enable him more readily to follow the reasoning. To the chapters on "Curve Tracing" and "Miscellaneous Propositions" the author has added figures; and in the solutions to some of the examples in chaps. xi., xiii., xv., xx., and xxii., improved methods have been adopted, making the book more useful and complete. Great care seems to have been taken to insure accuracy.

Electrical Instrument Making for Amateurs. By S. R. Bottone. (London: Whittaker and Co., 1888.)

IN this little book the author has placed before the reader very good and economical methods of making the more useful pieces of electrical apparatus, using only tools of the simplest kind, such as may be found in any household. The instructions are given in a clear and simple manner, and are illustrated by woodcuts, showing the various parts of the apparatus, with the proportions marked on them. Those who are attending courses of lectures on this subject will find this volume immensely useful, as a more thorough and practical insight is obtained by making and using these instruments, however rough, than by mere reading.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Language = Reason.

PROF. ST. GEORGE MIVART has read my letter on "Language = Reason" in NATURE of February 2 (p. 323) with very great care, and I feel grateful to him for several suggestive remarks. But has he read the heavy volume to which that letter refers—my "Science of Thought"? I doubt it, and have of course no right to expect it, for I know but too well myself how difficult it is for a man who writes books to read any but the most necessary books. I only mention it as an excuse for what might otherwise seem conceited—namely, my answering most of his questions and criticisms by references to my own book.

Prof. Mivart begins by asking why I should have explained reasoning by reckoning.

Now, first of all, from an historical point of view—and this to a man who considers evolution far more firmly established in language than in any other realm of Nature is always the most important—the Latin *ratio*, from which came *raison* and our own *reason*, meant originally reckoning, casting up, calculation, computation, long before it came to mean the so-called faculty of the mind which forms the basis of computation and calculation, judgment, understanding and reason.

Secondly, I began my book on the "Science of Thought" with a quotation from Hobbes, that all our thinking consisted in addition and subtraction, and I claimed the liberty to use the word thinking throughout my own book in the sense of combining. Such a definition of thinking may be right or wrong, but provided a word is always used in the sense in which from the beginning it has been defined there can at all events be no misapprehension nor just cause of complaint on the part of the critic

What I meant by combination, or by addition and subtraction being the true character of thinking, I explained very fully. "Any book on logic," I said, "will teach that all our propositions are either *affirmative* or *negative*, and that in acquiring or communicating knowledge we can do no more than to say that A is B, or A is not B. Now, in saying A is B, we simply add A to the sum already comprehended under B, and in saying A is not B, we subtract A from the sum that can be comprehended under B. And why should it be considered as lowering our high status, if what we call thinking turns out to be no more than adding or subtracting? Mathematics in the end consist of nothing but addition and subtraction, and think of the wonderful achievements of a Newton or a Gauss—achievements before which ordinary mortals like myself stand simply aghast."

Prof. Mivart holds that there are but two forms of intellectual activity: (1) acts of intuition, by which we directly apprehend certain truths, such as, *e.g.*, our own activity, or that A is A; and (2) acts of inference, by which we indirectly apprehend others, with the aid of the idea "therefore."

There is a wide difference between our apprehending our own activity and our apprehending that A is A. Apprehending our own activity is inevitable, apprehending that A is A is voluntary. Besides, the "therefore" on which Prof. Mivart insists as a distinguishing feature between the two forms of thought is present in the simplest acts of cognition. In order to think and to say "This is an orange," I must implicitly think and say, "This is round, and yellow, has a peculiar skin, a sweet juice," &c.; *therefore* it is an orange. The "therefore" represents in fact the justification of our act of addition. We have by slow and repeated addition formed the concept-name orange, and by saying "This is an orange," we say no more than that we feel justified, till the contrary is proved, in adding this object before us to the sum of oranges already known to us. If the contrary is proved, we subtract, and we add our present object either to the class and name of lemons, citrons, &c., or to a more general class, such as apples, fruit, round objects, &c. We ought really to distinguish, as I have tried to show, not only two, but four phases in every act of cognition, viz. sensation, perception, conception, and naming; and I contend that these four phases, though distinguishable, are not separable, and that no act of cognition is perfect without the last phase of naming.

But how is it, Prof. Mivart continues, that different words in our language have one meaning, and different meanings one word? Does not this show that thought and language cannot be identical?

It has been the principal object of all my mythological studies to account not only for the origin of *polyonymy* and *homonymy*, but to discover in them the cause of much that has to be called mythology, whether in ancient tradition, religion, philosophy, or even in modern science. I must therefore refer Prof. Mivart to my earlier writings, and can only mention here a few well-known cases of mythology arising from polyonymy and homonymy.

We can easily understand why people should have called the planet Venus both the morning and the evening star; but we know that in consequence of these two names many people have believed in two stars instead of one. The same mountain in Switzerland is called by the people on the south side *Blackhorn*, by the people on the north side *Whitehorn*, and many a traveller has been misled when asking his way to the one or the other. Because in German there are two words *Verstand* and *Vernunft*, originally meaning exactly the same thing, German metaphysicians have changed them into two distinct faculties, and English philosophers have tried to introduce the same distinction between the understanding as the lower and reason as the higher faculty.

Nothing is really easier to understand, if only we consult the ancient annals of language, than why the same object should have had several names, and why several objects should have had the same name. But this proves by no means that therefore the name is one thing and the concept another. We can distinguish name and concept as we distinguish between the concave and convex sides of a lens, but we cannot separate them, and in that sense we may call them inseparable, and, in one sense, identical.

Lastly, Prof. Mivart starts the same objection to my system of psychological analysis which was raised some time ago in these columns with so much learning and eloquence by Mr. Francis Galton. He appeals to his own experience, and maintains that certain intellectual processes take place without language. This is generally supposed to put an end to any further argument, and we are even told that it is a mistake to imagine that all men are alike, so far as their psychological processes are concerned, and that psychologists should study the peculiarities of individuals rather than the general character of the human intellect. Now, it seems to me that *l'un n'empêche pas l'autre*, but that in the end the object of all scientific inquiry is the general, and not the individual. The true life of language is in the dialects, yet the grammarian aims at a general grammar. In the same way the psychologist may pay any amount of attention to mere individual peculiarities and idiosyncrasies; only he ought never to forget that in the end man is man.

But it does not even seem to me that intellectual processes without language, as described by Mr. Galton and Prof. Mivart, are at all peculiar and exceptional. I have described similar cases, and tried to account for them, in different parts of my book. If Prof. Mivart says that "a slight movement of a finger may give expression to a meaning which could only be thought in words by a much slower process," I went much further by saying that "silence might be more eloquent than words."

Mr. Galton asked me to read a book by Alfred Binet, *La Psychologie du Raisonnement*, as showing by experiments how many intellectual acts could take place without language. I read the book with deep interest, but great was my surprise when I found that M. Binet's observations confirmed in the very strongest way my own position. I had shown how percepts—that is, images—could exist with a mere shadow of language, and that nothing was more wonderful than what Leibniz called the algebra of thought. Now, what do M. Binet's experiments prove? That there are two kinds of images, the *consecutive*, reproduced spontaneously and suddenly, and the *memorial*, connected with an association of ideas. The *consecutive* image, a kind of impression *avant la lettre*, may reappear long after the existing sensation has ceased to act, and it reappears without any rhyme or reason. But how are the memorial images recalled, seen by people, such as M. Binet describes, in a state of hypnotism? Entirely by the word. Show a hypnotized patient her portrait, and she may or may not recognize it. But tell her, in so many words, "This is your portrait," and she will see her likeness in a landscape of the Pyrenees (pp. 56–57). M. Binet is fully aware of what is implied by this. Thus, on p. 58, he writes: "*L'hallucination hypnotique est formée d'un image suggérée par* la parole." So, again, when describing the simplest acts of perception, M. Binet explains how much is added by ourselves to the mere impressions received through the senses by "*ce qu'on croit voir*," by "*ce qu'on croit sentir*," and by "*le nom qu'on croit entendre prononcer*." The facts and experiments, therefore, contained in M. Binet's charming volume seem to me entirely on my side, nor do I see that that thoughtful observer has ever denied the necessity of language or signs of some sort for the purpose of reasoning, nay even of imagination.

I find it difficult to answer all the questions which the Professor has asked, because it would seem like writing my own book over again. However, I shall confess that I have laid myself open to some just criticism in not renouncing altogether the metaphorical poetry of language. I ought not to have spoken of Truth as a kind of personal being, nor of Reason as a power that governs the universe. But no astronomer is blamed when he uses the old terminology of sunrise and sunset; no biologist is misunderstood when he speaks of mankind; and no philosopher is denounced when he continues to use the big I instead of "succession of states of consciousness." If, therefore, I said that I recognized in evolution the triumph of reason, I meant no more than that I could not recognize in it the triumph of mere chance. Prof. Mivart imagines that I misunderstood what the biologist means by the survival of the fittest. Far from it, I understand that phrase, and decidedly reject it. For, either the survival of the fittest means no more than that that survives which is able to survive,—this would be mere truism and a patent tautology,—or, if we take in the whole circumstance of Nature, the survival of the fittest implies some kind of inherent fitness and reasonableness. Prof. Mivart writes: "What there is less reasonable and right in a Rhytina than in a Dugong, or in a Dinornis than in an Apteryx, would, I think, puzzle most of our zoologists to determine; nor is it easy to see a triumph of reason in the extermination of the unique flora of St. Helena by the introduction of goats and rabbits." No doubt, it is not easy to see this. But need I remind Prof. Mivart that many things may be true, though it is not easy to see them? We often do what we think is reasonable and right, though we seem to see nothing but mischief to ourselves and others arising from our acts. Why do we do this? Because we believe in the ultimate triumph of reason

and right, though it may take millions of years to prove that right is right. I have the same faith in Nature; and, taking my stand on this scientific faith, I believe that natural selection must in the end prove rational selection, and that what has vaguely been called the survival of the fittest will have to be interpreted in the end as the triumph of reason, not as the mere play of chance. F. MAX MÜLLER.

Oxford, February 21.

"Coral Formations."

CAPTAIN WHARTON'S paper on coral formations in last week's NATURE (p. 393) will have been read with great interest by all who have examined and studied coral reefs. It is unlikely that any objections will be raised to the illustrations he has brought forward of how the coral plantations may be built up from deeply submerged banks, and eventually formed into complete atolls and barrier reefs at a great distance from continental and other shores. The mode of formation has been dwelt upon by Le Conte and Guppy in the case of barrier reefs, and I have pointed out the same thing in my remarks about the Maldive and similar atoll groups. The instances cited by Captain Wharton are of great value, especially as he has been able to consult large manuscript plans.

Captain Wharton apparently considers that the solution of carbonate of lime by sea-water plays no important part in deepening, widening, and modifying the form of such atolls and barrier reefs; in this I cannot agree with him.

By reference to what is now taking place in Nature, as well as to experiments conducted in the laboratory, it has been shown that the solution of the carbonate of lime of dead shells and skeletons by the sea is as constant and universal as its secretion by the living organisms. From some considerations which I recently laid before the Royal Society of Edinburgh, it is probable that there is more secretion and deposition of carbonate of lime in the ocean, as a whole, than removal by solution, and it is almost certain that at the present time there is a vast accumulation of carbonate of lime going on within the coral-reef regions of the ocean. The amount of secretion becomes less with increasing depth beyond one hundred fathoms, and laboratory experiments under great pressures have shown that the rate of solution becomes greater with increasing depth; but both processes are always in action wherever there are life and growth, death and decay. In some regions secretion is in excess, and there is a formation of calcareous deposits; in others solution is equal to secretion, as over the red clay areas of the ocean. Again, solution may be in excess of secretion, as in the larger and more perfect coral lagoons. The *rôle* of carbonate of lime in the ocean may not inaptly be compared to that of aqueous vapour in the atmosphere over land surfaces. Where precipitation is in excess of evaporation, fresh-water lakes are formed, and rivers carry the surplus water down to the ocean; where evaporation is in excess, there is a formation of inland drainage areas, deserts, and salt lakes.

In small coral atolls the periphery is large relatively to the size of the lagoon, and the secretion of lime and formation of coral sand are greatly in excess of the solution that takes place, hence the lagoon becomes filled up; in it are frequently found deposits of sulphate of lime, guano, magnesian and phosphatic rocks. On the other hand, when a comparatively large atoll reaches the surface, the periphery being small relatively to the size of the lagoon, there is less secretion and formation of coral sand by the living outer surface than is removed in solution from the lagoon; it is in consequence widened, deepened, and reduced to a more or less uniform appearance, while the islands on such reefs never, so far as I know, contain deposits of sulphate of lime, guano, magnesian or phosphatic rocks. On open banks, such as the Macclesfield and Tizard Banks, the coral sand is generally largely made up of bottom-living Foraminifera, Polyzoa, Serpulæ, and Calcareous Algæ, and the bank may be rising from the secretions of these organisms; but when the peripheral reefs reach the surface the conditions become more or less inimical to vigorous growth, and in a perfect atoll the fine calcareous mud is removed at a relatively rapid rate.

My answer to Captain Wharton's question is that in all normal conditions the extent of surface in the shell, coral, or fragment of coral sand exposed to the action of sea-water compared with the mass determines the rate at which these organisms will disappear in solution. It is improbable that this action is extremely slow at the bottom of the deep lagoons. Independently of the mixing by convection currents, even a very slight wind over the surface of the lagoon will set the whole water in motion. This is clearly shown by my observations in the western lochs of Scotland, which are much deeper than any lagoon; a moderate breeze produces motion at a depth of sixty fathoms in a very short space of time. The water mixed up with the mud at the bottom is thus changed long before the point of saturation is reached.

I have never seen any wide extent of fringing reef but what was very deeply cut up with channels, and from Captain Wharton's own description this appears to be the case at Rodriguez. That a ship channel has not there been formed is probably due to the shallow water surrounding the island and the probably rapid growth outward of the reef; the average depth outside the reef is usually less than ten fathoms, and at a distance of two miles seaward it is only from twenty to thirty fathoms. In some instances the large proportion of Calcareous Algæ on the reefs appears to compensate for the removal in solution, and thus to retard the formation of ship channels.

I doubt if any recent writer has attempted to give an "explanation which will fully account for the almost infinite variety of coral formations." It is unnecessary to state that each reef must have peculiarities depending on the nature and form of its foundation, and the meteorological and other conditions of the seas in which the reef is situated; it is only by a careful and detailed study of all these conditions that the peculiarities of any individual reef can be fully explained. At the same time it appears to me beyond doubt that the general and well-known characteristic features and form of coral reefs can be accounted for by reference to certain general considerations, chief among these being the vigorous growth of reef-forming species in positions and at depths where the supply of pelagic oceanic organisms, which form their food, are most abundant, and the removal of dead coral and coral debris wherever this is exposed to the action of sea-water.

Captain Wharton calls attention to our imperfect knowledge of the coral groups of the Pacific, but he understates the case in saying "that the waters of the Fiji and the Society Islands are the only ones which can be said to be in any sense surveyed." Cook, Kotzebue, Duperrey, Beechy, and Wilkes have given running surveys of many of the Paumotus, and we know something about the depths inside and outside of a good many of them. We know much about the islands containing guano. The French have made some excellent charts of the New Caledonia reefs, and the Americans have done the same for some of the Hawaiian Islands. Captain Wharton will acknowledge that we have a splendid survey of the Maldives, the most extensive group of atolls in the world; the islands marked with names in this British Survey number 602. Other groups in the Indian Ocean are well surveyed, and nearly all the Atlantic reefs have been correctly laid down on charts.

I feel sure that all who take an interest in this subject will hope for many more contributions from Captain Wharton's pen on coral formations. JOHN MURRAY.

I HAVE read with great interest the article on coral formations in your last number (p. 393), by Capt. Wharton. It is not because I wish to claim to have anticipitated the views which he gives as to the formation of atoll lagoons and barrier reef lagoons that I am writing to state that at the very date of the publication of Capt. Wharton's article I was engaged in writing a paper on coral formations, based upon a study of living corals at Diego Garcia, and on a consideration of the great submerged atolls known as the Great Chagos Bank and the Pitt and Centurion Banks, situated north and west of that island, in which I arrive at conclusions nearly identical with his. It has seemed to me, as it has to him, that the solution of dead coral rock in the interior of a reef does not sufficiently account for the formation of lagoons, and that the true cause of the atoll and barrier lagoons surrounded either by a reef which is awash, or by a strip of low land, lies in the peculiarly favourable conditions for coral growth present on the steep external slopes of the reef. In Diego Garcia I observed that although the shore reefs are for the most part covered with 1 or 2 feet of water, even at the lowest spring tides, yet their flat surfaces are nearly invariably barren of growing coral. Just at their edges, however, and on the steep external slopes beyond the edges, reef-building corals grow luxuriantly. According to Capt. Moresby, quoted by Mr. Darwin in his book on "Coral Reefs," the flat surface of the rim of the Great Chagos Bank is barren of living corals,

just as are the shore reefs of the neighbouring atoll of Diego Garcia; but the lagoon contains many knolls abundantly covered with living coral, and there is reason to think that living coral also occurs on the external slopes at Diego Garcia. Unlike Capt. Wharton, I do not consider the favourable conditions for coral growth on the external slopes to be connected with a better food supply, for this would be at variance with the existence of thriving coral patches within the lagoon, which, as I have seen at Diego Garcia, bear no relation to the lagoon mouths, through which food-bearing currents might be supposed to enter to the interior. Indeed, at the last-named atoll some of the most luxuriant coral patches are found at the south end of the lagoon, furthest away from the lagoon outlet. The favourable conditions are due, I believe, to the action of currents on coral growth. I noticed at Diego Garcia, and Dr. Hickson has made similar observations in the reefs near North Celebes, that corals do not thrive where they are subjected to the direct action of a strong current, nor do they grow in still water, where they are killed by the sand deposited upon them, but they flourish in places where a moderate current flows over them, not so strong as to dash them to pieces, but strong enough to prevent deposition of sand. Such conditions are found everywhere on the external slopes. At the side where a current impinges directly on a slope, the deeper parts of the current strike the slope first, and are in part thrown upwards over the sloping surface, thus moderating the direct force of the more superficial part of the same current. The main part of the current flows tangentially around the obstruction, and thus affords favourable conditions at the sides of the atoll or reef, and finally, on the side furthest from the current, the back-wash causes weak superficial currents which are also highly favourable to coral growth. Thus the coral grows to the greatest advantage around the periphery of a reef, and, as Capt. Wharton says, a ring-shaped reef is the result, and no theory of solution is required to explain the central depression.

Capt. Wharton states that live coral exists in abundance on the rim of the Tizard Reef. It is not clear whether this means on the external slopes and on the extreme edge of the reef, or on the flat upper surfaces of the reef itself. From what I have observed at Diego Garcia, it appears to me hardly probable that the latter can be the case. Coral debris, torn from the corals growing on the slopes, is always carried across those flat surfaces in such quantity as to destroy any living corals upon them. In some cases corals may grow there, but then there are other favourable conditions neutralizing the effect of the debris. I am hoping soon to publish a full account of my observations at Diego Garcia. G. C. BOURNE.

Anatomical Department, Oxford, February 28.

Natural Science and the Woolwich Examinations.

IN accordance with Mr. Irving's recommendation, I have carefully considered the letter in the *Times* from the head master of Clifton College; but, with all due respect to his distinguished position, I find myself unable to accept his conclusions. Men of science will pardon me, if I ask them to examine facts, rather than to follow blindly even the highest authority.

The obligatory mathematics to be required from candidates for Woolwich are defined as follows in the official regulations, dated December 1887:—

"Algebra up to and including the binominal theorem; the theory and use of logarithms; Euclid, Books i. to iv. and vi.; plane trigonometry up to and including the solution triangles; mensuration; statics—the equilibrium of forces acting in one plane and of parallel forces, the centre of gravity, the mechanical powers; dynamics—uniform, uniformly accelerated, and uniform circular motion, falling bodies and projectiles *in vacuo*. (Analytical methods of solution will not be required.)

"N.B.—A thorough knowledge of each of the above branches of mathematics will be required."

This amount of mathematics is not beyond the reach of a fairly intelligent lad of seventeen who has been properly taught.

The inductive process which leads Mr. Irving to denounce so severely my supposed inappreciation of the value of experimental demonstration, laboratory training, and field work is hardly worthy of so eminent a teacher. Although there are good grounds for my opinion that chemistry, physics, and geology, are not good educational subjects for ordinary lads under sixteen, I am entirely consistent in the expression of my regret that the War Office should have thought it desirable to discourage these sciences. Your able article conclusively proves that these subjects cannot be hastily and superficially learned in such a way as to gain unmerited marks. There are youths with apt intelligences, quick eyes, and skilful fingers, who ought to be allowed the advantage of their scientific capacity in the Woolwich competition. But I am unable to see that Mr. Irving's suggestion would do justice to these. A candidate who offered optional mathematics, one language, and two sciences, would be placed at a great disadvantage with those offering optional mathematics, and three languages, both on account of the lower maximum, and also because, with the same relative proficiency, it is so much harder to score in mathematics and experimental sciences and geology than in languages. I therefore respectfully submit that all who have the interests of science at heart should urge that the maximum should be raised to 3000 marks, but I do not think it would be desirable to allow candidates to take more than one subject from Class II., as it would tend to the neglect of more important studies.

2 Powis Square. HENRY PALIN GURNEY.

International Tables.

I AM instructed by the Meteorological Council to request your insertion of the following notice:—

The International Meteorological Congress, which met at Rome in 1879, recommended that a series of international tables should be prepared and issued.

The work was ultimately intrusted to a Sub-Committee, consisting of Prof. Wild and Prof. Mascart.

The Sub-Committee has prepared a scheme of tables, which has met with a general acceptance among the heads of European meteorological organizations.

The tables will be in royal quarto, and will cover about 400 pages. The price of the work, to be published by Gauthier-Villars, will be 35 francs.

The Council are requested by the gentlemen who have prepared the tables to ascertain the probable demand for the work in this country, and I am therefore to request through your columns that any intending purchaser will send his name to me.

ROBERT H. SCOTT.

Meteorological Office, 116 Victoria Street, London, S.W., February 16.

PLAN OF TABLES.

CHAPTER I.

Section I. Length.

1.	French lines	to mm.	...	0—100 lines
2.	,,	,, English inches	...	,,
3.	French inches and lines	,, mm.	...	20—30 inches
4.	French lines	,, English inches	...	250—350 lines
5.	English inches	,, mm.	...	0—100 inches
6.	,,	,, ,,	...	17—32 ,, (in ·001 inch)
7.	mm.	,, English inches	...	0—100 mm.
8.	,,	,, ,,	...	440—800 ,,
9.	Russian half-lines	,, mm.		
10.	,, ,,	,, English inches		
11.	French feet	,, metres		
12.	,,	,, English feet		
13.	English feet	,, metres		
14.	Metres	,, English feet		
15.	Kilometres	,, English miles		
16.	English miles	,, kilometres		

Section II. Weight.

1.	Grains	to grammes
2.	Grammes	,, grains

Section III. Time and Angular Measure.

1.	Days of year	to decimals of year and to angles
2.	Hours	,, ,, ,,
3.	Minutes	,, ,, ,,
4.	Hours	,, decimals of day
5.	Minutes	,, ,, ,,
6.	Seconds	,, ,, ,,
7.	Minutes or seconds	,, decimal of the hour or minute
8.	Seconds	,, decimals of hour
9.	Longitude	,, time
10.	Time	,, longitude

CHAPTER II.—GEODETICAL.

1. Variation of gravity with latitude and altitude.
2. Degrees on the meridian.
3. ,, on circles of latitude.
4. Duration of sunshine.

CHAPTER III.—THERMOMETER.

Section I. Conversion.

1. R. to C.
2. F. ,, C.
3. C. ,, F.
4. F. ,, C. differences
5. C. ,, F. ,,

Section II. Reduction of Temperature to Sea-level.

1. Metric.
2. English.

CHAPTER IV.—BAROMETER.

1. Barometer to 0° C. Metric (0°·1 C. and 5 mm.).
2. ,, ,, 32° F. (0°·5 F. and 0·2 ins.).
3. Gravity ... Latitude ... metric.
4. ,, ... ,, ... English.
5. ,, ... Altitude ... metric.
6. ,, ... ,, ... English.
7. Barometer to sea-level ... ... metric.
8. ,, ,, ... English.

CHAPTER V.—HYGROMETRY, RAIN, AND EVAPORATION.

1. Vapour-tension to 0·1 C. from − 30° C. to + 101° C.
2. ,, ,, 0·2 F. ,, − 20° F. ,, + 214° F.
3. Boiling-point (from 680 mm.—800 mm.) ... metric.
4. ,, ,, ,, ... English.
5. Vapour-tension about 100° C. ... ... metric.
6. ,, ,, 212° F. ... ... English.
7. Weight of water in cubic metre of air ... metric.
8. ,, ,, foot ,, ... English.
9. Relative humidity ... ... metric.
10. ,, ,, ... English.

CHAPTER VI.—WIND.

1. Lambert's formula.
2. Natural tangents.
3. Kilometres per hour to metres per second.
4. Metres per second ,, kilometres per hour.
5. Miles per hour ,, metres per second.
6. Metres per second ,, miles per hour.

CHAPTER VII.—MAGNETISM AND ELECTRICITY.

1. English mag. units to C.G.S. units.
2. C.G.S. ,, Eng. mag.

Weight and Mass.

THE review of Kennedy's "Mechanics of Machinery" in NATURE, December 29, 1887 (p. 195), strikes at least one responsive chord on this side of the world. There are some questions in reference to the nomenclature of dynamics which "will not down" until they are "downed" by a convention or agreement between those who have to do with the theory of mechanics and those who have to do mostly with practice, and in this some concessions will doubtless be necessary on both sides. While in hearty sympathy with much that the reviewer says in his discussion of dynamical terms (the book under notice I have not yet seen), I wish to dissent from and to protest against one of his leading propositions.

It must be admitted that in the "vernacular" the word pound is used in two distinct senses—that is, as a unit of force and a unit of mass. Authors of mathematical treatises have sometimes, and perhaps unconsciously, ignored the latter meaning, and at other times have failed to recognize the former.

The proposition of the reviewer is to eliminate the word *mass* altogether and to use weight in its stead. To accomplish this he is obliged to use the word *weight* as meaning what is now generally expressed by the word *mass*. This, it seems to me, would be a grave error. Is it not true that *weight*, as understood by both the "learned and the unlearned" always carries with it the idea of force, the force of attraction between the earth and the particular body under consideration? And is it not also true that there are many problems in the work of the practical engineer in which *mass*, in the ordinarily accepted sense, is the essential element, rather than weight, in the ordinarily accepted sense? In short, in my judgment, the engineer *does* require the word "mass," and he also needs the word "weight." It is a misfortune when one word must be used to mean two entirely different things (as is the case of the word "pound"), and we ought to congratulate ourselves that we have the words "mass" and "weight" so commonly and generally used to represent two distinct ideas. To discard one of them and force the other into its place would be to introduce confusion rather than order. To satisfy the requirements of both mathematical or theoretical and practical convenience I have been accustomed to use the following:—

The word *pound* is used in two senses; it may mean a unit of mass or a unit of force. It is always easy by the context to tell in which sense it is used.

As a unit of force it *has not yet been accurately defined*, but it means, in general, a force equal to the attraction between the earth and a mass of one pound. As this attraction varies slightly, the pound as a unit force cannot be regarded as absolutely constant, but is sufficiently so for practical purposes.

When, by a convention of authorities, the conditions under which this attraction is accepted as equal to one pound are prescribed, it will become an invariable unit.

There are in the English system two units of force, the poundal and the pound. There are also two units of work, the foot-poundal and the foot-pound; each is the work done by the corresponding unit of force working through a distance of one foot.

The ordinary equations of dynamics, when the foot-pound-second units are used, give results in poundals or foot-poundals, which may at once be reduced to pounds or foot-pounds.

The above is open to the objection that the pound as a unit of force is not constant, but the remedy for this is indicated, and the errors introduced are of no moment in "practice."

To lessen the confusion somewhat, I have often used, in writing, the symbol *lb.* to represent the unit of *mass*, and the word *pound* that of force. In my own experience the adoption of these definitions has greatly facilitated the work of students.

I entirely agree with the criticisms made upon the equation so constantly appearing, $w = mg$. To the learner it is generally "confusion confounded," and I would cheerfully join in a "boycott" against it. T. C. MENDENHALL.

Rose Polytechnic Institute, Terre Haute, Indiana, U.S.A., January 26.

ONCE more Prof. Greenhill devotes a large portion of a review to emphasizing and insisting on his peculiar, and I may say extraordinary, mode of regarding the meaning of elementary terms (see NATURE, February 16, p. 361; also December 29, 1887, p. 195).

One must assume, therefore, that these views are regarded by him as useful and conducive to clearness.

I find it difficult to express strongly enough my entire dissent from such a proposition without being apparently impolite.

That engineers are entitled if they see fit to employ as their third fundamental standard a standard of force rather than one of mass, I admit. I do not think the plan satisfactory or clear, but there are temptations towards it, and perhaps no very serious objections. My own experience of engineering students is, however, that they are beautifully uncertain whether to put g into the numerator or the denominator of a new expression, or whether to leave it out altogether; and that they generally get over the difficulty either by asking where it must go, or by seeing which plan will give an answer of most reasonable magnitude. The real rule on engineers' principles would be to put g somewhere into the expression for any quantity with which gravity has nothing to do, and to leave g out whenever gravity is primarily concerned.

But, irrespective of this standing and well-known controversy, Prof. Greenhill's attempt to simplify matters does indeed make confusion worse confounded. He says that in the vernacular the term "weight" does not mean the force with which the earth pulls a body, but does mean the body's mass or inertia.

What kind of "vernacular" can he be thinking of?

Ask any ordinary member of the British public what he or she means by the "weight" of a thing, and you will get answers such as "its heaviness," or "its heft," or the "force required to lift it," or "the difficulty of raising it," or "the pull up you must give it," or any number of such replies; but if he ever got the answer, "I mean the mass of the body, in other words its inertia, a measure of the quantity of matter the body contains," surely he would not be satisfied with this as a fair specimen of the vernacular, but would rather regard it as one of those answers so frequently given to examiners—the product of a mind so tortured by instructors that its common-sense and vernacular are completely atrophied. OLIVER J. LODGE.

The Composition of Water

TWO days after the publication of my letter in NATURE (p. 390), on the composition of water, I received the Manchester

Report of the British Association, in which (p. 668) further experiments by Dr. A. Scott are reported. Dr. Scott has succeeded in reducing the amount of nitrogen present as impurity to 1 part in 15,000, and the ratio of hydrogen to oxygen which he calculates from the newer and more accurate experiments is 1·996 or 1·997 to 1·000. This ratio agrees very well with that deduced by me from the older experiments, but is considerably higher than the ratio previously adopted by Dr. Scott, and quoted by Prof. Thorpe in his article on the composition of water. SYDNEY YOUNG.

University College, Bristol.

ON THE DIVISORS OF THE SUM OF A GEOMETRICAL SERIES WHOSE FIRST TERM IS UNITY AND COMMON RATIO ANY POSITIVE OR NEGATIVE INTEGER.

"Nein! Wir sind Dichter." [1]
—*Kronecker in Berlin.*

A REDUCED Fermatian,[2] $\frac{r^p - 1}{r - 1}$, is obviously only another name for the sum of a geometrical series whose first term is unity and common ratio an integer, r.

If p is a prime number, it is easily seen that the above reduced Fermatian will not be divisible by p, unless $r - 1$ is so, in which case (unless p is 2) it will be divisible by p, but not by p^2.

This is the theorem which I meant to express in the footnote to the second column of this journal for December 15, 1887, p. 153, but by an oversight, committed in the act of committing the idea to paper, the expression there given to it is erroneous.

Following up this simple and almost self-evident theorem, I have been led to a theory of the divisors of a reduced Fermatian, and consequently of the Fermatian itself, which very far transcends in completeness the condition in which the subject was left by Euler (see Legendre's "Theory of Numbers," 3rd edition, vol. i., chap. 2, § 5, pp. 223-27, of Maser's literal translation, Leipzig, 1886),[3] and must, I think, in many particulars be here stated for the first time. This theory was called for to overcome certain difficulties which beset my phantom-chase in the chimerical region haunted by those doubtful or supposititious entities called odd perfect numbers. Whoever shall succeed in demonstrating their absolute non-existence will have solved a *problem of the ages* comparable in difficulty to that which previously to the labours of Hermite and Lindemann (whom I am wont to call the Vanquisher of PI, a prouder title in my eyes than if he had been the conqueror at Solferino or Sadowa) environed the subject of the quadrature of the circle. Lambert had proved that the Ludolphian [4] number could not be a fraction nor the square root of a fraction. Lindemann within the last few years, standing on the shoulders of Hermite, has succeeded in showing that it cannot be the root of any algebraical equation with rational coefficients (see Weierstrass' abridgment of Lindemann's method, *Sitzungsberichte der A.D.W. Berlin*, Dec. 3, 1885).

It had already been shown by M. Servais ("Mathesis," Liège, October 1887), that no one-fold integer or two-fold odd integer could be a perfect number, of which the proof is extremely simple. The proof for three-fold and four-fold numbers will be seen in articles of mine in the course of publication in the *Comptes rendus*, and I have been able also to extend the proof to five-fold numbers. I have also proved that no odd number not divisible by 3 containing less than eight elements can be a perfect number, and see my way to extending the proof to the case of nine elements.

How little had previously been done in this direction is obvious from the fact that, in the paper by M. Servais referred to, the non-existence of three-fold perfect numbers is still considered as problematical; for it contains a "Theorem" that if such form of perfect number exists it must be divisible by fifteen: the ascertained fact, as we now know, being that this hypothetical theorem is the first step in the *reductio ad absurdum* proof of the non-existence of perfect numbers of this sort (see NATURE, December 15, 1887, p. 153, written before I knew of M. Servais' paper, and recent numbers of the *Comptes rendus*).

But after this digression it is time to return to the subject of the numerical divisors of a reduced Fermatian.

We know that it can be separated algebraically into as many irreducible functions as there are divisors in the index (unity not counting as a divisor, but a number being counted as a divisor of itself), so that if the components of the index be a^α, b^β, c^γ, . . . the number of such functions augmented by unity is

$$(\alpha + 1)(\beta + 1)(\lambda + 1). \quad . \quad . \quad . \quad .$$

All but one of these algebraical divisors, with the exception of a single one, will also be a divisor of some other reduced Fermatian with a lower index: that one, the core so to say (or, as it is more commonly called, the irreducible primitive factor), I call a cyclotomic function of the base, or, taken absolutely, a cyclotome whose index is the index of the Fermatian in which it is contained.

It is obvious that the whole infinite number of such cyclotomes form a single infinite complex. Now it is of high importance in the inquiry into the existability of perfect numbers to ascertain under what circumstances the divisors of the same reduced Fermatian, *i.e.* cyclotomes of different indices to the same base can have any, and what, numerical factor in common. For this purpose I distinguish such divisors into superior or external and inferior or internal divisors, the former being greater, and the latter less, than the index.

As regards the superior divisors, the rule is that any one such cannot be other than a unilinear function of the index (I call $kx + 1$ a unilinear function of x, and k the unilinear coefficient) and that a prime number which is a unilinear function of the index will be a divisor of the cyclotome when the base in regard to the index as modulus is congruous to a power of an integer whose exponent is equal to the unilinear coefficient.

As regards the inferior divisors, the case stands thus. If the index is a prime, or the power of a prime, such index will be itself a divisor. If the index is not a prime, or power of a prime, then the only possible internal divisor is the largest element contained in the index, and such element will not be a divisor unless it is a unilinear function of the product of the highest powers of all the other elements contained in the index.

It must be understood that such internal divisor in

[1] Such were the pregnant words recently uttered by the youngest of the splendid triumvirate of Berlin, when challenged to declare if he still held the opinion advanced in his early inaugural thesis (to the effect that mathematic consists exclusively in the setting out of self-evident truths,—in fact, amounts to no more than showing that two and two make four), and maintained unflinchingly by him in the face of the elegant raillery of the late M. Duhamel at a dinner in Paris, where his interrogator—the writer of these lines—was present. This doctoral thesis ought to be capable of being found in the archives of the University (I believe) of Breslau.

[2] The word Fermatian, formed in analogy with the words Hessian, Jacobian, Pfaffian, Bezoutiant, Cayleyan, is derived from the name of Fermat, to whom it owes its existence among recognized algebraical forms.

[3] I find, not without surprise, that some of the theorems here produced, including the one contained in the corrected footnote, have been previously stated by myself in a portion of a paper "On certain Ternary Cubic Form Equations," entitled "Excursus A—On the Divisors of Cyclotomic Functions" (*American Journal of Mathematics*, vol. ii., 1879, p. 357) the contents and almost the existence of which I had forgotten: but the mode of presentation of the theory is different, and I think clearer and more compact here than in the preceding paper; the concluding theorem (which is the important one for the theory of perfect numbers) and the propositions immediately leading up to it in this, are undoubtedly not contained in the previous paper.

I need hardly add that the term *cyclotomic* function is employed to designate the core or primitive factor of a Fermatian, because the resolution into factors of such function, whose index is a given number, is virtually the same problem as to divide a circle into that number of equal parts.

[4] So the Germans wisely name π, after Ludolph van Ceulen, best known to us by his second name, as the calculator of π up to thirty-six places of decimals.

either case only appears in the first power; its square cannot be a divisor of the cyclotome.

It is easy to prove the important theorem that no two cyclotomes to the same base can have any the same *external* divisor.[1]

We thus arrive at a result of great importance for the investigation into the existence or otherwise of perfect odd numbers, which (it being borne in mind that in this theorem the divisors of a number include the number itself, but *not* unity) may be expressed as follows:—

The sum of a geometrical series whose first term is unity and common ratio any positive or negative integer other than $+1$ *or* $1-$ *must contain at least as many distinct prime divisors as the number of its terms contains divisors of all kinds; except when the common ratio is* -2 *or* 2, *and the number of terms is even in the first case, and* 6 *or a multiple of* 6 *in the other, in which cases the number of prime divisors may be one less than in the general case.*[2]

In the theory of odd perfect numbers, the fact that, in every geometrical series which has to be considered, the common ratio (which is an element of the supposed perfect number) is necessarily odd prevents the exceptional case from ever arising.

The establishment of these laws concerning the divisors and mutual relations of cyclotomes, so far as they are new,

[1] The proof of this valuable theorem is extremely simple. It rests on the following principles:—

(1) That any number which is a common measure to two cyclotomes to the same base must divide the Fermatian to that base whose index is their greatest common measure. This theorem need only to be stated for the proof to become apparent.

(2) That any cyclotome is contained in the quotient of a Fermatian of the same index by another Fermatian whose index is an aliquot part of the former one. The truth of this will become apparent on considering the form of the linear factors of a cyclotome.

Suppose now that any prime number, k, is a common measure to two cyclotomes whose indices are PQ, PR respectively, where Q is prime to R, and whose common base is Θ. Then k must measure $\Theta^P - 1$ and also $\dfrac{\Theta^{PQ} - 1}{\Theta^P - 1}$; it will therefore measure Q, and similarly it will measure R; therefore $k = 1$ [unless $Q = 1$ or $R = 1$; for suppose $Q = 1$, then $\dfrac{\Theta^{PQ} - 1}{\Theta^P - 1}$ is unity, and no longer contains the *core* of $\Theta^{PQ} - 1$]. Hence k being contained in R can only be an internal factor to one of the cyclotomes (viz. the one whose index is the greater of the two). [See footnote at end.]

The other theorem preceding this one in the text, and already given in the "Excursus," may be proved as follows:—

Let k, any non-unilinear function of P, the index of cyclotome χ, be a divisor thereto. Then, by Euler's law, there exists some number, μ, such that k divides $x^{\frac{P}{\mu}} - 1$, but the cyclotome is contained algebraically in $\dfrac{x^P - 1}{x^{\frac{P}{\mu}} - 1}$; hence k must be continued in μ, and therefore in P. Also, k will be a divisor of $x^{\frac{P}{k}} - 1$ and of $\dfrac{x^P - 1}{x^{\frac{P}{k}} - 1}$, which contain $x^{\frac{P}{\mu}} - 1$ and χ respectively; consequently, if k is odd, k^2 will not be a divisor of $\dfrac{x^P - 1}{x^{\frac{P}{k}} - 1}$, and *a fortiori* not of χ. [A proof may easily be given applicable to the case of $k = 2$.]

Again, let $P = Qk^i$, where Q does not contain k. Then, by Fermat's theorem, $x^{k^i} \equiv x$ [mod. k]. and therefore k divides $x^Q - 1$; but it is prime to Q. Hence, by what has been shown, k must be an external divisor of this function, and consequently a unilinear function of Q. Thus, it is seen that a cyclotome can have only one internal divisor, for this divisor, as has been shown, must be an element of the index. and a unilinear function of the product of the highest powers of all the other elements which are contained in the index.

For an extension of this law to "cyclotomes of the second order and conjugate species," see the "Excursus," where I find the words *extrinsic* and *intrinsic* are used instead of *external* and *internal*.

[2] A reduced Fermatian obviously may be resolved into as many cyclotomes, less one, as its index contains divisors (unity and the number itself as usual counting among the divisors). But, barring the internal divisors, all these cyclotomes to a given base have been proved to be prime to one another, and, consequently, there must be at least as many distinct prime divisors as there are cyclotomes, except in the very special case where the base and index are such that one at least of the cyclotomes becomes equal to its internal divisor or to unity. It may easily be shown that this case only happens when the base is -2 and the index any even number, or when the base is $+2$ and the index divisible by 6; and that in either of these cases there is only a single unit lost in the inferior limit to the number of the elements in the reduced Fermatian.

has taken its origin in the felt necessity of proving a purely negative and seemingly barren theorem, viz. the non-existence of certain classes of those probably altogether imaginary entities called odd perfect numbers: the moral is obvious, that every genuine effort to arrive at a secure basis even of a negative proposition, whether the object of the pursuit is attained or not, and however unimportant such truth, if it were established, may appear in itself, is not to be regarded as a mere gymnastic effort of the intellect, but is almost certain to bring about the discovery of solid and positive knowledge that might otherwise have remained hidden.[1] J. J. SYLVESTER.

Torquay, February 11.

LORD RAYLEIGH ON THE RELATIVE DENSITIES OF HYDROGEN AND OXYGEN.[2]

THE appearance of Prof. Cooke's important memoir upon the atomic weights of hydrogen and oxygen,[3] induces me to communicate to the Royal Society a notice of the results that I have obtained with respect to the relative *densities* of these gases. My motive for undertaking this investigation, planned in 1882,[4] was the same as that which animated Prof. Cooke—namely, the desire to examine whether the relative atomic weights of the two bodies really deviated from the simple ratio 1 : 16, demanded by Prout's law. For this purpos a knowledge of the densities is not of itself sufficient; but it appeared to me that the other factor involved, viz. the relative atomic *volumes* of the two gases, could be measured with great accuracy by eudiometric methods, and I was aware that Mr. Scott had in view a redetermination of this number, since in great part carried out.[5] If both investigations are conducted with gases under the normal atmospheric conditions as to temperature and pressure, any small departures from the laws of Boyle and Charles will be practically without influence upon the final number representing the ratio of atomic weights.

In weighing the gas the procedure of Regnault was adopted, the working globe being compensated by a similar closed globe of the same external volume, made of the same kind of glass, and of nearly the same weight. In this way the weighings are rendered independent of the atmospheric conditions, and only small weights are required. The weight of the globe used in the experiments here to be described was about 200 grammes, and the contents were about 1800 c.c.

The balance is by Oertling, and readings with successive releasements of the beam and pans, but without removal of the globes, usually agreed to one-tenth of a milligramme. Each recorded weighing is the mean of the results of several releasements.

The balance was situated in a cellar, where temperature was very constant, but at certain times the air currents, described by Prof. Cooke, were very plainly noticeable. The beam left swinging over night would be found still in motion when the weighings were commenced on the following morning. At other times these currents were absent, and the beam would settle down to almost absolute rest. This difference of behaviour was found to depend upon the distribution of temperature at various levels in the rooms. A delicate thermopile with reflecting cones was arranged so that one cone pointed towards the ceiling

[1] Since receiving the revise, I have noticed that it is easy to prove that the algebraical resultant of two cyclotomes to the same base is unity, except when their indices are respectively of the forms $Q(kQ + 1)^h$ and $Q(kQ + 1)^i$, where $(kQ + 1)$ is a prime number, and Q any number (unity *not* excluded), in which case the resultant is $kQ + 1$. This theorem supplies the *raison raisonnée* of the proposition proved otherwise in the first part of the long footnote.

and the other to the floor. When the galvanometer indicated that the ceiling was the warmer, the balance behaved well, and *vice versâ*. The reason is of course that air is stable when the temperature increases upwards, and unstable when heat is communicated below. During the winter months the ground was usually warmer than the rest of the room, and air currents developed themselves in the weighing closet. During the summer the air cooled by contact with the ground remained as a layer below, and the balance was undisturbed.

The principal difference to be noted between my arrangements and those of Prof. Cooke is that in my case no desiccators were used within the weighing closet. The general air of the room was prevented from getting too damp by means of a large blanket, occasionally removed and dried before a fire.[1]

In Regnault's experiments the globe was filled with gas to the atmospheric pressure (determined by an independent barometer), and the temperature was maintained at zero by a bath of ice. The use of ice is no doubt to be recommended in the case of the heavier gases; but it involves a cleaning of the globe, and therefore diminishes somewhat the comparability of the weighings, vacuous and full, on which everything depends. Hydrogen is so light that, except perhaps in the mean of a long series, the error of weighing is likely to be more serious than the uncertainty of temperature. I have therefore contented myself with inclosing the body of the globe during the process of filling in a wooden box, into which passed the bulbs of two thermometers, reading to tenths of a degree centigrade. It seems probable that the mean of the readings represents the temperature of the gas to about one-tenth of a degree, or at any rate that the differences of temperature on various occasions and with various gases will be given to at least this degree of accuracy. Indeed the results obtained with oxygen exclude a greater uncertainty.

Under these conditions the alternate full and empty weighings can be effected with the minimum of interference with the surface of the globe. The stalk and tap were only touched with a glove, and the body of the globe was scarcely touched at all. To make the symmetry as complete as possible, the counterpoising globe was provided with a similar case, and was carried backwards and forwards between the balance room and the laboratory exactly as was necessary for the working globe.

In my earliest experiments (1885) hydrogen and oxygen were prepared simultaneously in a U-shaped voltameter containing dilute sulphuric acid. Since the same quantity of acid can be used indefinitely, I hoped in this way to eliminate all extraneous impurity, and to obtain hydrogen contaminated only by small quantities of oxygen, and *vice versâ*. The final purification of the gases was to be effected by passing them through red-hot tubes, and subsequent desiccation with phosphoric anhydride. In a few trials I did not succeed in obtaining good hydrogen, a result which I was inclined to attribute to the inadequacy of a red heat to effect the combination of the small residue of oxygen.[2] Meeting this difficulty, I abandoned the method for a time, purposing to recur to it after I had obtained experience with the more usual methods of preparing the gases. In this part of the investigation my experience runs nearly parallel with that of Prof. Cooke. The difficulty of getting quit of the dissolved air when, as in the ordinary preparation of hydrogen, the acid is fed in slowly at the time of working, induced me to design an apparatus whose action can be suspended by breaking an external electrical contact. It may be regarded as a Smee cell thoroughly inclosed. Two points of difference may be noted between this apparatus and that of Prof. Cooke. In my mnnner of working it was necessary that the generator should stand an internal vacuum. To guard more thoroughly against the penetration of external air, every cemented joint was completely covered with vaseline, and the vaseline again with water. Again, the zincs were in the form of solid sheets, closely surrounding the platinized plate on which the hydrogen was liberated, and standing in mercury. It was found far better to work these cells by their own electromotive force, without stimulation by an external battery. If the plates are close, and the contact wires thick, the evolution of gas may be made more rapid than is necessary, or indeed desirable.

Tubes, closed by drowned stopcocks, are provided, in order to allow the acid to be renewed without breaking joints; but one charge is sufficient for a set of experiments (three to five fillings), and during the whole of the time occupied (10 to 14 days) there is no access of atmospheric air. The removal of dissolved air (and other volatile impurity) proved, however, not to be so easy as had been expected, even when assisted by repeated exhaustions, with intermittent evolution of hydrogen; and the results often showed a progressive improvement in the hydrogen, even after a somewhat prolonged preliminary treatment. In subsequent experiments greater precautions will be taken.[1] Experience showed that good hydrogen could not thus be obtained from zinc and ordinary "pure" sulphuric acid, or phosphoric acid without the aid of purifying agents. The best results so far have been from sulphuric and hydrochloric acid, when the gas is passed in succession over liquid potash, through powdered corrosive sublimate, and then through powdered caustic potash. All the joints of the purifying tubes are connected by fusion, and a tap separates the damp from the dry side of the apparatus. The latter includes a large and long tube charged with phosphoric anhydride, a cotton-wool filter, a blow-off tube sealed with mercury until the filling is completed, besides the globe itself and the Töppler pump. A detailed description is postponed until the experiments are complete. It may be sufficient to mention that there is but one india-rubber connection—that between the globe and the rest of the apparatus, and that the leakage through this was usually measured by the Töppler before commencing a filling or an evacuation.

The object of giving a considerable capacity to the phosphoric tube was to provide against the danger of a too rapid passage of gas through the purifying tubes at the commencement of a filling. Suppose the gas to be blowing off, all the apparatus except the globe (and the Töppler) being at a pressure somewhat above the atmospheric. The tap between the damp and dry sides is then closed, and that into the globe is opened. The gas which now enters somewhat rapidly is thoroughly dry, having been in good contact with the phosphoric anhydride. In this way the pressure on the dry side is reduced to about 2 inches of mercury, but this residue is sufficient to allow the damp side of the apparatus to be exhausted to a still lower pressure before the tap between the two sides of the apparatus is reopened. When this is done, the first movement of the gas is retrograde; and there is no danger at any stage of imperfect purification. The generator is then re-started until the gas (after from two to five hours) begins to blow off again.

In closing the globe, some precaution is required to secure that the pressure therein shall really be that measured by the barometer. The mercury seal is at some distance from, and at a lower level than, the rest of the apparatus. After removal of the mercury, the flow of gas is continued for about one minute, and then the tap between the dry and damp sides is closed. From three to five minutes more were usually allowed for the com-

[1] I can strongly recommend this method. In twenty-four hours the blanket will frequently absorb two pounds of moisture.

[2] From Prof. Cooke's experience it appears not improbable that the impurity may have been sulphurous acid. Is it certain that in his combustions no hydrogen (towards the close largely diluted with nitrogen) escapes the action of the cupric oxide?

[1] Spectrum analysis appears to be incapable of indicating the presence of comparatively large quantities of nitrogen.

plete establishment of equilibrium before the tap of the globe was turned off. Experiments on oxygen appeared to show that two minutes was sufficient. For measuring the atmospheric pressure, *two* standard mercury barometers were employed.

The evacuations were effected by the Töppler to at least 1/20000, so that the residual gas (at any rate after one filling with hydrogen) could be neglected.

I will now give some examples of actual results. Those in the following tables relate to gas prepared from *sulphuric* acid, with subsequent purification, as already described:—

Globe (14), *empty*.

Date.	Left.	Right.	Balance reading.
1887.			
Oct. 27–Nov. 5	$G_{14}+0{\cdot}394$	G_{11}	22·66
Nov. 7–Nov. 8	—	—	22·89
Nov. 9–Nov. 10	—	—	23·00
Nov. 11–Nov. 12	—	—	21·72

Globe (14), *full*.

Date.	Left.	Right.	Balance reading.	Barometer.	Temperature.
1887.				in.	°C.
Nov. 5–7 ...	$G_{14}+0{\cdot}2400$	G_{11}	20·52	29·416	14·7
Nov. 8–9 ...	$G_{14}+0{\cdot}2364$	G_{11}	19·77	29·830	12·3
Nov. 10–11...	$G_{14}+0{\cdot}2360$	G_{11}	19·18	22·807	11·2
Nov. 12–14...	$G_{14}+0{\cdot}2340$	G_{11}	29·51	30·135	10·3

The second column shows that globe (14) and certain platinum weights were suspended from the left end of the beam, and the third column that (in this series) only the counterpoising globe (11) was hung from the right end. The fourth column gives the mean balance reading in divisions of the scale, each of which (at the time of the above experiments) represented 0·000187 gramme. The degree of agreement of these numbers in the first part of the table gives an idea of the errors due to the balance, and to uncertainties in the condition of the exteriors of the globes. A minute and unsystematic correction depending upon imperfect compensation of volumes (to the extent of about 2 cubic centimetres) need not here be regarded.

The weight of the hydrogen at each filling is deduced, whenever possible, by comparison of the "full" reading with the mean of the immediately preceding and following "empty" readings. The difference, interpreted in grammes, is taken provisionally as the weight of the gas. Thus, for the filling of Nov. 5—

$$H = 0{\cdot}154 - 2{\cdot}25 \times 0{\cdot}000187 = 0{\cdot}15358.$$

The weights thus obtained depend of course upon the temperature and pressure at the time of filling. Reduced to correspond with a temperature of 12°, and to a barometric height of 30 inches (but without a minute correction for varying temperature of the mercury) they stand thus—

November	5	0·15811
,,	8	0·15807
,,	10	0·15798
,,	12	0·15792
	Mean ...	0·15802

The hydrogen obtained hitherto with similar apparatus and purifying tubes from hydrochloric acid is not quite so light, the mean of two accordant series being 0·15812.

The weighing of oxygen is of course a much easier operation than in the case of hydrogen. The gas was prepared from chlorate of potash, and from a mixture of the chlorates of potash and soda. The discrepancies between the individual weighings were no more than might fairly be attributed to thermometric and manometric errors. The result reduced so as to correspond in all respects with the numbers for hydrogen is 2·5186.[1]

But before these numbers can be compared, with the object of obtaining the relative densities, a correction of some importance is required, which appears to have been overlooked by Prof. Cooke, as it was by Regnault. The weight of the gas is *not* to be found by merely taking the difference of the full and empty weighings, unless indeed the weighings are conducted *in vacuo*. The external volume of the globe is larger when it is full than when it is empty, and the weight of the air corresponding to this difference of volume must be *added* to the apparent weight of the gas.

By filling the globe with carefully boiled water, it is not difficult to determine experimentally the expansion per atmosphere. In the case of globe (14) it appears that under normal atmospheric conditions the quantity to be added to the apparent weights of the hydrogen and oxygen is 0·00056 gramme.

The actually observed alteration of volume (regard being had to the compressibility of water) agrees very nearly with an *a priori* estimate, founded upon the theory of thin spherical elastic shells and the known properties of glass. The proportional value of the required correction, in my case about 4/1000 of the weight of the hydrogen, will be for spherical globes proportional to a/t, where a is the radius of the globe, and t the thickness of the shell, or to V/W, if V be the contents, and W the weight of the glass. This ratio is nearly the same for Prof. Cooke's globe and for mine; but the much greater departure of his globe from the spherical form may increase the amount of the correction which ought to be introduced.

In the estimates now to be given, which must be regarded as provisional, the apparent weight of the hydrogen is taken at 0·15804, so that the real weight is 0·15860. The weight of the same volume of oxygen under the same conditions is $2{\cdot}5186 + 0{\cdot}0006 = 2{\cdot}5192$. The ratio of these numbers is 15·884.

The ratio of densities found by Regnault was 15·964, but the greater part of the difference may well be accounted for by the omission of the correction just now considered.

In order to interpret our result as a ratio of atomic weights, we need to know accurately the ratio of atomic volumes. The number given as most probable by Mr. Scott, in May 1887,[2] was 1·994, but he informs me that more recent experiments under improved conditions give 1·9965. Combining this with the ratio of densities, we obtain as the ratio of atomic weights—

$$\frac{2 \times 15{\cdot}884}{1{\cdot}9965} = 15{\cdot}912.$$

It is not improbable that experiments conducted on the same lines, but with still greater precautions, may raise the final number by one or even two thousandths of its value.

The ratio obtained by Prof. Cooke is 15·953; but the difference between this number and that above obtained may be more than accounted for, if I am right in my suggestion that his gas weighings require correction for the diminished buoyancy of the globe when the internal pressure is removed.

[1] An examination of the weights revealed no error worth taking into account at present.

[2] *Loc cit.*

NOTES.

The Woolwich Examinations question, to the importance of which we again direct attention in our first article to-day, is not to be allowed to lapse. Three or four Members of Parliament who are interested in science mean to press the Government for some rational change in the rules.

In accordance with the rule which empowers the election of nine persons annually "of distinguished eminence in science, literature, or the arts, or for public services," Dr. Lauder Brunton, F.R.S., has been elected a member of the Athenæum Club.

The extraordinary interest and value of the botanical collections made by Signor Odoardo Beccari during a residence of several years in the Malay Archipelago, and especially in Borneo, are well known to naturalists. For some time past Signor Beccari has been occupied at Florence with the publication of his results in the work with which botanists, whether systematists or morphologists, are familiar under the name of *Malesia*. Owing to the threatened withdrawal of the modest support which the Italian Government have extended to this publication (his collections having been acquired by the State), there is some reason to fear that it may come to an abrupt termination. Under these circumstances the Bentham Trustees have placed at Signor Beccari's disposal the sum of 1000 francs, which they were informed would secure the continuance of the work for one year. In accepting this support Signor Beccari has informed the Trustees that he hesitates the less to do so as it affords the strongest possible proof of the estimation in which his labours are held in the botanical world generally.

Prof. Isaac Bayley Balfour, of the University of Oxford, has been elected Professor of Botany at the University of Edinburgh in the room of the late Prof. Dickson. Prof. Bayley Balfour is the son of the late Prof. Balfour, Prof. Dickson's predecessor in the Chair.

M. T. Ribot has been appointed to the new Chair of Experimental and Comparative Psychology, founded by the Paris Municipal Council at the Collège de France.

Dr. F. L. Patton succeeds Dr. McCosh as the President of Princeton College. *Science* says:—"Dr. Patton is still a young man, being but forty-five years of age, and has yet to put forth to their fullest extent his marvellous intellectual powers. We seriously question whether any College has a President of so high an intellectual stamp as Dr. Patton."

Mr. Griesbach, the well-known geologist to the Afghan Boundary Commission, and Deputy-Superintendent of the Geological Survey of India, has been permitted to take employment under the Ameer of Afghanistan for the purpose of developing the mineral resources of the country.

Mr. H. O. Forbes has just arrived in England from New Guinea. Mr. Forbes succeeded in reaching the foot of the Owen Stanley range, after the very greatest difficulties owing to the broken nature of the country. When he returned to his camp to make the necessary arrangements for ascending the range, he found it had been attacked and his people dispersed by the natives. He had the greatest difficulty in reaching the coast, and narrowly escaped with his life.

M. Edouard Dupont, Director of the Brussels Natural History Museum, has just returned to Belgium, after an absence of eight months for the purpose of visiting the Congo. M. Dupont has made a very careful study of the region between the coast and the mouth of the Kassai, with a special view to its geology and natural history. The detailed results he will shortly communicate to the Brussels Societies.

The Rev. W. H. Dallinger, F.R.S., will on Thursday next (March 8) begin a course of three lectures at the Royal Institution, on microscopical work with recent lenses on the least and simplest forms of life.

The *Times* understands that King's and University Colleges have been informed that the Privy Council will hear them at some date after April 16 next in support of their joint petition for incorporation as the nucleus of a Teaching University for London. The Privy Council have further desired that, as the petition of the two Colleges appears to be substantially at one with that of the Teaching University Association, the Colleges should present a joint case with that Association not later than March 31.

A deputation from the School Boards of England and Wales had an interview last week with Lord Cranbrook and Sir W. Hart Dyke, to press upon their attention some considerations with regard to technical instruction. In the course of his reply to the various statements made, Lord Cranbrook said that the Technical Instruction Bill would be introduced as soon as possible. The Government, he assured the deputation, fully intended, if possible, to pass the measure, and he ventured to ask those who were interested in it, if they did not get all that they required, to be content with a beginning, and not be too anxious to press extreme conclusions which might raise opposition that did not at present exist.

M. Pasteur, having entered the lists as a competitor for the reward of £25,000 offered by the Government of New South Wales for exterminating the superabundant rabbits, has sent three delegates with a supply of "*microbes du choléra des poules*," with which he hopes to win the prize. Whatever may be thought of this particular remedy, there can be no doubt as to the serious nature of the plague of rabbits in Australia. During last August the rabbit inspectors travelled 20,202 miles and destroyed 2,069,128 rabbit scalps, and from January 1 to August 1 they destroyed 10,538,778 rabbit scalps. The New South Wales Parliament lately provided funds for the making of a rabbit-proof fence from Bourke to the Queensland border.

The earthquake which caused so much alarm at Grenada on the 10th ult. was felt in many parts of the West Indies. There were oscillations at Barbados, St. Lucia, St. Vincent, Grenada, Demerara, and Trinidad, and it is said that in many places much damage was done to house property. The earthquake was also felt on the other side of the Gulf of Paria. In Guiria three houses were destroyed and the earth opened in chasms and closed again. At Yrapa the shock was so severe that a terrified old woman threw herself into the sea and was drowned.

About midnight on January 15 a shock of earthquake was felt by a party of five persons on the road four kilometres west of Trysil Church in Central Norway. The shock was accompanied by a dull rumbling noise like that of a heavy cart passing across a bridge.

On the night of January 5 showers of ashes fell in certain parts of Elverum in Central Norway, in some places making the snow quite gray. It is surmised that the fall may have been connected with some volcanic eruption in Iceland, as has formerly been the case in this locality.

According to the *Panama Star and Herald* a huge wave lately struck the beach at Baraçoa, Cuba. After sweeping in fully 400 feet, it flowed back to the ocean. Nearly 300 huts and houses are said to have been destroyed, but no lives were lost, for the people saw the wave coming and fled to the hills. The beach was swept clear of every habitation that stood upon it. The wave was not a tidal wave, but the result of a three days' north wind.

M. L. TEISSERENC DE BORT discusses, in the *Annales* of the French Central Meteorological Office for 1885, part iv. (Paris, 1887), the importance of the high barometric pressures of Asia for weather forecasts over Europe. The paper deals with various types of isobars existing simultaneously over Asia and Europe, illustrated by charts. The result arrived at is that European offices would derive great advantage from daily telegrams from Asia, especially from the stations already in existence in Siberia which report to St. Petersburg by wire. Hitherto the idea has generally prevailed that the movements of the atmosphere from the westward were alone useful for the prediction of weather changes over Europe.

THE Austrian Meteorological Office has just published its *Jahrbuch* for 1886. The service was established in 1847, and the first volume contained observations for 1848–49. The new series of volumes, of which the present is the twenty-third, began with the year 1864. The stations now number 380, including three abroad, and are closer together than in any other of the larger systems; there are no less than nine stations in Vienna alone. Daily observations are published for eighteen stations; for all the others monthly and yearly *résumés* are given. The Hungarian observations are published in a separate volume.

THE *Pioneer* of Allahabad mentions a circumstance connected with two recent cyclonic storms which is worthy of the attention of meteorologists. These storms struck the Scinde desert between January 24 and 30, and passed in a straight line across the continent to Cuttack at the rate of 250 to 300 miles daily. The second continued unbroken across the Bay of Bengal to Burmah. If the line they followed were prolonged straight westward it would reach Vienna, which is about 3600 miles from Scinde. There seems (says the *Pioneer*) to have been an unusually violent atmospheric disturbance in Vienna in the early part of January, so the time and the rate of travelling would agree with the assumption that the storms were identical with that disturbance.

Two remarkable new fluorides of potassium have been discovered by M. Moissan, the isolater of fluorine. Hydrofluoric acid is well-known to be readily capable of combining with neutral fluorides to form fluorhydrates similar to that of potassium, KF . HF; indeed it was by the use of this latter compound that fluorine was eventually so successfully obtained in the free state. Moreover, the formation of such compounds has been completely accounted for by the vapour-density determinations of Kletzinsky and Mallet, who have shown that the composition of the molecule of hydrofluoric acid just above its boiling-point is H_2F_2. But M. Moissan now shows that this double fluoride of potassium is by no means the only one, that two others, KF . 2HF and KF . 3HF may be readily obtained in well-formed crystals. When dry powdered KF . HF is placed in anhydrous hydrofluoric acid, it disappears almost instantaneously, the liquid becoming sensibly warm; in fact, M. Moissan in a few moments dissolved five to six grammes in ten grammes of the acid. On cooling this mixture to −23° C. white crystals separated out; these were rapidly dried between filter paper, transferred to a platinum tube closed by a paraffined cork, weighed and analyzed. The results of the analyses indicated the composition KF . 3HF. The compound was then synthetically prepared by mixing potassium fluoride and the acid in these proportions, evading any sudden rise of temperature; the liquid was subsequently warmed to 85° in a platinum capsule, but not a trace of hydrofluoric acid vapour escaped, although that substance boils at 19°. Hence it was evident that the HF was locked up in chemical combination, and this was soon observed to be the case, for on removing the source of heat, crystals began to form even while the thermometer indicated 68°; on resuming the ordinary temperature of the room, the whole became a mass of interlaced crystals, which analysis proved to be those of KF . 3HF. These crystals are extremely deliquescent, being decomposed by water into the free acid and potassium fluoride, emitting the acid fumes in a humid atmosphere, and dissolving in water with production of the most intense cold. If they are suddenly heated with crystalline silicon, the mass becomes incandescent, and a violent disengagement of silicon tetrafluoride gas occurs. The stability of this fluorhydrate was strikingly shown by placing a few crystals *in vacuo*, when even after two hours the manometer only showed a difference of 0·01 m. In a somewhat similar manner the compound KF . 2HF was isolated and found to be a liquid at 105°, but crystallizing in the cold. It is to the formation of these fluorhydrates that M. Moissan attributes the preservation of his fluorine-isolating apparatus, and the regular evolution of gaseous fluorine during the electrolysis.

DURING the last two or three years an extensive search for natural gas has been made in the United States. In a paper on the subject, just issued by the U.S. Geological Survey, Mr. J. D. Weeks says the results of this exploration indicate:—(1) That along the Atlantic coast, east of the Appalachian Chain, including in this term the Green Mountains, no gas is found, or, if found at all, in such small quantities as to indicate that it is of comparatively recent origin. It is also found in such horizons, and under such conditions, as to give but little evidence that it is in such storage reservoirs as to promise any considerable supply. (2) That the chief sources of the supply of natural gas in the United States are to be found in the Mississippi Valley, and, so far as present explorations show, in that portion of it east of the Mississippi River. The chief localities that had assumed any prominence as gas-centres at the close of 1886 were in South-Western New York, Western Pennsylvania, North-Western Ohio, and Central Eastern Indiana. To these may be added a locality in Michigan and one in Eastern Kansas.

IN the report of the U.S. Commission of Education for the year 1885–86, just issued, it is stated that seldom in the history of the United States have superior institutions of learning occupied so large a share of public attention or given signs of such vigorous and fruitful life as at the present time. Among these institutions are classed schools of science, pure and applied, which, according to the writer of the report, "have greatly increased the provision for superior instruction, extended its province, and borne an important part in the adjustment of its processes to the demands arising from the extraordinary increase of scientific knowledge and its applications to the leading industries of modern times."

WE have received the annual address to the Asiatic Society, Calcutta, delivered by the President, Mr. E. T. Atkinson. Speaking of the Survey of India, Mr. Atkinson says that most of the operations connected with it during the past year have been devoted to remunerative as distinguished from purely scientific investigation. In many districts the survey has been cadastral with a record of rights. The Baluchistan parties have done a considerable amount of large-scale work around Quetta and towards the Khwajah Amran range, and are now engaged on the half-inch survey of that province. The Himalayan party has been working under Colonel Tanner towards Kulu, and the Andaman party has completed the survey of the coasts of the Nicobars.

WE have received the "Geological Record for 1879," containing an account of works on geology, mineralogy, and palæontology, published during the year, with supplements for 1874–78. The volume is edited by Mr. Whitaker and Mr. W. H. Dalton, and published by Messrs. Taylor and Francis. In the preface Mr. Whitaker explains that as the position of editor of the "Geological Record" has proved to be one that can be held only with great

difficulty by a busy man who does not live in London, it has been taken over by Mr. Topley. The "Record" is to be brought up to date by giving the titles only of papers, &c., for the years 1880 to 1887. The portion for 1880 to 1884 is finished, and in great part printed; and so large is the amount of geological literature that in this contracted form (without abstracts) two volumes will be needed for the five years.

RECENT Shanghai papers contain the report of the "Chinese Scientific Book Depot," an institution which was established three years ago for the purpose of facilitating the spread of all useful literature in the native language throughout China, and especially of books, maps, and other publications of a scientific or technical character. It does not publish works, but has merely organized a system by which the translations and compilations on scientific subjects issued by the various Departments of the Chinese central and local Governments, by missionary and other philanthropic Societies, are more widely distributed amongst the Chinese people. The demand for such books is fast increasing, and the establishment of the central depot, with branches at the more important cities, suggested itself three years since. Self-support has been the motto of the institution, and, in order to overcome Chinese prejudices, everything smacking of foreign influence has been eliminated as far as possible. During the second year a branch was opened at Tientsin, and subsequently Hangchow, Swatow, Pekin, Hankow, Foochow, and Amoy were similarly provided. During the three years about £2500 worth of books, maps, &c., have been sold, some of them finding their way to the most distant parts of China, Corea, and Japan. Taking the average price per volume at 4*d.* to 5*d.*, this would give a circulation of about 150,000 volumes of useful literature, chiefly of a scientific and educational character. The shops have also served to some extent as reading-rooms, where inquirers after Western knowledge have been able to sit down and examine any works in which they felt interested. The number of scientific and other treatises already translated or compiled and published in Chinese under foreign management amounts at present to over 200. To these have been added about 250 of the most useful native works, including scientific treatises by the early Jesuit fathers.

SIR EDWARD BIRKBECK, President of the National Sea Fisheries Protection Association, is now promoting in Parliament a Bill, the object of which is to secure reasonably cheap and rapid transport for common kinds of sea fish, in quantities of 1 cwt. and upwards, from the coast to the various inland centres of population, and thus, by securing a plentiful distribution, to render an ine timable benefit alike to the poor of our inland towns and villages and the fishermen of our coast. The Bill does not attempt to interfere with the rates now charged by railway companies for prime fish, nor with quantities of less than 1 cwt. of common fish. Sir Edward Birkbeck should have no great difficulty in securing sufficient support for so moderate and good a measure.

DR. F. NANSEN, of the Bergen Museum, Norway, who thinks of journeying across Greenland next summer from east to west, intends to land on the east coast at Cape Dan (66° N.), and proceed in a north-westerly direction to Disco Bay. He will be accompanied by three men—a Norwegian soldier well known for his prowess on *Ski*, or snow-runners, and two Lapps, probably the same who accompanied Nordenskiöld. In order to qualify himself for the contemplated task, Dr. Nansen is preparing to travel on *Ski* from Bergen to Christiania, right across the mountains of Central Norway, a feat never before accomplished by anyone.

THE additions to the Zoological Society's Gardens during the past week include an African Civet Cat (*Viverra civetta*) from South Africa, presented by Capt. Webster, R.M.S. *Hawarden Castle*; three Barred Doves (*Geopelia striata*) from Batavia, Java, presented by Mrs. G. A. Thomson; a Cape Crowned Crane (*Balearica chrysopelargus*) from South Africa; a Gold Pheasant (*Thaumalea picta*) from China, deposited; a Common Wolf (*Canis lupus* ♀) European, received in exchange; two Red Kangaroos (*Macropus rufus*), two Suricates (*Suricata tetradactyla*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SOLAR ACTIVITY IN 1887.—The decline in the three orders of solar phenomena, spots, faculæ, and prominences which had been so marked during 1886, and particularly during the latter part of that year, continued in 1887, and although there was no spotless period so long continued as that of November 1886 (see NATURE, vol. xxxv. p. 445), the mean spotted area for the year just passed has been much below that for the year preceding it, and faculæ and prominences have shown a similar falling off. During the first four months of 1887, sunspots were both few and small, and there were several intervals of a week or longer in which no spots were seen at all; January 9–18, February 7–16, March 3–9, April 4–11, being such intervals. There was also very little on the sun from March 10–15, and from March 27 to April 18. But after this a revival set in and a fine group of spots was seen on the sun, May 14–23, appearing again in the three following rotations, June 5–18, July 3–14, and July 30–August 9. The days of greatest spotted area during the year were July 6, 7, and 8, but after this the spots began to decrease again, and were few and small in September, October, and November. August 23 to September 12 was a very quiet period, spots only being seen on about four days; and October 6–17, October 28 to November 4, and November 21 to December 1, were spotless intervals. The last month of the year, however, showed a second rally, a fine group of spots being observed during its first fortnight, and another appearing as the first passed off at the west limb. On the whole the mean daily spotted area for 1887 was about two-fifths of that which it was for 1886. Comparing the results for 1885, 1886, and 1887, with the years preceding the last minimum, 1885 shows a somewhat greater mean daily spotted area than 1874, 1886 than 1875, and 1887 than 1876. If, therefore, the decline continues to proceed as during the last cycle, the next minimum will fall early in 1890.

The following figures, taken from Prof. Tacchini's tables, as given in the *Comptes rendus*, may be compared with those given for 1885 and 1886 (NATURE, vol. xxxiii. p. 398, and xxxv. p. 445):—

	Sunspots.			Faculæ.
	Relative Frequence.	Relative Size.	Mean Daily Number of Groups.	Relative Size.
January	2·87	9·35	1·17	11·52
February	3·35	7·83	1·32	10·09
March	1·00	3·35	0·42	16·00
April	1·12	7·76	0·68	6·80
May	4·18	22·04	1·11	9·29
June	4·15	29·74	1·37	20·37
July	5·07	25·25	1·68	14·11
August	4·60	23·53	1·32	14·29
September	2·47	15·75	0·56	9·23
October	1·27	20·21	0·70	10·53
November	1·70	6·41	0·71	17·30
December	6·68	40·10	1·21	16·84

In general accord with the above figures are Wolf's "relative numbers." These are given below for 1886 and 1887, together with the monthly means of the variations in magnetic declination as observed at Milan. The agreement in the general form of the curves for spot numbers and magnetic variation has not been so close in 1887 as in some previous years, nor is the calculated mean value for the magnetic variation so near the observed as in 1885 and 1886; the values calculated by M. Wolf's formula being 6'·79 for 1886, and 6'·21 for 1887, but the observed being 6'·72 and 6'·61.

	Wolf's Relative Numbers (Zürich). 1886	1887	Variation in Magnetic Declination (Milan). 1886	1887
January	28·4	13·1	4·07	3·71
February	23·6	15·7	4·91	3·69

The fluctuations in the numbers and dimensions of the prominences have not been so great as for the spots, but the prominences likewise showed a maximum in July and a decline afterwards. The highest prominence observed by Prof. Tacchini during the year was on July 2, 2½′ in height. Both faculæ and prominences failed to show a depression similar to that so conspicuous in November in the numbers of the spots, or the revival these displayed in December, the faculæ thus according in their behaviour rather with the prominences than with the spots. The following figures, given by the Rev. S. J. Perry in the *Observatory* for February 1888, show the general decline in prominence activity during 1887, as compared with 1886:—

	Mean Height of Chromosphere. ″	Mean Height of Prominences. ″	Mean Extent of Prominence Arc. °
1886	8·05	24·78	13·26
1887	8·13	23·86	9·29

A NEW COMET.—A comet was discovered by Sawerthal on February 18. It was observed at Cape Town, February 18, 14h. 32·5m., in R.A. 19h. 11m. 32·5s., and N.P.D. 146° 3′ 44″. Daily motion, R.A. + 7m.; N.P.D. − 1° 15′. Its physical appearance was as follows:—It was about the seventh magnitude, had a well-defined nucleus, and a tail a degree in length. It was visible to the naked eye.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 MARCH 4–10.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 4

Sun rises, 6h. 40m.; souths, 12h. 11m. 45·0s.; sets, 17h. 44m.: right asc. on meridian, 23h. 2·5m.; decl. 6° 9′ S. Sidereal Time at Sunset, 4h. 36m.

Moon (Last Quarter on March 5, 3h.) rises, 0h. 26m.; souths, 5h. 14m.; sets, 9h. 54m.: right asc. on meridian, 16h. 3·8m.; decl. 15° 53′ S.

THE RELATIONS BETWEEN GEOLOGY AND THE BIOLOGICAL SCIENCES.[1]

II.

IN the remarks which I have hitherto made, I have confined myself to the purely biological aspects of palæontology. As astronomy exhibits to us the orderly working of physical and chemical laws in other and far distant orbs, so palæontology presents us with the biological phenomena of many and widely-separated periods.

But besides the biological, there are two other aspects in which fossils may be viewed; and in these aspects their relations are almost entirely with zoological science. It is the recognition of this fact which prevents the geologist from acquiescing with the claims of biologists to treat palæontology as nothing more than a branch of their own science.

The assemblage of fossils found in a particular deposit furnishes us with the most valuable evidence concerning the conditions—such as salinity of water, depth, temperature, pressure, &c.,—under which the deposit must have been formed. And, again, in the changes which the materials of fossils can be shown to have undergone we have very accurate data for determining the succession of processes to which the materials of the deposit must have been subjected since their original accumulation.

It is true that this evidence of fossils concerning the conditions under which deposits have been formed, is of a kind which has been sadly misread in the past. Until the study of deposits which are being formed at the present day was taken up in a systematic manner, it was almost hopeless to avoid numerous sources of error; but at the present day the advantages accruing to geology from the results of deep-sea researches, are at least as great as those which by the same means have been conferred upon biology.

It is almost needless to call attention to the fact that there are vast masses of rock, including most of the calcareous and carbonaceous, and many of the siliceous and ferruginous types, of which the materials have been accumulated entirely by the agency of living organisms; it is impossible to study the petrology of such deposits without an acquaintance with the nature and functions

[1] Address to the Geological Society by the President, Prof. John W. Judd, F.R.S., at the Anniversary Meeting, on February 17. Continued from p. 404.

of the organisms by which they were formed. But, even in the case of many arenaceous and argillaceous deposits, living organisms have played a very important part in their formation. Much of the materials of such rocks can be shown to have been used in building the coverings of organisms, to have filled up their dead shells, or to have been passed through their bodies, before being finally buried under other masses. Rocks destitute of all traces of the solid parts of animals often abound with worm-tracks, burrows, or casts.

The study of the processes by which similar rock masses are being formed at the present day constitutes the only safe guide to us in interpreting the structures presented by ancient rock-masses. Geologists look forward with much interest to the publication of those volumes of the *Challenger* Reports, in which Mr. Murray and M. Renard will deal with these important questions.

We may especially call attention to two classes of errors that have had much to do with the false conclusions which have been arrived at concerning the conditions under which various deposits have been formed in past geological times.

In the first place, it has been tacitly assumed that all marine organisms which come from regions bordering the equator must necessarily have lived under tropical conditions. It would be quite as reasonable to treat the mosses and dwarf willows which border the eternal snows of Chimborazo and Kilima-Njaro as tropical plants. Just as mountains rising in equatorial lands to the limit of perpetual snow exhibit on their slopes every gradation of climate from tropical to frigid, so the depths of the oceans, as we now know, exhibit a perfectly similar transition. As we go downwards not only heat, but light also, rapidly diminishes, and many forms which, because they came from equatorial regions, we have hitherto regarded as tropical, we now know to live in icy-cold water as well as in almost utter darkness.

The large size and abundant development of Cephalopods, Crustaceans, and fish we now know, from recent deep-sea researches, to be no evidence whatever of the presence either of warmth or of light; and Sir Joseph Hooker has abundantly shown the fallacy of similar reasoning when applied to plant-life. I feel sure that, when the full consequences of these important considerations come to be appreciated, the apparent anomalies of many of the supposed climatal conditions of past geological times will altogether disappear. For my own part, I have never felt any difficulty in accepting, as fully equal to the explanation of the facts of the case, the Lyellian doctrine of climate being determined by great changes in the relative positions of the land and water of the globe.

The other cause of misconception with respect to the conditions which must have prevailed during the deposition of geological deposits consists in the acceptance of an utterly false proposition, which, though seldom formulated, is often tacitly acted upon; namely, "If two organisms exhibit similarity of structure, their environment must have been the same."

There never has been wanting abundant evidence of the fallacy of this doctrine. The general structure of the piscivorous bear of the Arctic regions, and of the frugivorous bear of the Malay peninsula, the osteology of the deer of Lapland and of India respectively, exhibit no such differences as would lead us to infer their diversity of habits and surroundings. It has long been known that elephants, rhinoceroses, and hippopotami, with lions, tigers, and hyænas, flourished under Arctic conditions. The deep-sea researches have so added to our knowledge concerning the conditions under which different forms of life exist—especially those belonging to marine faunas—as to demand a complete reconsideration of the conclusions usually accepted by geologists. For there is a general consensus of opinion among the naturalists who have studied the different groups of the deep-sea faunas, that, contrary to what might have been anticipated from the very remarkable conditions under which they live, the deep-sea forms belong, for the most part, to the same families, and often indeed to the same genera, as shallow-water forms.

The bearing of this important conclusion upon the great problem of the distribution of marine forms of life is obvious. Botanists have naturally availed themselves of the proved occurrences of colder climates in many areas to explain difficult facts of plant-distribution, such as the occurrence of well-known Arctic species on the tops of mountains in what are now temperate, or even tropical, districts. But zoologists, now that they know it to be possible for littoral forms to stray into abysmal portions of the ocean, and then subsequently, without profound modification, to re-emerge in other littoral areas, may find a clue to some very remarkable facts concerning the distribution of marine forms of life, without having to resort to explanations which seem necessary in the case of the terrestrial forms of life which appear to be more dependent than the marine types on the circumstances of their environment.

The whole problem of the distribution of marine forms of life requires indeed to be worked out afresh on the basis of these new discoveries; and when this is done, the first to profit by the new generalizations will be geologists, who have long been confronted by seemingly insuperable difficulties in connection with this problem.

As for the very prevalent notions that Ammonites and Belemnites, Trigoniæ and Brachiopods, with Ichthyosaurs, Pliosaurs, and Plesiosaurs, could only have lived in warm, if not actually tropical, climates, I know of no grounds whatever for any such belief. The nearest living allies of the invertebrates referred to flourish at considerable depths in icy-cold water; and, seeing that large marine mammals now live amid snow and ice, I cannot understand why the great marine reptiles might not have done the same. Just as little reason is there for inferring that Sigillarids, Lepidodendrids, and Calamites could only have lived in tropical jungles, as there is for the once popular notion that they flourished in an atmosphere supplied with a very exceptional proportion of carbonic acid!

The sooner geologists recognize the fact that all our ideas concerning the distribution of the forms of marine life have been completely revolutionized by the discovery that there are cold and dark abysses, which are tenanted by numerous organisms having many affinities with those which live in shallow water, warmed by a tropical sun and flooded with light, the more likely will they be to avoid the errors into which we have fallen in the past. Not until the exact distribution of life-forms at different depths in the ocean has been much more perfectly worked out than it has been at present, will it be safe to reason with any confidence concerning the distribution of extinct types; and, even then, we shall ever have to be on our guard against the prevalent fallacy which assumes that analogies in structure are indicative of similarities in the conditions of life.

And here it may be remarked that the imperfect methods employed on board the *Challenger* and most other surveying ships leave almost everything yet to be done in the way of determining the limits of depth, temperature, pressure, and other conditions under which the different forms of marine life can flourish. It is much to have obtained so great an insight into the characters of some of the creatures inhabiting the deepest parts of the ocean, and of the peculiar conditions which must exist in some of those places where marine life is abundant. But the work which has yet to be done requires the employment of dredges and nets which can be opened when they have reached a certain depth in the ocean, and which can be closed again before being drawn to the surface. Only by the employment of such apparatus can we hope to avoid those sources of error which vitiate all our present generalizations concerning the bathymetrical distribution of the existing forms of marine life.

When, in addition to these biological studies, we have equally careful determinations of the physical characters of deposits formed at varying depths and distances from the shore, and under diverse influences of tides and currents, we may hope, by combining the physical and biological evidence, to arrive at something like certain conclusions concerning the exact conditions under which various geological formations have been accumulated; for at present our speculations upon the subject are often little better than haphazard guesses.

The conditions which must have prevailed during the deposition of a particular bed having been determined, the present mineral condition of the organic remains becomes a subject of very interesting study; for here we may find a clue which will enable us to unravel the series of physical and chemical changes which must have gone on in the mass, since the first accumulation of its materials. In cases of difficulty of this kind, the condition of alteration of a shell or bone, of which the original composition is known, becomes an especially valuable piece of evidence.

I am convinced that the future progress of geological thought is closely bound up with the increase of our knowledge concerning the conditions under which the various forms of marine life flourish, and under which their remains become embedded in sedimentary deposits; though what has been already accomplished in this direction, it must be admitted, is but small, and much of it will have to be done over again.

We hear much—far too much, as I think—at the present day of an "irrational uniformitarianism." Is not the real source of danger in an exactly opposite direction? Does not the irrationality characterize him who, without attempting to obtain a more complete knowledge of the processes going on during the original deposition and subsequent changes of rock-masses, is ready, as each new difficulty presents itself, to fall back upon some old discredited *Deus ex machinâ* in the form of deluges of water, floods of fire, boiling oceans, caustic rains, or acid-laden atmospheres!

Considering how little we as yet know of many of the conditions under which deposits are being formed at the present day, and remembering how large a part of the little we do know has been acquired only within the last few years, we might pause before declaring that the path upon which geology entered in earnest only some fifty years ago is a wrong one, and that the sooner we begin to retrace our steps the better.

Can we even now be in danger of forgetting that "Slough of Despond," wherein the geologist, laden with a grievous burden of traditional assumptions and irrational theories, so hopelessly floundered, till one Help pointed out a way of escape, and sent him on his way rejoicing, with the "Principles of Geology" in his hand?

The second aspect in which palæontological science presents itself to the geologist, is as affording a key to the chronology of the rock-masses of the globe. We still regard fossils as the "medals of creation," and certain types of life we take to be as truly characteristic of definite periods as the coins which bear the image and superscription of a Roman emperor or of a Saxon king.

But in the application of the principle that "strata are to be identified by their organic remains," we have now to admit as many limitations, and to exercise as much caution, as when judging of the conditions under which rock-masses must have been deposited, from the characters of the fossils which they contain.

With the restricted area of the south-west of England, where William Smith achieved his epoch-making discovery, the doctrine which he announced seemed to be absolutely true; each formation exhibited a peculiar and perfectly characteristic assemblage of organic remains, by means of which it could at once be recognized. The still more detailed studies of strata of the same age, by Hunton and Williamson in Yorkshire, by Marcou in the Jura, and by Quenstedt in Swabia, seemed to show that the principle had a wider application than even its author himself could have imagined, and that zones a few feet or even inches in thickness might be followed over considerable districts; everywhere marked by some particular type of Ammonite or other characteristic fossil.

But the more thorough and systematic study of corresponding formations over wide areas, which was inaugurated by Oppel, and has been carried on by many palæontologists since, has abundantly demonstrated that, striking as is the parallelism of the zones in such a formation as the Lias, when studied in England, France, and Germany, yet the species and varieties found on the same horizon at distant points are in many cases not identical, but merely representative; and, further, that as we pass away from any typical area, the sharp distinction between the several zones seems gradually to vanish.

The same facts come out very strikingly when we study any other great geological period. In the oldest fossiliferous strata, those of the Cambrian, nothing can be more striking than the similarity of the faunas in North America, Britain, Scandinavia, and Bohemia; and yet the species which occur at the several different horizons in these countries are certainly, for the most part, not identical, but only representative. No fact, it seems to me, could more clearly indicate that, even at that early period, there were life-provinces with a distribution of organisms in space quite analogous to that which exists at the present day.

To pass to slightly younger rocks. What can be more striking than the evidence of the limits of two life-provinces, afforded by the Calciferous strata of North America and the similar rocks of Scotland and Northern Europe, which contain the remarkable *Maclureas* and a peculiar assemblage of Cephalopods and other fossils; for these are seen at Girvan to come into close contiguity with the more southern type of Silurian, containing a very different fauna, so well seen in the Lake District and North Wales.

Another striking example of the same kind is afforded by the Cretaceous, of which the Southern type, marked by the abundance of *Hippurites*, *Orbitolites*, and other remarkable forms, comes into close relations, as has been so well shown by Hébert, with the type which yields the ordinary Cretaceous fauna of Central Europe. In these and similar cases which might be mentioned we trace the existence of two approximating marine provinces, like those which at the present day are separated by the Isthmus of Panama.

Profs. Neumayr and Mojsisovics have indeed shown that there are good causes for believing that the distinction between the marine zoological provinces in Triassic and Jurassic times was at least as clearly marked as between the similar provinces of the present day; and the former naturalist has in addition pointed out that within the geographical provinces we have also very recognizable climatic zones.

In the year 1862, Prof. Huxley, speaking from this chair, uttered a much-needed warning against the growing practice among palæontologists of treating geological equivalence as meaning the same actual contemporaneity; and against the assumption, without positive proof, that ancient faunas and floras had an indefinite and even world-wide distribution. Palæontological discoveries during the last quarter of a century in Western North America, in India, in the Cape Colony, Australia, and New Zealand, have abundantly justified these cautions, and have shown how much such a term as "homotaxis" is needed, in order to guard against errors resulting from the abuse of the phrase "geological contemporaneity."

But when Prof. Huxley went on to suggest that "a Devonian fauna and flora in the British Isles may have been contemporaneous with Silurian life in North America and with a Carboniferous fauna and flora in Africa," I think that geologists, with the evidence they have now before them, must take exception to so sweeping a generalization. Finding, as we do, on both sides of the Atlantic the same succession of Cambrian, Ordovician, Silurian, Devonian, and Carboniferous strata, containing strikingly representative, if not identical faunas, it is impossible to doubt their general parallelism; however ready we may be to admit that the migration or development of new forms of life in the two areas need not have occurred synchronously, and that thus a certain amount of overlapping of the periods represented at distant points by the same system may exist.

On the other hand, I believe that the study of fossils from remote parts of the earth's surface has abundantly substantiated Prof. Huxley's alternative suggestion that "geographical provinces and zones may have been as distinctly marked in the Palæozoic epoch as at present." The ever-accumulating mass of palæontological evidence seems to me to be all pointing in this direction; and I confidently anticipate that the palæontological anomalies which in the past have caused so much doubt and difficulty, will, by the establishment of this principle, receive a full and satisfactory explanation.

As long ago as 1846, Darwin, in his "Observations on South America," showed that certain assemblages of fossils presented a blending of characters, which in Europe are only found apart in faunas which are of Jurassic and Cretaceous age respectively. Since that date, the study of the fossil faunas and floras of South Africa, India, Australia, New Zealand, and the Western Territories of North America has furnished an abundance of facts of the same kind, showing that no classification of geological periods can possibly be of world-wide application: that we must be contented to study the past history of each great area of the earth's surface independently, and to wait patiently for the evidence which shall enable us to establish a parallelism between the several records. Attempts to establish a universal system of nomenclature or classification of sedimentary rocks are indeed greatly to be deprecated, for if the zoological and botanical distribution of past geological times were at all comparable to that of the present day, any such universal system must be impossible.

The suggestion made to this Society by Prof. Huxley at a somewhat later date is equally valuable and important. Referring to the fauna of the Trias, he said:—"It does not appear to me that there is any necessary relation between the fauna of a given land and that of the seas of its shores. At present our knowledge of the terrestrial faunæ of past epochs is so slight that no practical difficulty arises from using, as we do, sea-reckoning for land-time. But I think it highly probable that, sooner or later, the inhabitants of the land will be found to have a history of their own."

The growth of our knowledge concerning the terrestrial floras and faunas of ancient geological periods, since these words were written in 1869, has constantly forced upon the minds of many geologists the necessity of a duplicate classification of geological periods, based on the study of marine and terrestrial organisms respectively.

Upon this important question the judicious remarks of my colleague, Dr. Blanford, must still be fresh in the minds of all geologists and biologists. He showed that not only are terrestrial provinces independent of marine ones, but that at the present, as well as in the past, the former are more circumscribed and have an amount of distinctness which does not exist in the case of the latter.

Nor is it difficult, in the present state of our biological knowledge, to give a reason for the existence of this state of things. Between completely separated land-areas, migration can only take place by such accidents as the transport of seeds or eggs, or as the consequence of the great but slow changes in the relations of sea and land. Forms adapted only for living in cold climates are isolated by tracts of low-lying tropical land, and, conversely, tropical forms are divided off from one another, by snow-covered mountain-chains, almost as distinctly as by actual oceans. The fact that well-known Arctic plants are found at the top of mountains in tropical or temperate lands, has seemed to many botanists as quite inexplicable without calling in the agency of a general refrigeration, like that which marked the Glacial period.

But with marine forms of life the case is totally different. The oceans are not only much larger than the continents, but they are all more or less completely connected with one another.

Forms which live at the surface of the ocean may wander freely in all directions, and know but few limitations except those imposed by temperature, absence of food, &c.; forms living at moderate depths may migrate along shore-lines or submarine ridges from one area to another; and even when abysmal tracts of ocean intervene between two littoral faunas, recent researches seem to show that the littoral forms of life may wander into such tracts, and eventually, perhaps, cross them, without undergoing extreme or profound modification. In this way, I think, we may account for the important fact so prominently brought into view by Dr. Blanford, that terrestrial life-provinces are and always must have been more restricted in area, and more sharply cut off from one another, than marine provinces.

With the clear recognition of this principle there falls to the ground one of the most frequently urged objections to the uniformitarian doctrines—that, namely, which is based on the supposed differences in geographical distribution in ancient times as compared with the present. I have always doubted whether there is any evidence to show that the marine life-provinces of Silurian or Carboniferous times were of greater extent than those of the present day.

I believe that the doctrine that strata can be identified by the organic remains which they contain is as sound as when it was first enunciated by William Smith; but the problems of stratigraphical palæontology, as they now present themselves to us, are infinitely more complicated than they could possibly have seemed to him. In every fauna and flora which we are called upon to study, we have to resolve a function of three variables, these being environment, space, and time. Only after the most careful investigation, in the first place, of the complicated effects produced by the varied conditions which we group together under the term environment—temperature, food, absence of enemies, and the innumerable influences which, as we now know, determine the existence and affect the multiplication of living beings; and by the thorough study, in the second place, of the laws of geographical distribution of plants and animals, can we hope to eliminate the effects due to environment and position, and arrive at the conclusion of what must be ascribed to time.

The task will be long, the work to be done arduous, and the efforts to be made prodigious and sustained; but the result is one which is not hopeless and unattainable, or, indeed, even doubtful. But let us by all means remember that the real work is really only just commenced, and that we are very far indeed from our goal.

One of our greatest sources of danger to the progress of geological knowledge at the present day is the impatience which is so frequently shown at the rate of that progress, an impatience which leads to attempts to cut the tangled skeins of research by hasty and ill-considered speculation. Geologists, no less than biologists, need to recollect and keep ever before their minds the important fact that the geological record, although it is one of enormous value, is exceedingly imperfect, and that this imperfection is quite as conspicuous in respect to physical as it is to palæontological data. How sadly is this important truth lost sight of by those who, on the strength of a few isolated facts and fragmentary observations, are prepared to construct maps of large portions of the earth's surface at far distant periods of its history. Such maps are to the geologist what "genealogical trees" are to the biologist—"will-o'-the wisps" leading us aside from the safe paths of scientific induction.

It is, I suspect, from the obvious failure of attempts of this kind—attempts which had better never have been made—that such frequent suggestions of revolt against the principles of uniformitarianism take their origin. For myself, instead of disappointment, I feel a constant surprise that these doctrines have enabled us to explain so much, when our knowledge of the causes still at work around us is still so imperfect; and I am continually impressed by the fact that each new discovery concerning the present order of Nature removes old difficulties in the explanation of the past. In saying that I adhere to the doctrines of uniformitarianism, I, of course, mean the uniformitarianism which Lyell himself taught, and not the absurd travesty of that doctrine sometimes ascribed to him.

The well-grounded conviction which results from observing the triumph of a great principle, when applied in an overwhelming number of cases, and which refuses to abandon that principle at the first appearance of difficulty, is surely not out of place in a student of Nature. It was this scientific "faith" which led Scrope to believe, in spite of difficulties arising from the imperfect knowledge in his day of physics, chemistry, and mineralogy, that massive and schistose crystalline rocks have been formed from ordinary lavas and sediments, when subjected to enormous pressures and complicated earth-movements; which induced Lyell to seek for and find the key to physical changes during past times in the operations going on everywhere around us; and which finally conducted Darwin, by the application of the same principle, in the case of living beings, to the doctrine of organic evolution.

But, alas! this "faith" seems often sadly wanting among us to-day. At a time when the mineralogical constitution of rocks and of the changes which they undergo is becoming daily more clearly revealed, when innumerable researches are throwing fresh light on the great physical processes taking place everywhere in the world around us, and when each department of biological science is contributing new "facts and arguments for Darwin," such scientific pusillanimity on the part of geologists seems, to say the least of it, singularly inopportune.

Doubtless there are difficulties still unresolved; but does not every advance in our knowledge see the removal of some of them? True the task of interpreting the fragmentary record of the rocks is one the end of which seems very far off; but is not every step we take clearly an approximation towards that end?

If any arguments were needed in favour of the continued and close co-operation of geologists and biologists, it would be found in the circumstance that the most important step in the progress of scientific thought which has been accomplished in modern times has been the direct result of a combination of geological and biological researches.

That remarkable biography, for which we are so greatly indebted to Mr. Francis Darwin, is not simply the record of a life, simple, blameless, and noble beyond that of ordinary men, the story of the workings of an intellect, truth-loving, patient, and powerful, above that of all his contemporaries; it is the history of a most wonderful revolution in human thought—one which will perhaps be regarded in future times as the most striking event of the nineteenth century.

The grand secret of Darwin's success in grappling with the great problem of "the origin of species" is found in the fact that he was at the same time a geologist and a biologist. The concentration of the later years of his life upon zoological and botanical researches has led many to forget the position occupied by Darwin among geologists. Not only are his geological writings of the highest value for the wealth of accurate observations which they contain, and the important generalizations which they put forward; but in his more purely biological works the value of his geological training and experience are constantly exemplified.

It was, indeed, a fortunate circumstance that Darwin, after being repelled by the narrow and soulless system of "geognosy" taught by Jameson at Edinburgh, came at Cambridge under the spell of Henslow, a man of most catholic taste, extensive acquirements, and widest sympathy with all branches of natural science. By intercourse with Henslow, Darwin's flagging interest in science was rekindled and kept alive. It is a proud boast for a University to have nourished the intellectual development of Darwin; and as that University has in the past remained faithful to the memory of Newton, making his mathematical teachings the characteristic and leading feature of its studies, so, we may hope, it will in the future aim at that complete union of geological and biological investigation of which Darwin's labours constitute so grand an example.

In the dedication of his "Journal of Researches," Darwin acknowledged "with grateful pleasure" that "the chief part of whatever scientific merit this journal and the other works of the author may possess, has been derived from studying the well-known and admirable 'Principles of Geology';" and well do I recollect how, in almost every conversation I had with him, he would enlarge with warmth of feeling upon his indebtedness to Lyell, not only for his lucid teaching, but for his constant and helpful sympathy. How did he use to speak in terms of reverence of his "master," and extol the magnanimity of one who, though twelve years his senior, had abandoned slowly and cautiously, as was the habit of his mind, yet in the end completely and ungrudgingly, his own conclusions and prepossessions, and had accepted the doctrines of a pupil.

Of Darwin's three geological books, the record of the observations made by him during the voyage of the *Beagle*, it is impossible to speak in terms of praise that will seem, to those acquainted with the merits of those admirable writings, as too high; and some portions of those works, especially the chapters dealing with the great problem of foliation, are, I am convinced, very far indeed from having received from geologists the amount of attention which they deserve.

After Darwin's return to England, in 1836, his attention was for some years almost exclusively devoted to geological researches; and it was to this Society and to its officers that he constantly came for help, advice, and sympathy. He writes at this time, "If I was not more inclined for geology than the other branches of natural history, I am sure Mr. Lyell's and Lonsdale's kindness ought to fix me."

Before reaching England, Darwin had written to Henslow from St. Helena, on July 9, 1836, asking that he might be proposed a Fellow of this Society, and on November 30 of that year he was elected. In the following February he became a member of our Council, and at the next anniversary, in 1838, undertook the duties of Secretary. This office, after he had held it for five years, he was compelled to resign through ill health: but even after he had been driven from London through the same cause, it was the evening meetings of this Society which from time to time tempted him from the seclusion of Down, till at last painful experience proved to him that he must forgo even this too-exciting pleasure. Even after being compelled to lay aside his hammer, when he had taken up scalpel and microscope to study the Cirripedia, he did not forget the fossil forms of the same group.

Whether it was the distribution of organic forms in space, or the order of their appearance in time, which had had most to do in turning Darwin's thoughts into those currents which finally led him to evolution, it would be idle to speculate; but it may safely be asserted that the geological aspects of natural history had at least as much to do with the conception of the origin of species as had the biological.

How warm was Darwin's interest, all through his life, in the progress of every branch of geological research may be gathered from his letters to Lyell and other geological friends. In what he had a presentiment would be, and which actually proved, his latest work, "The Formation of Vegetable Mould through the Action of Worms," he returned in his old age to a geological problem which had occupied him during the years of his most intimate connection with our Society.

No memories can possibly have such fascination for myself as those of the conversations which, during the last seven years of his life, I was privileged to hold with Mr. Darwin upon the current topics of geological interest. It was his habit when he came to town, twice a year, to ask me to meet him, in order to talk over geological questions, and thus I had opportunities for close intercourse and discussion. No researches in our science were too minute, none too remote from the ordinary subjects of his study, to engage his attention and command his sympathies. How keenly did he recall the pleasures of his labours in this Society, and the happiness of the friendships which he had formed here! How generously and with what warmth of appreciation did he ever speak of the labours of those who had succeeded him in endeavouring to carry out the objects of this Society! Of the gentleness, the sympathy, the contagious enthusiasm of the man, I dare not trust myself to speak!

At a time when there is perhaps some danger that the excessive specialization which seems to have become a necessity in both the geological and the biological sciences, may lead to narrowness of view, restriction of aims, and petty jealousies among the workers in circumscribed departments of those sciences, it may be well to remember how Darwin, while engaged in the most minute and detailed investigations upon barnacles, earthworms, or pigeons, upon orchids, primroses, or climbing plants, could ever keep his mind open to the influence of each new discovery in every branch of geological and biological science.

The great principles which lie at the foundation of modern geology and of modern biology are the same; and Darwin did but furnish a new testament to the old covenant already accepted by geologists. Now, more than ever in the history of natural science, is there reason for the warmest sympathy, the most thorough understanding, and the completest union in effort between the cultivators of the geological and the biological sciences. It is not by petulant unfaithfulness to the tried methods of those two sciences, and a readiness to abandon the principles which have led us to such real and important conquests, for the older methods that have been so often discredited and found wanting, that we can hope to advance those sciences.

Lyell once wrote to Darwin as follows: "I really find, when bringing up my preliminary essays in 'Principles' to the science of the present day, so far as I know it, that the great outline, and even most of the details, stand so uninjured, and in many cases they are so much strengthened by new discoveries, especially by yours, that we may begin to hope that the great principles there insisted on will stand the test of new discoveries."

And to this Darwin replied with characteristic enthusiasm:—

"*Begin to hope?* Why the *possibility* of a doubt has never crossed my mind for many a day. This may be very unphilosophical, but my geological salvation is staked upon it! . . . It makes me quite indignant that you should talk of *hoping*."

Fifty years have elapsed since these words were written. How infinitely more complicated seem to us the problems involved in the explanation of the past by the study of the process going on around us at present, than they possibly could have done to the great pioneers of the Uniformitarian doctrines! But the reasons for Lyell's hope and Darwin's confidence are still valid, nay, are stronger than ever. For does not every new discovery remove some difficulty or supply fresh illustrations of these views? May every geologist to-day be endowed with a due share of Lyell's caution; but, for my own part, I see no reason why he should not also possess a full portion of Darwin's faith.

ON THE NUMBER OF DUST PARTICLES IN THE ATMOSPHERE.[1]

At the beginning of the paper, reference is made to the great advance recently achieved by physiologists, regarding our knowledge of the solid matter floating in the atmosphere, as they have already provided us with a considerable amount of information regarding the number of live germs in the air under different conditions; while we have but little information regarding the dead organic and inorganic particles. The following investigation was undertaken in the hope of bringing the physical side of the subject abreast of the physiological; and in this paper is given an account of a method devised by the author for counting the dust particles in the air, and also some results obtained by means of it.

One difficulty presented in this investigation is the extreme minuteness of the particles to be counted; most of them are

[1] Communicated by permission of the Council of the Royal Society of Edinburgh, having been read to the Abstract Society on February 6, by John Aitken, F.R.S.E.

not only invisible, but are beyond the highest powers of the microscope. It was therefore necessary to adopt some method of making them visible. The simplest plan of doing this is to put the air—the particles in which we wish to count—inside a glass receiver, and saturate it with water vapour; then to supersaturate the air by slightly expanding it by means of an air-pump. When this is done, a fog is produced in the receiver, and we know that each fog particle has a dust particle as a nucleus; if then we counted these fog particles we would get the number of the dust particles. By this process, however, we would not by any means have counted all the dust particles present, as the fog particles so formed do not represent nearly all the dust particles. If, after time has been given for these fog particles to settle, another supersaturation be made, the receiver will become packed with another set of fog particles, which would require to be counted; and this process would require to be repeated a great number of times before the last particles would become visible and be counted. It is then shown that if there is only a little dust in the air, so that the particles are wide apart, then only one supersaturation is required to make all of them visible. Further, when there are few dust particles present the fog particles are large, and are easily seen falling like fine rain inside the receiver; and it appeared that if these rain drops could be counted then the solution of the problem promised to be easy.

The following gives a general idea of the method adopted of working out this suggestion. A small glass receiver was connected on the one side with an air-pump and on the other with a cotton-wool filter. Inside the receiver was fixed a small stage, about 1 cm. square, on which the drops were to fall and to be counted. This stage was fixed at a distance of 1 cm. from the top of the receiver, it was ruled into little squares of 1 mm., and was examined through the top of the receiver by means of a magnifying glass. To illuminate this stage a gas flame was used, the light being concentrated on it by means of a globular lens full of water. The air in the receiver was pumped out, and filtered air admitted. This air was perfectly dust-free, and gave no condensation when expansion was made. Into this pure air was admitted a small and measured quantity of the air the particles in which we wished to count. After allowing a short time for the air to get saturated, one stroke of the pump was made, which supersaturated the air, and brought down a shower of fine rain; while making the stroke with the pump, the stage was carefully observed through the magnifying glass, and the number of drops that fell on a square millimetre counted. This was repeated a number of times, and the average number of drops per square millimetre was obtained, and used for calculating the number of particles in the air. For every drop that fell on the square millimetre, 100 fell per square centimetre; and as there is only 1 cm. of air above the stage that number will represent the number per cubic centimetre in the air of the receiver. Then, knowing the proportion in which the air tested was mixed with pure air, and knowing also the amount to which the air was expanded by the pump, we have all the figures necessary for making the calculation of the number of particles in the air under examination.

In constructing the apparatus the first thing to which attention was given was to design the arrangement of stage or platform on which the drops could be most easily seen and counted. The first stage tried was a small piece of glass mirror, ruled on the back into little squares. This seemed at first to give excellent results, the drops being easily seen on its surface; but on attempting to count them its unsuitableness was at once evident—the confusion produced by the reflected images of the drops caused it to be abandoned at once. Then a mirror of very thick glass was tried, the glass being so thick that the reflected images were out of focus, but it did not give satisfactory results. Very thin mirrors made of microscope glass were then tried, but had to be rejected, because, though they brought the drops and their reflections together, they were unsuitable, being too rough and covered with fine specks on their surface; only the most highly finished glass can be used for this purpose. The arrangement was then altered, and a transparent stage lit from beneath was tried. This stage was made of a small piece of carefully selected glass, and had the fine lines etched on its surfaces. It was, however, abandoned, as it did not give such promise as the mirror arrangement. All difficulties in the use of mirrors were at last got rid of by making them of silver, and now silver mirrors are the only kind used. They are very highly polished, care being taken to keep the rubbing marks in straight lines and in one direction; they are ruled with fine lines at right angles to each other and at 1 mm. apart. When a silver mirror is mounted in its place, properly adjusted and lighted, it appears, when seen through the lens, like a black surface on which the lines are quite distinct, and on which the small drops shine out brilliantly and are easily counted.

Some difficulty is experienced in keeping the stage at the proper temperature. If it is too hot, the drops on falling on it do not adhere, but present a beautiful illustration of the spheroidal condition, as they roll over its surface towards the lower side of the stage, and drop into the ruled lines, in which they continue rolling till quite evaporated. On the other hand, if the stage is too cold it gets dewed, and counting becomes impossible. Directions are given in the paper for mounting and keeping the counting stage in the best working condition.

In working the apparatus two methods have been employed of mixing the air to be tested with dust-free air. In one, the dusty air is introduced into a flask which communicates with the test receiver by means of a pipe provided with a stopcock. The small quantity of air that is to be mixed with the pure air in the receiver is displaced from this flask and driven into the receiver by means of a carefully measured quantity of water which is run into the flask. In this way the air to be tested can be measured with a fair degree of accuracy, and as the capacity of the receiver is easily obtained, the experimental errors need not be great.

In the other method of working, the test receiver is connected with a small gasometer, and the air to be tested is mixed with pure air in the gasometer. The gasometer used has a capacity of 20 litres, is carefully graduated and delicately hung, so that the air can be measured in it with a considerable degree of accuracy. In working this arrangement, 1 litre of the air to be tested is generally first mixed with 19 litres of filtered air. After mixing, nine-tenths of the mixture is let out, and the gasometer again filled up with pure air, and the mixture tested in the receiver. If the drops are still too close, more air is let out, and filtered air added till the desired condition is attained. There must not be too many particles present, or all of them will not fall when expansion is made. Till experience is gained, a check on the quantity is easily obtained by admitting filtered air, in place of the air from the gasometer, and seeing if any drops appear on expansion; if none, then the correct number has not been exceeded.

After a satisfactory counting stage had been devised, and the apparatus got into working order, testing began, when at once difficulties presented themselves. The numbers counted in the successive tests of the same air agreed fairly well for a number of times, then all at once the process seemed to break down, and from time to time a great increase in the number was counted, far exceeding the errors of experiment; then all would go right for a time, but only to be followed by failure before long. The first thing suspected for these and for other failures was always the joints of the pipes and the stopcocks, and time after time have the joints been remade with india-rubber solution and stopcocks cleaned and greased, but to find that they are almost never at fault.

It was then suspected that the failure might be due to the filtered air, with which we mixed the dusty air, not being perfectly freed from its dust. The filtering power of cotton-wool was therefore studied, when it was found that 1 inch of cotton-wool will filter perfectly if the air is passed very slowly through it, but that even 12 inches of cotton-wool will not check all the particles if the air is made to rush violently through it. Filters must therefore be tested under exactly the conditions in which they are to be used.

It was, however, found that though the air was only allowed to pass very slowly through even 12 inches of cotton-wool, condensation frequently took place if the expansion and therefore the supersaturation was great. It was thought that in this case the failure might be due to an imperfect action of the filter—that, while it checked most of the dust, yet it allowed the extremely small particles to pass, and that these extremely small particles became active centres of condensation when exposed to the high degree of supersaturation used in the tests. It therefore here became necessary to test whether the *size* of the particles has *practically* any effect on the degree of supersaturation necessary to cause the vapour to condense on them. From the investigations of Clerk Maxwell we have theoretical reasons for expecting that the size of the particles will have an influence of this kind, but at present we cannot say that it is sufficiently great to have a perceptible effect in an experiment such as that described.

To test this point the following experiment was therefore made. A little dusty air was mixed with filtered air, and put into the test receiver, and saturated with water vapour. An expansion of only 2 c.c. was made; this caused the formation of a fog. After these fog particles had settled, the air was returned to the receiver; and after a short time another 2 c.c. expansion was made, when other fog particles appeared. After this had been done a number of times, the density of the fog got less and less, and at last entirely ceased. After this an expansion of 5 c.c. was made; this produced a rainy condensation in the receiver, which appeared a number of times on successive expansions being made, getting less and less dense, and at last it also ceased entirely. After all condensation had stopped with the 5 c.c. expansion, the expansion was increased to 10 c.c., when another shower made its appearance, and after one or two expansions all condensation again ceased. After this condition was attained, an expansion of 150 c.c. was made with the pump, when scarcely one drop made its appearance.

It is concluded that in the above experiment we have distinct evidence that the *size* of the particle does affect the degree of supersaturation required to produce condensation on it. Because, though an expansion of 2 c.c. produced a supersaturation sufficient to cause more than one-half of the particles to become visible, yet it required a higher degree of supersaturation to cause condensation to take place on others. It is also concluded from the experiment that the failure of the air to keep clear, in the tests where high supersaturation was used, was not due to the presence of extremely small particles, as an expansion of 10 c.c. is practically great enough to produce a supersaturation sufficient to cause condensation on the smallest particles.

The failures in the tests not being due to the presence of extremely small particles, it is concluded that they are true cases of condensation without nuclei, similar to those referred to in a previous communication. It was thought that, if they were true cases of spontaneous condensation, they might be checked if the expansion was made slowly and free from shocks. And on the other hand any shock would tend to produce condensation in dust-free air if highly supersaturated. On trying this, it was found that no condensation took place if the stroke of the pump was made slowly and steadily, and that if done quickly, and the piston made to strike the cover of the cylinder violently, then copious showers were always produced in the dust-free air. Here, then, was the key to one of the difficulties, and accounted for the occasional increase in the number of the particles counted; many of the drops having no dust-nucleus. Failure from this cause is now entirely prevented by causing the air on its passage from the receiver to the pump to pass through a small opening, or better through a small cotton-wool filter; this checks all violent rush of air, and shocks, and keeps the filtered air perfectly free from condensation even when highly supersaturated.

Again, the failure of perfectly filtered air to keep free from condensation was frequently observed after the inside of the test receiver had been newly wetted. It looked as if the newly wetted sides had saturated the air more thoroughly, and that the condensation was due to the higher degree of supersaturation which took place when expansion was made. This class of failures was, however, traced to the manner of wetting the inside of the receiver. If it was done roughly, and the water splashed, then many nuclei were manufactured in the receiver; if it was done quietly, none, and no condensation followed. Another cause of failure was traced to a drop of water getting into the pipe by which the air entered, and the inrush of air tearing the water into fine spray, which became active centres of condensation.

As yet no great number of tests of air have been made under different conditions, natural or artificial; but in the following table will be found some of the results obtained by this method of counting.

Dust Particles in the Atmosphere.

Source of the Air.	Number per c.c.	Number per c.in.
Outside Air—Raining ...	32,000 ...	521,000
,, ,, —Fair ...	130,000 ...	2,119,000
Room	1,860,000 ...	30,318,000
,, near ceiling ...	5,420,000 ...	88,346,000
Bunsen Flame ...	30,000,000 ...	489,000,000

In the first column of the table is entered the source of the air; in the second, the number of particles per cubic centimetre; and, for the benefit of those who think in English measures, the number per cubic inch is entered in the third column. The first number in the table, for ordinary outside air, was obtained on January 25, after a wet night. The number given for fair weather is an average got when the weather was in that condition. As yet far too few measurements have been made to enable us to trace any connection between the number of particles and the weather, but it is hoped that something practical may result from observations of this kind. The first number given for the air in a room is the number counted in the air of a room where gas was burning, and taken at a height of 4 feet from the floor; the other number was counted in air drawn from near the ceiling; and the last number was got in the air collected over a bunsen flame.

The value of numbers given in the table has not been carefully considered, and they are not given as absolutely correct; great accuracy, indeed, does not seem possible, when we consider the conditions; and, further, the number is constantly varying. For this reason it has not been thought necessary to make any corrections for temperature and pressure. Though we can get with a fair degree of accuracy the number of particles in the air in the test receiver, yet in all probability the calculated numbers given in the table are rather under than over estimates, as it is difficult to manipulate air without losing much of its dust. For instance, in one hour about one-half of the particles settle out of the air in the gasometer. Though the numbers do seem very large, yet so far as can be judged at present they are fairly correct, and at least represent the kind of numbers we have to deal with. It does seem strange that there may be as many dust particles in 1 cubic inch of the air of a room at night when the gas is burning as there are inhabitants in Great Britain, and that in 3 cubic inches of the gases from a bunsen flame there are as many particles as there are inhabitants in the world.

JOHN AITKEN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Frank Smart Studentship of Botany, founded at Gonville and Caius College by Mr. F. G. Smart, M.A., M.B., and Mrs. Smart, by the transfer of £2400 Great Eastern Railway 4 per cent. Debentures, is to be awarded for the first time at the beginning of Easter Term. Candidates are to send in their names to the Master of the College, Dr. Ferrers, on or before March 20. The electors are the governing body of the College, acting after consultation with the Professor and the Reader of Botany for the time being in the University. The Studentship is to be open to all members of the University who have taken honours in the first part of the Natural Sciences Tripos, and of not more than five years' standing; but the elected Student must become a member of Gonville and Caius. No competitive examination is to be held for awarding the Studentship. The Student is to apply himself to original investigation in botany, and must be able to show that he is doing so at any time, on penalty of forfeiting the Studentship. The Studentship is to last two years, but may under special circumstances be prolonged for one year more. The regulations of the Studentship are only to be changed, after the death of Mr. and Mrs. Smart, by consent of the Council of the Linnean Society of London. A prize of £6 in books is to be given out of the interest of the fund to the undergraduate student of Caius College who shall distinguish himself most in botany at the annual College examination.

The collection of British birds' eggs made by the late Mr. J. P. Wilmot, of Trinity College, containing a specimen of the great auk's egg, and other specimens figured in Hewitson's "British Oology," has been presented to the University by Lady Caroline and Mr. C. H. Russell, in memory of Mr. George Lake Russell, Lady Caroline's late husband.

Plans are submitted for the proposed new plant-houses at the Botanic Garden, to cost £2760, and of a laboratory in the garden, to cost £250.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 9.—"The Small Free Vibrations and Deformation of a Thin Elastic Shell." By A. E. H. Love, B.A., Fellow of St. John's College, Cambridge.

In this paper the method employed by Kirchhoff and Clebsch for the treatment of a thin plane plate is applied to the case of a

thin shell, or plate of finite curvature. It is proved (1) that only for an inextensible spherical surface is the potential energy-function the same function of the changes of principal curvature as for a plane plate; (2) that in general the shell cannot vibrate in such a manner that no line on the middle-surface is altered in length, because this condition makes it impossible to satisfy the boundary conditions which hold at a free edge; (3) that surfaces of uniform curvature with no bounding edges are the only ones which admit of purely normal vibrations; and (4) that vibrations in which the displacement is purely tangential are possible on all shells whose middle-surfaces are surfaces of revolution bounded by small circles. The possible modes of vibration of the spherical and cylindrical shell receive special discussion. The equilibrium of the shell is also considered.

Linnean Society, February 2.—Mr. Carruthers, F.R.S., President, in the chair.—The President called attention to the loss which the Society had sustained by the deaths of Prof. Asa Gray, Prof. Anton De Bary, and Mr. Irwine Boswell (formerly Syme) which had occurred since the date of the last meeting, and gave a brief review of the life and labours of each.—Mr. C. T. Druery exhibited a collection of abnormal British ferns, and made some remarks on the extraordinary number of named varieties which had been recognized, and which now required to be carefully examined and compared, with a view to some systematic arrangement of them. A discussion followed, in which the President, Mr. J. G. Baker, F.R.S., Dr. Murie, and others took part.—Dr. Amadeo exhibited and made some observations on a new species of *Tabernæmontana*.—A long and interesting paper was then read by Mr. Henry T. Blanford, F.R.S., on the ferns of Simla, based upon a collection which he had himself made there, "not much below 4500 feet, nor above 10,500 feet." His remarks were illustrated by a map, and by an exhibition of a number of the more noticeable ferns collected, many of which were extremely beautiful. Criticisms were offered by Mr. C. B. Clark, F.R.S., Mr. Gamble (Conservator of Forests, Northern Circle Madras) and Dr. William Schlich (Inspector-General of Forests to the Government of India).—A paper was then read by Mr. H. J. Veitch, on the fertilization of *Cattleya labiata*, var. *Mossiæ*, in which the author detailed an elaborate series of observations undertaken with the object of detecting, if possible, the act of fertilization of the ovules, to determine the time that elapses between pollination and that event, and to trace the development of the ovules into perfect seeds. After explaining the structure of the sexual apparatus of *Cattleya labiata* with the aid of drawings showing the separate parts, the processes following pollination were dealt with, first from the development of the rudiment into the perfect ovule, and then the ripening of the ovules into seeds, these processes being also illustrated by drawings made at particular stages. A discussion followed, in which Mr. J. G. Baker, Mr. H. N. Ridley, and others took part, and to their inquiries for further particulars Mr. Veitch replied.—The next paper, by Mr. Joseph S. Baly, contained descriptions of new species of *Galerucinæ*, and being of a technical character was taken as read.

Entomological Society, February 1.—Dr. D. Sharp, President, in the chair.—The President nominated Sir John Lubbock, Bart., M.P., F.R.S., Mr. Osbert Salvin, F.R.S., and the Right Hon. Lord Walsingham, F.R.S., Vice-Presidents for the session 1888 to 1889.—Mr. F. Pascoe exhibited a species of the Hemipterous genus *Ghilianella*, which he found at Pará with the young larva. He said it was the only occasion he ever saw the species with the larva, which was new to Mr. Bates.—Dr. Sharp exhibited some insects collected by Mr. A. Carson on Kavalla, an island in Lake Tanganyika. The Coleoptera were nearly all well-known species, exemplifying the fact that many of the commoner insects of tropical Africa have wide distribution there, some of these species being common to both Natal and Senegal. The most remarkable of the insects was a large Lepidopterous caterpillar.—Mr. Champion exhibited specimens of *Casnonia olivieri*, *Œdichirus unicolor*, *Paussus favieri*, *Colydium elongatum*, *Endophlœus spinulosus*, *Hetærius arachnoides*, *Pseudotrechus mutilatus*, *Singilis bicolor*, *Phyllomorpha laciniata*, recently collected by Mr. J. J. Walker, R.N., at Gibraltar, Tetuan, and Tangier.—Mr. R. South exhibited a remarkable variety of *Polyommatus phlœas*, caught by him in North Devon in 1881.—Mr. R. W. Lloyd exhibited a living specimen of a species of *Ocnera* from Ispahan.—Mons. A. Wailly exhibited, and read notes on, a number of cocoons of *Antheræa assamensis*, *A. roylei*, *Actias selene*, and *Attacus ricini*, lately received from Assam; also a number of nests of cocoons of *Bombyx rhadama*—the silk of which is used by the Hovas in the manufacture of their stuffs called "Lambas"—from Madagascar.—Captain H. J. Elwes read a paper on the butterflies of Sikkim, the result of many years' collecting. He said he had been enabled to complete his observations during the enforced delay at Darjeeling of Mr. Macaulay's Mission to Thibet, of which he was a member. He stated the number of species occurring in this district to be about 530, which is greater than the number hitherto found in any other locality in the Old World. Of these the greater part only occur in the hot valleys at an elevation of 1000 to 3000 feet, and these are for the most part of a purely Malayan character, whilst those found in the middle zone are in many cases peculiar to the Himalayas; and the few species from the alpine parts of the country at 12,000 to 16,000 feet are of a European or North Asiatic type. An important feature in this paper was the numerous observations taken on the habits, variation, seasons of appearance, and range of altitude of the various species, for which the author said he was largely indebted to Herr Otto Möller, of Darjeeling. The paper concluded with an analysis of the species and genera compared with those found in the North-West Himalayas and in the Malay Peninsula. Mr. J. H. Leech, Dr. Sharp, Captain Elwes, and others took part in the discussion which ensued.

Zoological Society, February 7.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of January.—Mr. E. G. Loder exhibited and made remarks on a very large African Elephant's tusk, which weighed 180 pounds, and was, as he believed, the largest tusk hitherto authentically recorded.—Mr. A. Thomson exhibited a living specimen of the larval form of Stick-Insect (*Empusa pauperata*) from the Insect House.—Mr. G. A. Boulenger, read the third of his series of contributions to the herpetology of the Solomon Islands. The collection now described have been obtained by Mr. C. M. Woodford during a visit to the islands of Guadalcanar and New Georgia. The author observed that though the collection contained over 200 specimens, only four species were thereby added to the herpetological list of the Solomons, showing that our knowledge of that fauna was approaching completion.—A communication was read from Mr. Arthur G. Butler, containing descriptions of some new Lepidoptera from Kilima-njaro. Some of the specimens described had been collected by the late Bishop Hannington, and others by Mr. F. J. Jackson.—Mr. Frank E. Beddard read a paper upon certain points in the visceral anatomy of the Lacertilia. The paper dealt principally with *Monitor*, in which the presence of a peritoneal fold covering the abdominal viscera and separating them from the lungs was referred to; this membrane was compared with a corresponding structure in the Crocodilia.—Mr. D. D. Daly gave an account of the Birds'-nests Caves of Northern Borneo, of which no less than fifteen were now known to exist in different parts of the North Bornean Company's territories. Most of these were situated in limestone districts in the interior, but two of them were in snadstone formations near the sea-coast.—A communication was read from Mr. R. Bowdler Sharpe, containing the description of a new species of Tyrant-bird of the genus *Elainea*, from the Island of Fernando Noronha. This was proposed to be called *E. ridleyana*, after Mr. H. N. Ridley, who had obtained the specimens during his recent exploration of that island.—Mr. Osbert Salvin, F.R.S., read a note on *Ornithoptera victoriæ*, from Guadalcanar Island of the Solomon Group, and pointed out the characters which separated this species from a closely allied form of the Island of Maleite, proposed to be called *O. reginæ*.

Geological Society, February 8.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On some remains of *Squatina cranei*, sp. nov., and the mandible of *Belonostomus cinctus*, from the Chalk of Sussex, preserved in the collection of Mr. Henry Willett, of the Brighton Museum, by Mr. A. Smith Woodward.—On the history and characters of the genus *Septastræa*, D'Orbigny (1849), and the identity of its type species with that of *Glyphastræa*, Duncan (1887), by Dr. George Jennings Hinde.—On the examination of insoluble residues obtained from the Carboniferous Limestone at Clifton, by Mr. E. Wethered.

Royal Microscopical Society, February 8.—Annual Meeting.—The Rev. Dr. Dallinger, F.R.S., President, in the chair.—The Report of the Council was read, showing a further increase in the number of Fellows, and in the revenue of the

Society.—Mr. Crisp referred to the great loss the Society had sustained by the death of Dr. Millar, who had always taken a lively interest in the affairs of the Society, and for nearly thirty years had been a member of Council.—Dr. Dallinger delivered his annual address.

PARIS.

Academy of Sciences, February 20.—M. Janssen in the chair.—Third note on the doctrine of probabilities as applied to target practice, by M. J. Bertrand. The object of this paper, which has been prepared at the request of several artillery officers specially interested in the subject, is to present in a form capable of immediate application the results already arrived at as set forth in the previous communications.—On the species of Proneomenia on the coast of Provence, by MM. A. F. Marion and A. Kowalevsky. In a previous note the authors described a new genus of Solenogaster from the Gulf of Marseilles differing from the Proneomenia by its thorny integument. Here he describes four distinct species of the genus Proneomenia which occur on the coast of Provence, and which present features by which they may be readily distinguished from *P. sluiteri* described by Hubrecht. These species, none of which exceed 15 mm. in length, are respectively named *P. vagans*, *P. caulini*, *P. desiderata*, and *P. aglaophenicæ*. Incidental reference is made to a fifth species (*P. gorgonophila*) discovered on the coast of Algeria.—Observations of the new planet Charlois, 272, made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Rambaud and Sy. The observations for right ascension, declination, apparent position, &c., extend over the period February 10–11.—Observations of the same planet are also recorded for February 8–13 made at the Observatory of Marseilles with the Eichens equatorial, by M. Borrelly.—Permanent deformations and thermodynamics (continued), by M. Marcel Brillouin. The chief subjects here discussed are the principle of equivalence, specific and latent heats, and the differential relations between the specific heats.—On the electrostatic attraction of electrodes in water and attenuated solutions, by M. Gouy. The theory of the propagation of electricity in the permanent state suggests the presence of free electricity during the passage of the current, not only on the outer surface of the conductors, but also on the surface separating two conductors of different specific resistance, the electric force necessarily having different values on either side of this surface. The author here endeavours to ascertain whether this hypothetic layer of free electricity on the contact surface might be capable of exercising any electrostatic actions. For this purpose he studies the case of two metallic conductors placed in a moderately conducting liquid and maintained by a pile with different potentials, in order to determine how far they may be acted upon by appreciable forces. His experiments seem to show that these forces really exist, and are in fact much more considerable than could have been foreseen.—On the coefficients of proportionality in radiating heat, by M. L. Godard. The experiments here described seem to show that the coefficients of proportionality given by the study of the diffusion of heat, and confirmed by the spectro-photometric analysis of coloured substances, are the same as the numbers obtained by M. L. Mouton in his researches on the distribution of heat in the normal spectrum of the sun.—Preparation and properties of a bi-hydrofluate and of a tri-hydrofluate of fluoride of potassium, by M. H. Moissan. While hydrochloric acid yields with difficulty the hydrochlorates of chlorides, hydrofluoric acid combines readily with the neutral fluorides to produce hydrofluates of the general formula KFl, HFl. But these compounds, including 1 equivalent of hydrofluoric acid, are not the only ones that may be obtained, at least with the alkaline metals. The author has succeeded in preparing two new combinations containing 2 and 3 equivalents of acid for 1 of fluoride of potassium. These ombinations, abounding in hydrofluoric acid, and capable of being kept in the fluid state at temperatures ranging from 65° to 105° C., may perhaps under certain conditions enable the hydrofluoric acid to react readily on a certain number of organic or mineral compounds.—On a new reagent of the products of saponification of cotton-oil, by M. Ernest Milliau. The chemical reagent here described, which is not observed in the fatty acids of olive-oil, is so sensitive that by its means the presence may easily be detected of 1 per cent. of cotton-oil in olive-oil. All risk of error is removed, as the operation is effected, not on the oil itself, but on the fatty acids free from all impurity. Science has thus supplied the long sought-for means of infallibly detecting any adulteration of olive-oil by cotton-oil in the proportion of from 5 to 20 per cent., as is usually practised in the trade.—On the essence of lavender, by MM. R. Voiry and G. Bouchardat. The results of the analysis of this essence differ in some respects from those hitherto published. The authors have determined the presence of an oxygenated compound identical with eucalyptol, and the almost complete absence of carburets of hydrogen.—The sardine fisheries on the west coast of France in 1887, by M. Georges Pouchet. Last year was characterized by an extreme abundance of sardine on the French fishing-grounds, at the very time when the most opposite reasons were being advanced to account for a supposed gradual disappearance of the species from the French waters. On this point nothing positive can be asserted in the absence of any accurate knowledge of the migrations and spawning-grounds of the sardine.—On the Quaternary station of La Quina, Charente, by M. Emile Rivière. This station of prehistoric man, which lies near the banks of the Voultron in the Canton of La Valette, has recently been carefully explored by the author, who agrees with M. Chauvet in assigning it to the Mousterian (reindeer) epoch. The animal remains include the cave-bear, jackal, wild cat, horse, *Bos primigenius*, *Cervus elephas*, and especially the reindeer, in great abundance. No human bones were found, but there is an abundance of chipped flints, some very fine, and evidently worked on the spot.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Navigation and Nautical Astronomy: W. R. Martin (Longmans).—The Method of Creation: H. W. Crosskey (Sunday Sch. Assn.).—Elementary Physiography: J. Thornton (Longmans).—Life in Corea: W. R. Carles (Macmillan).—Discursive Essays on the Phenomena of the Heavens and Physical History of the Earth, Part 1 (London Literary Society).—Technological Dictionary, 3 vols., English, German, and French: Röhrig and Schiller (Trübner).—Emin Pasha in Central Africa (Philip).—Das Antlitz der Erde, vol. ii.: E. Suess (Tempsky, Wien).—Jahrbuch der k. k. Geologischen Reichsanstalt, Jahrg. 1887, xxxvii. Band, 2 Heft; Abhandlungen der k. k. Geologischen Reichsanstalt, Jahrg. 1887, xi. Band, 2 Abthg. (Wien).—Industrial Instruction: R. Seidel (Heath, Boston).—The Manual Training School: C. M. Woodward (Heath, Boston).—A Pocket-book of Electrical Rules and Tables, 5th Edition: Munro and Jamieson (Griffin).—ii. Jahresbericht (1886) der Ornithologischen Beobachtungstationen im Königreich Sachsen: Dr. A. B. Meyer and Dr. F. Helm (Dresden).

THURSDAY, MARCH 8, 1888.

PHYSICAL SCIENCE AND THE WOOLWICH EXAMINATIONS.

WE are interested to learn that the views we have expressed on this subject are probably shared by representatives of military opinion; for we are informed that the treatment of scientific candidates for Line cadetships, under the similar regulations for admission to Sandhurst that were introduced in 1884, met with a very unfavourable reception from at least one of the service journals. At the time of their introduction, the *Army and Navy Gazette* pointed out, as we have done, the serious objections that exist to giving modern languages so great an ascendency as is allotted to them in the present Sandhurst competitions. All that was said on this subject in 1884 applies with much greater force to the proposed mode of selecting officers for the scientific branches of the Army. We do not underrate the value of modern languages to soldiers, or to any other class, but an education in which mathematics and modern languages occupy so dominant a position as they are likely to possess in the education of many of the successful Woolwich cadets of the future [1] is scarcely more defensible than would be the adoption now of the purely classical training of former years. We trust, therefore, that no pains will be spared by those who are interested in this question to further the efforts that are being made to bring about the adoption of a more liberal scheme, which shall encourage early specializing on the part of the candidates to a less degree, and be more just to the particular class whose claims we have urged.

These regulations seem calculated to perpetuate the system of education of which it has been repeatedly complained that "it has too much to do with books and too little to do with things"; and, apart from their unfairness, they will tie the hands of those head masters who are willing, or even anxious, to adapt the work of their schools to the needs of the times, by forcing upon them a narrow curriculum of which they do not approve. This is not only unfortunate but unnecessary, for there is no real obstacle in the way of formulating a scheme of examination that shall both give fair play to all the candidates, and leave the hands of the teachers comparatively unshackled.

Much as the claims of science are still underrated by the unthinking among us, it was hardly to be expected that the representatives of a scientific profession would sanction regulations which will tend to prevent the admission to that profession of youths of scientific power, and which are also calculated to discourage any element of science teaching in the previous education of those who may wish to join it. Complaints of the absence of such training are familiar enough, and regulations intended to encourage such preliminary work are not uncommon. This adds not a little to our surprise at the proposals of the War Office Committee. We regret to perceive in them a fresh illustration of the tendency of Examining Boards to sacrifice the interests of the examined to a desire for simplicity in their schemes of examination, a tendency that constitutes a source of serious danger to proper freedom of education in these days, when admission to all the higher avocations is so jealously guarded by competitive or qualifying examinations.

In the discussion of this subject that has occurred in our columns a statement has been made, and repeated, by one of our correspondents, that requires notice. We allude to the contention that chemistry, physics, and geology are not good educational subjects for boys under sixteen years of age. This is a statement with which very few who have given these sciences a fair trial will agree; moreover, it is not pertinent to the question under discussion. Successful candidates for the Woolwich cadetships are, we believe, on an average, not much less than seventeen and a half years of age, and in future the average of age is more likely to rise than to fall in consequence of the increased severity of the examination in obligatory mathematics. No liberal-minded man will deny that the above-named sciences are exceedingly good educational subjects, between the ages of fifteen and seventeen and a half years, in the case of those who have ability and liking for them, by whom alone they will as a rule be studied among the candidates for Woolwich. Of course there are some for whom such studies are unfitted, but we very much doubt whether the military authorities will greatly regret the rejection of such as these. Their powers are likely to be more profitably employed in other directions.

If we may judge from the memorandum lately issued with the Army Estimates by Mr. Stanhope, we may conclude that the present time affords a good opportunity for urging upon his notice the thoroughly unpractical character of the proposed changes. The frankness with which Mr. Stanhope admits other deficiencies in the system of our military administration encourages the expectation that in this matter also he will act with an equal degree of practical sense, and that it will not be long before we shall hear that the efforts of those who have taken up this matter are bearing fruit.

[1] Since mathematical and modern languages will count for 12,000 marks out of a maximum of 16,500, and as about 5000 will be sufficient for success in future, it is not unlikely that many candidates may deem it safest or easiest to almost confine their studies to these two branches.

PROFESSOR FLEEMING JENKIN.

Papers, Literary, Scientific, &c., by the late Fleeming Jenkin, F.R.S., LL.D. Edited by Sidney Colvin, M.A., and J. A. Ewing, F.R.S. With a Memoir by Robert Louis Stevenson. 2 vols. (London: Longmans, Green, and Co., 1887.)

THIS is a work of great interest to many classes of scientific men, as well as to the public at large. Its contents are of an extremely varied character. Readers of NATURE, as such, are not deeply concerned with discussions of Female Dress in ancient Greece, with Rhythm in English verse, or with the characteristics of Mrs. Siddons as an actress. Nor will they, as a body, care much for the merits and demerits of Trade Unions, the relations of Supply and Demand, or other branches of the would-be science called Political Economy. The literary and economic Journals, on the other hand, will probably regard these as among the more valuable contents of these volumes.

But the Biographical Sketch of Prof. Jenkin is of high interest to all:—first, because it traces the successive advances made by the indomitable perseverance of a brave man in his protracted struggles against difficulties of no common order:—secondly, because it is the work of one of the most remarkable writers of our time, who has thus given fresh proof of the versatility of his genius. The result, however, cannot we think be looked on as wholly satisfactory by those who really knew Prof. Jenkin. The power displayed in the narrative is unquestionable, the various characters stand forward in clear-cut outline, and we seem to see them act out their lives before us as we read. But the weird imagination of the writer has proved too much for him, and some of his "situations" are altogether overcharged.

The late Prof. Jenkin was essentially a frank, straightforward, hard-working, clear-headed, practical scientific man:—and it is in this capacity that he will be held in honourable remembrance by the scientific world. What was the character of his grandmother, or what forms of relaxation he himself sought from study or business, are matters of infinitely less importance. Scientific men would have been glad to learn many things not mentioned here:—*e.g.* the secret of his singularly methodical management of complicated correspondence:—for it is in such matters that they are, as a rule, most sorely tried as well as most miserably inefficient. But his Biographer is a true Artist, for whom business, method, and even science itself have no attractions; except in so far as they may serve occasionally to heighten the lights or to darken the shadows of an ideal picture. And it must be acknowledged that Mr. Stevenson has, in a very remarkable degree, succeeded in the work *as he understood it;* viz. in tracing the behaviour of that wholly unscientific (and therefore imaginary) structureless germ which renders "the biography of the man . . . . only an episode in the "epic of the family."

We are introduced at starting to a powerful but repulsive sketch of a family of country bumpkins, sots and sorners:—culminating in a weak but handsome and well-meaning midshipman of "a simplicity that came near to "vacancy." He married, in the West Indies, the daughter of a somewhat lively lady who "would tie her house slaves "to the bed and lash them with her own hand." Of the daughter we are told that, on occasion, she exhibited "characteristic barbarity." The domestic fate of the poor midshipman can of course be foreseen. "His wife, "impatient of his incapacity and surrounded by brilliant "friends, used him with a certain contempt. She was the "managing partner; the life was hers, not his; after his "retirement they lived much abroad, where the poor "Captain, who could never learn any language but his "own, sat in the corner mumchance; and even his son, "carried away by his bright mother, did not recognize "for long the treasures of simple chivalry that lay buried "in the heart of his father."

Such, we are told, were the parents of Professor Jenkin. Now we would ask in all earnestness *cui bono?* What class of readers is likely to be the better of such information as this? Surely such things, if such there were, ought to have been passed over in silence, or at least reserved to adorn, incognito, a new sensational narrative of the Jekyll and Hyde, or Dynamiter, type!

This powerful but cold-blooded description of monsters, and their atrocities, is succeeded by another quite as realistic whose *motif* is the struggle for existence on the part of the impecunious parents. Here, however, we find some relief in the frank boyish letters from young Jenkin, describing to an old school-fellow what he saw in Paris in the memorable days of 1848. For a few pages the merciless scalpel is allowed to remain inactive:—only to be applied again with fresh vigour, but now to Prof. Jenkin himself. All who knew him were aware that in the course of his singularly errant career he had lived much and happily with rough working men, and that he had made no great efforts to acquire that artificial veneer of "manners" (as it is called) which often serves the vilest of our race as a passport into "Society." But surely a single sentence on the subject would have sufficed any reasonable biographer! Why this Pre-Raphaëlite minuteness and copiousness of detail, except to add to the miserable heap of "Things one would rather not have said"? We gladly leave this aspect of the book with the remark that it affords fresh proof that literary men, even of the highest rank, are not necessarily qualified to be writers of biography, specially of scientific biography.

But there are statements of a darker stamp, such as in fact tend to impeach the sterling honesty which was one of the prominent features of Jenkin's character. The Biographer's story of his Class Certificate in Engineering will, we are certain, find no credence with any one who knew Prof. Jenkin. Under the conditions stated, nothing worthy the name of certificate could have been given by him. The story is susceptible, however, of an easy explanation. The Biographer has already told a similar tale of himself regarding his relations to another of the Edinburgh Professors. We have therefore only a recurrence of one of those half sportive, half serious, fits of introspection which form part of his literary art. Still, we do not like to meet with such things in such a connexion.

An exceedingly interesting and graphic chapter gives, in Jenkin's own words, a sketch of the busy times he had in laying and lifting submarine cables in the Mediterranean and in the Atlantic. His capacity for hard work, and his readiness of resource, appear at once from this singularly modest narrative. Appended to the Biography we have a brief but comprehensive summary of Jenkin's electrical work, drawn up by Sir William Thomson. From this we cannot make extracts. It must be read as a whole. Col. Fergusson has added an excellent sketch of Jenkin's services to general sanitation. Had Jenkin done nothing but this, his name would still be well worthy of remembrance as that of a signal benefactor of humanity.

The other contents of these volumes, so far as they can be discussed here, consist of reprints of some of Jenkin's published papers. Particularly interesting and valuable are two from the *North British Review:*—the first on *Lucretius, and the Atomic Theory*, the second on *Darwin, and the Origin of Species*. Both have important bearings on questions at present prominently before the public, so that it is specially convenient to have them in this easily accessible form. From the second we quote but a single sentence, of itself quite sufficient to confirm the above statements:—

"Any one of the main pleas of our argument, if "established, is fatal to Darwin's theory."

This is not, as some might hastily suppose, the self-laudation of a flippant "paper-scientist"; it is the deliberate statement of a clear-headed man who took nothing for granted, and who never wrote on anything till he felt convinced that he understood it.

We next come to a thoroughly practical Essay on *Scientific and Technical Education*, a subject on which Jenkin was peculiarly qualified to speak. The following extract may be taken as a specimen. Jenkin has been alluding to the willing and valuable assistance which a Teacher often receives from his higher practical students in conducting some new research; and proceeds to say:—

"The rank and file—the ordinary well-meaning student "who will never become a leading light in science—is "worthy of our attention. If he is well educated he may "become a successful manufacturer, contractor, engineer, "or farmer, and sensibly increase the power and wealth "of our country. It seems to me that this student is not "so well provided for in our scientific teaching as is "desirable. And the main question I propose for dis- "cussion is, how we are to improve the education of this "second-best young man. My own answer put briefly, "is that we can teach him systematically the art of "measurement. We cannot give him the hunger for "knowledge, the acute logical discrimination, nor the "imaginative faculty required for research; but we can "teach him how to ascertain and record facts accurately; "we can bring home to him the truth that no scientific "knowledge is definite except that based on the numeri- "cal comparison which we call measurement; we can "teach him the best modes of making that comparison "in respect of a vast number of magnitudes, and in teach- "ing this we shall teach him to use his hands and eyes. "This practical teaching gives clear conceptions to the "minds of many who receive a verbal definition as a "mere string of dead words. I should be glad if it were "generally proclaimed that the elementary training in all "our science laboratories should be a training in the art "of measurement. I wish that the classes were called "measurement classes. Then a student of ordinary in- "telligence would know that by entering a given class he "would learn how to measure those magnitudes with "which he will have to deal in after life. The attempt to "measure them will lead him to consider their nature, "and he will approach scientific study in the class room "with a faith in the reality of science which no verbal "exhortation will ever give him. You may define the "absolute unit of electrical resistance as accurately as "you will, and your definition shall affect the average "brain to no perceptible extent; but a young man of "very ordinary education and intelligence can learn to "measure resistances in ohms, and having learnt this, an "ohm becomes a reality to him. Not only does the "knowledge he has acquired make him a more valuable "assistant to the engineer and contractor, but having "acquired a working faith in the existence of ohms, he "is prepared to take some trouble to understand the "scientific definition."

Prof. Ewing reprints in full, in the last division of the work, three characteristic papers selected from Prof. Jenkin's writings on *Applied Science*:—and he gives in brief but clear abstract, and with full references, the contents of all. This part of the work seems to be very well done, and it forms a sort of commentary on, as well as complement of, the short article of Sir W. Thomson's to which we have already alluded. These handsome volumes will be specially welcomed by practical scientific men, but as we said at starting, there is much in them of interest and value to all.

P. G. T.

OIL ON TROUBLED WATERS.

Le Filage de l'Huile. Par le Vice-Amiral G. Cloué. (Paris: Gauthier-Villars, 1887.)

THAT the great effect produced by oil in smoothing troubled waters should have been so well known in times past as to have passed into a proverb, and yet that no general practical use of this effect should have been made until the last few years, is a remarkable instance of the tardiness of mankind to apply the benefits that natural phenomena provide. To the Hydrographic Office of the United States is mainly due the credit of bringing into prominence, and forcing on the notice of seamen, in various publications, the great importance of this property of oil under circumstances when life and property are endangered by breaking seas, and the extreme facility and trifling expense of its employment. Thanks to the efforts of the Americans, the facts are now well known to all English-speaking mariners, and many are the instances of the successful use of oil; but, nevertheless, the prejudices of many are still against it.

The Admiralty, in 1886, issued a memorandum on the subject to the fleet, largely founded on the American publications. Admiral Cloué has done a like service for his countrymen, and has written the best and most complete essay on the subject, in the little *brochure* before us. Drawing on the mass of experiences collected by the American Office, and giving them due credit for their action, he reports additional striking cases which have occurred during the last year or two, and suggests many practical means of employing oil under circumstances other than those yet tried, or where it has to some extent failed.

The facts are briefly these. In the heaviest gales at sea, when breaking seas are a source of danger to small or heavily laden vessels, or an inconvenience and discomfort to larger or more seaworthy ones, a very small quantity of oil, skilfully applied to suit the circumstances, spreads upon the surface of the water with marvellous rapidity, and forms a perfect breakwater, the raging waves being instantaneously transformed into a harmless swell, which quietly lifts the ship without any of the violent shocks and blows caused by the impact of an almost wall-like mass of water about to break. Spray alone comes on board in place of the sheets of water and green seas which often do so much damage. Admiral Cloué calculates, from a number of instances where the quantity of oil used and the speed of the vessel are given, that the film of oil which causes this marvellous and beneficent effect can be little more than 1/100,000 of a millimetre in thickness!

Experience already goes to show that a small quantity of oil is more efficacious than a free application of it, the film apparently spreading more quickly. Less than half a gallon an hour seems to secure the largest ship from being boarded by the waves.

The ordinary method of its application is to hang small canvas bags, containing about a couple of gallons of oil, so

as to dangle or float on the water, the bags being pierced with small holes by a sail needle, through which the oil slowly exudes. These bags are placed in different positions, according to whether the ship is flying before the tempest, or lying-to comparatively motionless. This simple appliance is therefore within the means of every ship, and there can be little doubt that already many vessels owe their immunity from damage, and in some cases even their safety, to its employment.

Among remarkable instances of saving life, is one, cited by Admiral Cloué, of the boats of a ship burnt in 1885, 800 miles from the Seychelles Islands, in which the crew were making their way to land. A cyclone was encountered, which raised a terrific sea, but the boats, provided with oil by the prescience of the captain, weathered it out in perfect safety for sixty hours, riding to a floating anchor of their masts and oars, to which was attached a bag of oil.

Our author points out that from the time of Pliny oil has been thus used, but only by small communities, or by individuals, whose efforts to bring it into general use have always failed. Benjamin Franklin presented a paper on the subject to the Royal Society of London, which is printed in the Philosophical Transactions, 1774, but it remained without fruit.

Experiments were carried out in this country in 1883 by Mr. Shields, at Peterhead and Folkestone, with a view of diminishing the heavy sea at the entrance of these harbours. These experiments were successful, but at the expense of a great quantity of oil; the fact being that the conditions of breaking seas in shallow water are totally different from those in the open ocean.

Admiral Cloué remarks on the great utility of oil when wrecks have to be boarded; and suggests that the builders of rock lighthouses, when their work is delayed by the difficulty of landing material, might find it to be of much service.

The general application of oil is in fact yet in its infancy, and everyone must welcome any such good collection of facts, and of suggestions tending to extend its sphere of usefulness, as that given in "Le Filage de l'Huile."

W. J. L. WHARTON.

OUR BOOK SHELF.

Comparative Morphology and Biology of the Fungi, Mycetozoa, and Bacteria. By A. De Bary. Translated by Henry E. F. Garnsey, M.A. Revised by Isaac Bayley Balfour, M.A., M.D., F.R.S. (Oxford: Clarendon Press, 1887.)

ANYONE acquainted with the numerous researches of De Bary, published in German, will readily indorse Prof. Balfour's remark in the preface to this English translation, viz. "it brings within reach of all English-speaking students the most thorough and comprehensive treatise upon these groups which has appeared in any language," and after perusing this volume we should add that "a finer volume, and a more handsomely and exhaustively illustrated one," is not known in the literature of this subject.

The book seems to us more like a well and comprehensively arranged collection of classical monographs on Fungi and allied organisms, written by a master mind, translated by a scholar, and revised and edited by a practical worker and teacher of these subjects.

It is difficult to pick out any one chapter in which this is not conspicuous. The array of facts, and of phenomena as to form, growth, and development of Fungi, and minute details bearing important relations to one another and to the whole, are told with singular lucidity and in comprehensive sequence; and numerous suggestions that at once engage and invite the reader's and student's inquisitive mind are everywhere, almost on every page, to be met with. As the title of the book indicates, the subjects of Fungi, Mycetozoa, and Bacteria are each separately treated in the first, second, and third parts of the volume respectively.

As was to be expected from De Bary's researches, the first part forms the bulk of the volume. As far as our present knowledge of the ever-enlarging subject of the thallus, spores, and development of Fungi goes, hardly anything could be added to make the book complete both for students and workers; but we venture to think that in Chapter V., besides the important bibliography added to the description of the different groups of Fungi, an appendix setting forth briefly the various species hitherto recognized, not only in name but also in distinguishing characters, would be a valuable addition.

This is still more the case in the third part—Bacteria. We doubt whether this will advance the knowledge of the student beyond a general insight into the nature and mode of life of Bacteria, though he will find here a most valuable and suggestive account of the different modes of spore-formation.

The illustrations are very numerous and well rendered. The bibliography in the first part (Fungi) is carefully and judiciously arranged.

As to the translation little need be said. It is excellent, and the book reads more like an original than a translation, if it were not that one is repeatedly reminded of the contrary by the presence, after an exact rendering in English, of the original German. There seems to be really no necessity to put (p. 1) after filamentous Fungi (*Fadenpilze*); (p. 2) after compound Fungus body (*Zusammengesetzter Pilzkörper*); (p. 4) after sprouting Fungi (*Sprosspilze*); (p. 73) endogenous spore-formation (*Endogene Sporenbildung*); (p. 84) solution or gelatinous swelling (*Auflösung, gallertige Verquellung*).

Why should (on p. 110) to "tube germination" be added (*Schlauchkeimung*); to "sprout germination" (*Sprosskeimung*); to "germ tube" (*Keimschlauch*)?

It is different with "abjunction" and "abscission" explained on p. 61 in a footnote, for here confusion might arise as to the exact meaning of the German "*Abgliederung*" and "*Abschnürung*."

The "Explanation of Terms" at the end of the volume is in this respect most welcome.

E. KLEIN.

Emin Pasha in Central Africa. A Collection of his Letters and Journals. Edited and Annotated by G. Schweinfurth, F. Ratzel, R. W. Felkin, and G. Hartlaub. Translated by Mrs. R. W. Felkin. (London: George Philip and Son, 1888.)

THE personal interest connected with this volume is even greater than its scientific interest. Emin Pasha already ranks as one of the heroes of the modern world, and the record of the bare facts of his career has all the fascination of a good romance. Appointed in 1878 to be Governor of the Equatorial Province, he ruled his territories with astonishing vigour and discretion, so that in 1882 he was able to report that slave-dealers had been wholly banished from his borders, and that the people subject to him were prosperous and contented. The troubles in the Soudan created for Emin many most formidable difficulties, but his courage never failed him, and we may hope that long before this time he has been stimulated to fresh hope and activity by aid received from Mr. Stanley. The letters translated in this volume begin with one dated Dufilé, July 16, 1877, and include several received

by friends in the course of last year. They bring out indirectly all the qualities of Emin's character, and no one can read them without being filled with admiration for his sustained enthusiasm, his inexhaustible energy, and his unaffected simplicity and modesty. He has been too much occupied with official duty to devote as much time as he would have liked to scientific investigation; but he is an ardent student of zoology, botany, and ethnography, and he says enough to show that we may expect from him hereafter very important contributions to our knowledge of all these subjects. So far as the present volume is concerned, the most valuable of the letters, from a scientific point of view, are those relating to the various tribes whose habits and customs he depicts. His descriptions are remarkably vivid, and are evidently the result of much careful observation. His description of the Wanyoro, for instance, is a model of what such a piece of work ought to be. The writer omits no characteristic that is likely to be suggestive to anthropologists, while he has taken care not to spoil the general effect of his sketch by the intrusion of unnecessary details. Dr. Felkin's introduction is written with perfect tact and judgment, and Mrs. Felkin has done her work as a translator admirably. An excellent map has been prepared by Mr. Ravenstein, who has also done good service by marking the latitude and longitude of every place mentioned in the index and glossary.

Colour. By A. H. Church, M.A. (London: Cassell and Co., 1887.)

IN a work which has been limited to somewhat less than 200 pages, there has of necessity been a good deal omitted which would have been found in a larger work. In the part devoted to the production of the spectrum, the details are almost absent in some particulars and perhaps are rather too full in others. The subject of polarized light is also dismissed too briefly. There are one or two statements to which exception can be taken. The first is where the author states (p. 44) that "calorescence may be regarded as a variety of fluorescence." The introduction of the term calorescence at all is a mistake; but it is a greater mistake to mix it up with what is a really distinctive phenomenon.

Another is at p. 78, where the author says, when speaking of a person who is "red" colour-blind, that "the nerve fibrils which in the normal retina receive the sensation of red are not, indeed, wanting, but transmit to the brain the same sensation as that transmitted by the second set of fibrils, the green." This doctrine is rather against facts: the fibrils are either wanting or else are paralyzed, as the total amount of light perceived by the red colour-blind person in white light is less than that perceived by the normal-eyed person. The sensations of the green and blue primary colours are on the average equal in both, but the normal-eyed person has in addition the red sensation. If the fibrils which in the normal-eyed person respond to the red respond to the green in the red colour-blind person, this would not be the case.

With these and one or two minor exceptions the work is to be recommended for accuracy; and the author may claim to have accomplished what he states in his preface he has endeavoured to do, viz. "to present and to explain in a concise yet popular form many of the chief facts connected with the origin, the phenomena, and the employment of colour."

Astronomy for Amateurs. By J. A. Westwood Oliver. (London: Longmans, Green, and Co., 1888.)

THIS volume, to quote the preface, "is intended to afford the amateur astronomer, possessed of limited instrumental means, but yet anxious to devote his labours to the furtherance of astronomical science, such hints and suggestions as will help him to direct his efforts into the channels which experience has indicated as best fitted to his qualifications and equipment." Its pages are accordingly entirely devoted to practical astronomy, theories of every description being disregarded. The different branches of the subject are dealt with by well-known specialists, Mr. Oliver's share in the work being chiefly editorial. The fundamental chapter on the telescope and observatory, which is full of practical information, is appropriately contributed by Sir Howard Grubb. Mr. Maunder contributes an instructive chapter on the sun; Mr. Gore deals with variable stars, of which an admirable list is given; and Mr. Denning gives directions to those who are anxious to distinguish themselves as comet-discoverers. The chapter on the moon is very detailed, and, with the index map, will be of great service to observers of our satellite. Special stress is in all cases laid upon the importance of adapting the ends to the means. The book is thoroughly practical throughout, and Mr. Oliver deserves the thanks of all who are interested in the progress of astronomy, for bringing together such an excellent series of papers. Celestial spectroscopy and photography are reserved for a forthcoming volume, which we sincerely hope will not be behind the one already issued.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Micromillimetre.

PROF. RÜCKER'S note in NATURE, of February 23 (p. 388) induces me to ventilate a suggestion in nomenclature which, among other advantages, might reconcile the practice of botanists and biologists with the C.G.S. system by leading to the disuse of the prefixes *mega-* and *micro-* in favour of *self-significant* prefixes.

It is not improbable that, in spite of Prof. Rücker's protest, the arbitrary definition of the prefixes *mega-* and *micro-*, laid down in the C.G.S. system may come, or continue, to be disregarded in different departments of science, until the ambiguity thence arising necessitates their disuse, as the disuse of the words *billion*, *trillion*, &c., is necessitated by their different senses in English and French. Be this as it may, it is certainly desirable that those who are not in the daily habit of speaking of *megohms*, *megadynes*, *micromètres*, &c., should be saved the necessity of recalling, or hesitation in realizing, the precise meaning of the prefixes.

Instead of denoting *decimal multiples* by Greek, and *decimal parts* by Latin, prefixes to the name of the unit, let the multiples be denoted by the addition of a termination *-n* (say), with a suitable vowel, and the parts by that of a termination *-t* (say), and let the *order* of multiples and parts alike be denoted by numeral prefixes indicating the *power* of ten by which the unit is multiplied or divided, or, what is the same thing, the distance of the digit denoting it from the units digit.

Thus, starting from the *metre*, instead of the scale—

metre { decametre, hectometre, kilometre, &c., / decimetre, centimetre, millimetre, &c.,

we might adopt the following:—

metre { metron (or monometron), dimetron, trimetron, tetrametron, &c., / metret (or monometret), dimetret, trimetret, tetrametret, &c.

Then the *micromètre* (the botanists' *micromillimetre*), would become the *hexametret*; the *megohm*, the *hexohmen*; the *megadyne*, the *hexadynen*, &c.

As an aid to the memory, such a system would be valuable, reinforcing the *visual* memory, which has (I think) in many cases to be relied on, by a corresponding *oral* reading. Thus, the unit of attraction of gravitation in the C.G.S. system is about $6\frac{1}{2} \times 10^{-8}$ dynes, that is, in the proposed language, $6\frac{1}{2}$

octodynets. So, too, Joule's equivalent J, which is about "$4 \cdot 2 \times 10^7$ ergs per gramme-degree Centigrade" (Everett's "Units and Physical Constants"), would be more easily remembered as 4·2 *heptergons*. Again, the velocity of light would be (approximately) expressed as 3 *octometrons* per second, or 3 *decavelons*, if the word *vel* were adopted for the unit speed in the C.G.S. system—namely, that of 1 centimetre (or *dimetret*) per second. I have chosen these instances, as cases where the prefixes mega- and micro- would be of little use as aids to expression or memory.

The system I am advocating coincides exactly with the method, which I believe most intelligent teachers of arithmetic are adopting, of reckoning the place of any digit of a number by its distance, not from the decimal point, but from the unit's digit. This distance it has been proposed to call the *order* of the digit, so that the order of the unit's digit is 0; those of the tens, hundreds, &c., 1, 2, &c.; and those of tenths, hundredths, &c., −1, −2, &c. Then, if the *order* of a number be regarded as that of its highest digit, its *order* is the *characteristic* of its logarithm. I forbear to dilate on the advantages of this reform in arithmetical language, but it is obvious that the proposed system naturally arises out of it. If the British Association or the Physical Society should, after discussion, accept the principle of the proposed nomenclature, and give it the stamp of their authority, I believe they would add to the benefits they have already conferred on science by the introduction of the C.G.S. system of units. My proposal would not extend to attempting to replace the words in ordinary use—kilometre, millimetre, kilogramme, &c.—unless they, in the course of time, died out, replaced by the synonyms here proposed on the principle of the "survival of the fittest."

Harrow, February 27. ROBT. B. HAYWARD.

IN NATURE of February 23 (p. 388) there appears an interesting letter from Prof. A. W. Rücker with reference to the equivalent value of the "micromillimetre." It is therein mentioned that the micromillimetre is commonly employed by biologists as equivalent to one-thousandth of a millimetre; but that the proper name for the thousandth of a millimetre (μ) is "micromētre," and not "micromillimetre."

Permit me, however, to suggest that even the denomination "micromētre," may be hardly acceptable to scientific workers. The denomination for the measure of the one-thousandth of a millimetre (μ), or 0·000001 metre, is "micron," and not "micromētre."

For the "micron" we have the authority of the "Comité International des Poids et Mesures." One shudders at the thought of the confusion likely to arise when computers are required to deal with both micromētre-units and micrometer-divisions.

The Comité International have also recommended the use of the following metric denominations for minute measurements:—

Denomination.	Symbol.	Equivalent.
Micron	μ ...	0·001 millimetre.
Microgramme ...	γ ...	0·001 milligrame.
Millilitre	*ml* ...	0·001 litre.
Microlitre	λ ...	0·000001 litre.

For the millionth of a millimetre we have at present the (C.G.S.) denomination "micromillimetre" ($\mu\mu$), as pointed out by Prof. Rücker. H. J. CHANEY.

7 Old Palace Yard, Westminster, February 27.

ALLOW me to add a few remarks to Prof. A. W. Rücker's letter, published in your issue of February 23 (p. 388).

Mr. O. J. Broch, Correspondent of our Institute in its Section of Mechanics, and Director of the International Board of Weights and Measures, having kindly undertaken to ascertain by actual measurement my pendulum's coefficient of expansion by heat, began by asking how old it was. On my expressing surprise at such a question, he told me that, having carefully measured the length of a brass rod recently made and 1 metre long, he found that it became shorter by 8 *microns* in the first year, and 3 more in the second one. *Micron* is currently used here to express 1/1000 of a millimetre. French botanists call it μ, and seldom use its first decimal because they cannot see such a small space.

The only objection against *micron* is that, unlike other subdivisions of the metre, it does not define its length by its name. But the word *metre* has itself the same fault. It is the ten-millionth part of a quarter meridian, and is, according to Clarke's computations, too short by 0·2 millimetre, or, more exactly, 187·7 microns. Improvements in geodesy will probably alter in either sense that fraction which is too small to disturb terrestrial requirements.

The quarter meridian being the true basis of our metrical system, it ought to have a name of its own, and might be called *megist*, as being the greatest space accurately measured. It should be the *metre* used in astronomy. Thus the velocity of light would be 30 megists, the motion of the star Aldebaran in the line of sight would be 18 megists per hour, and the sun's distance 15,000 megists ± 50. To give the latter in kilometres or miles is tantamount to describing the height of St. Paul's in London as being 1,100,000,000 microns. It is useless to express a distance in units so small that one of them may be added or subtracted without altering our useful notion of the whole sum. Moreover, those who can grasp at once a practical idea of such huge numbers are few and far between.

February 29. ANTOINE D'ABBADIE.

Coral Formations.

MR. G. C. BOURNE'S observations, as far as described in last week's NATURE (p. 414), appear to corroborate fully the view that corals grow more rapidly and luxuriantly on those parts of a reef or bank where there is an abundant supply of food, and only in scattered patches where the food supply is limited or where there is a quantity of sand or other inorganic materials in the currents. He states his belief that "the favourable conditions are due to the action of currents on coral growth." If it be not the food in these great oceanic currents, then Mr. Bourne should tell us what it is in "the action of currents" bathing the outer slopes of a reef that renders them favourable to growth; does he hold to the old view of more oxygen in the water?

It is to be hoped that Mr. Bourne has observed some of the corals feeding on the outer slope or in the lagoon, and can tell us of what their food consists. It will be interesting to know if he has worked his tow-nets in the outer currents, in the "strong currents," and in the still water, and has made a comparison of the results. If he has done so, his paper will doubtless be one of great interest and value.

There would appear to be a slip of the pen in the passage where Mr. Bourne refers to a current impinging directly on a slope. JOHN MURRAY.

An Incorrect Footnote and its Consequences.

THANKS to the wide circulation of NATURE, my original note with the above heading has attracted attention in quite a number of the proper quarters. Several letters have reached me on the subject, and more than one of the writers, after reporting that the *Demonstratio eliminationis Cramerianæ* had been found properly catalogued under De Prasse, proceed in consequence to express their surprise at Baltzer's mistake. Mr. Copeland's letter in yesterday's NATURE (p. 343) adds another instance of this correctness of cataloguing. The additional fact, which he mentions, that there are two copies of the *original edition* of the *Demonstratio* in the Dun Echt library is very interesting, and is a fresh proof of the existence there of valuable rarities.

When, however, Mr. Copeland diverges into the fruitless path of "the might have been" he is much less pleasantly instructive. Having read my letter on the search for a work by Mollweide, and on the discovery that the work meant was not by Mollweide at all but by De Prasse, Mr. Copeland turns to his catalogue under Mollweide, finds a cross-reference to De Prasse, looks up De Prasse, picks out the desired plum, and is pleased accordingly. In all this there is nothing singularly lucky or otherwise: it is exactly what ought to have happened. Mr. Copeland apparently thinks that the cross-reference in the Dun Echt catalogue was the missing link; but if he had occasion to look up other catalogues besides his own he would have found the same cross-reference or a more complete one, and might then have given my helpers in the search a little more credit. The fact is that the booklet of mathematical tables which was the cause of the cross-reference (and whose title Mr. Copeland carefully transcribes) is a comparatively common book, having gone in its time through several editions. Its name is thus of not infrequent occurrence in catalogues, being placed under De Prasse with a reference to Mollweide, or *vice versâ*; and, so catalogued,

it was repeatedly met with by us. There were, however, two points of difference between Mr. Copeland's position and ours. We unfortunately knew from the first what the cross-reference was for, and Mr. Copeland did not: we did not know that Mollweide was not the author, and Mr. Copeland, having read NATURE, did.

The hint is further let slip that something in Poggendorf "might have given a clue to the authorship." All I can answer is that at least two librarians looked up Mollweide in Poggendorf, and were not erratic enough to think of the clue. Indeed, the main part of my original letter has been written in vain if I have failed to make clear that at first we did not seek for "a clue to the authorship," Baltzer having so cruelly misled everybody by asserting in the usual matter-of-fact way that the author was Mollweide. And what I wanted to insist upon was the following simple canon—*Never, so long as books are catalogued as at present, insert without comment an author's name in a title where no author's name exists.* THOMAS MUIR.

Bothwell, Glasgow, February 11.

Cause of September Typhoons in Hong Kong.

AN investigation of the average distribution of atmospheric pressure in South-Eastern China and neighbouring regions has proved the existence of a trough of relatively low pressure in the channel between Formosa and Luzon, and in the northern part of the China Sea during September. This appears to be the reason why typhoons so frequently enter the China Sea during that month of the year, and cause north-east veering to south-east gales to be felt in Hong Kong. Like storms that visit the British Isles, they move along between two areas with higher pressures, and are sometimes developed under the influence of those areas. This remark would be of considerable value in forecasting typhoons in Hong Kong if the district round the China Sea were better furnished with telegraphic reporting stations than it is at the present time. W. DOBERCK.

Hong Kong Observatory, January 11.

The Composition of Water by Volume.

IN my paper "On the Composition of Water by Volume" (Proc. R.S. 1887, 398) the ratio 1·994 volumes of hydrogen to 1 volume of oxygen was given as the most probable value, as I assumed that both gases were of an equal degree of purity. The ratio 1·9967 : 1 was given from the best six experiments if the impurity be supposed to be altogether in the oxygen. At the last meeting of the British Association (B.A. Trans., 1887, 668) I pointed out that this was the most probable ratio, as I had found the impurity to be chiefly oxides of carbon arising from the combustion of traces of the vaseline used in lubricating the stop-cocks finding their way into the eudiometer. Dr. Sydney Young's interesting and ingenious letter (p. 390) is a most valuable corroboration of the hypothesis that the impurity is almost entirely due to the oxygen. A new and larger apparatus, enabling me to use twice the volume of gas, and to measure with much greater accuracy the residue, as well as make a complete analysis of it, still gives a ratio of less than 2 : 1, as the four last experiments made with it show..

	Measured volumes.		Residue.				Combining volumes.		Ratio.
	H	O	H	CO_2	CO	N	H	O	
I.	6909·4	3451·2	... 38·9.	7·2	7·9	0·7	... 6870·5	3440·1	... 1·9972 : 1
II.	6882·2	3414·2	... 74·9	2·6	5·3	3·6	... 6807·3	3409·0	... 1·9968 : 1
III.	7657·2	3798·7	... 63·3	—	—	0·8	... 7593·9	3798·7	... 1·9980 : 1
IV.	7561·4	3777·9	... 19·9	—	—	0·7	... 7541·5	3777·9	... 1·9962 : 1

In Experiments I. and II. vaseline was used as the lubricant, and in III. and IV. syrupy phosphoric acid, by using which all traces of the oxides of carbon are eliminated, and the gases shown to be of a high degree of purity. If we allow that half the amount of oxygen which was used to burn the carbon would be required in addition to burn the hydrogen combined with it in the vaseline, then the ratio becomes 2 : 1.

To use phosphoric acid as a lubricant with security, I find it is necessary to use safety-taps, and am having them in place of the ordinary ones now on my apparatus, and hope very shortly to settle beyond all doubt the true ratio in which hydrogen and oxygen combine to form water.

The ratios of the CO and CO_2 in Experiments I. and II. recall Bunsen's experiments. ALEXANDER SCOTT.

Durham, February 27.

Water Supplies and Reservoirs.

HAVING observed in NATURE (p. 375) an article on the drought of past years, and the probability of one this year also, from deficient rainfall, I take the occasion of suggesting that the old reservoirs might still be made more available for an additional storage of water to counteract its effects. As there is always abundance of rainfall, 40 inches, in Lancashire, and on its surrounding hills, from the cities of which district come complaints of want of water supplies, no fear need be entertained of lack of water if the rain could be all impounded without loss.

It has appeared to me surprising that our hill reservoirs have not been excavated deeper into the valleys and ravines they are made out of, after the manner of the water tanks in India.

In this country a reservoir seems to be simply formed by making a rampart across a ravine, and letting the upper part fill itself, as it stands naturally, with rain in course of time.

The ravine still lies encumbered with sodden grass, stumps of trees, rotting herbage, old walls, and fences, with organic remains, and submerged under the impounded lake, so that an emptied reservoir looks like a long mud ditch, through which a flood or a sea tide had lately passed.

Now if the sides were cut down perpendicularly, and the bottoms levelled horizontally, such valley reservoirs would be able to contain twice as much water as they now do, on the principle that the area of a rectangle is twice as great as that of a triangle between the same parallels.

The whole area of the reservoir might possibly be excavated cleanly out, so as to have its sides and bottom as good as any wet dock in a seaport, and our water supplies would then be considered quite sufficient, and of better quality, for the great towns. If this were done, say, for Liverpool and Manchester, there might be found less need for constructing new and distant waterworks, as the present reservoirs when thus enlarged would hold nearly double the amount they now do.

Besides the lessened rainfall, all reservoirs must suffer serious loss by evaporation, especially in dry seasons, and this is not occasioned so much by the sun's heat as by the action of drying winds, which may carry off as much as 0·20 inch per diem, or 6 inches in a month, or more than an average monthly rainfall. To counteract this tendency, belts of trees planted round the margins of reservoirs are found very useful in sheltering the surface of the waters from the winds, and they act beneficially besides in attracting rain itself to the pools. Further, on the same idea it might be found advisable to cover over entirely the head tanks for city supply, with sheds or roofs, so as to keep off the sun's rays from the water; or else to erect a high screen on the windward side to keep the prevailing winds off the surface, and counteract unnecessary evaporation.

Edinburgh. W. G. BLACK.

A Photographic Objective.

MY attention was called some time since to a letter from Prof. Pickering in your issue of October 13, 1887 (vol. xxxvi. p. 562), describing a form of objective adaptable either to photographic or visual work, by reversion of crown lens and alteration of its distance from the flint.

The form described is exactly similar to that which had been suggested to me by the President of the Royal Society, and which I reported on at the June meeting, 1887, of the Royal Astronomical Society, as having been actually constructed and found to give good results (see *Observatory*, No. 125, pp. 253 and 254).

I should perhaps have mentioned this matter before, but thought that Prof. Pickering would certainly have seen the published account of my previous communication. I have, however, lately seen a newspaper report that a patent has actually been granted for this form of objective.

It therefore appears necessary to point out that this form had been previously suggested by Prof. Stokes, and put in actual practice here.

I may mention that long previous to Prof. Pickering's communication, I had arranged with the Astronomer-Royal to construct the new 28-inch objective for Greenwich Observatory on this principle on certain conditions, and also that this particular form of photographic objective has a distinct place in the last edition of my catalogue. HOWARD GRUBB.

Rathmines, Dublin, February 27.

A Green Sun.

I WAS looking, a few days ago, at three o'clock in the afternoon, towards the sun, which was shining in a clear sky. Exhaust-steam from an engine employed in the new Thames Tunnel works, and situated just below my window, was passing intermittently over his face. Many puffs had already crossed it, some partially, others completely obscuring the luminous disk, when presently, three puffs, following each other quickly, successively covered the sun, which then shone brightly through the steam with a vivid light-green colour. The effect was strikingly noticeable, and the green colour intense. I watched for twenty minutes, but in vain, for another "green sun," and at 3.30 clouds came up.

I have since tried to reproduce the same effect by observing the arc lights in Cannon Street Station through steam rushing upwards from the safety-valve of a locomotive. Seen through the thickest part of such a column of vapour, the electric light exhibits a deep red colour, and I *think* there is a green transmission near the edge of the column; but the latter was unsteady, while the point is evidently critical, and it is impossible to say positively that it was so. D. PIDGEON.

Holmwood, Putney Hill, February 11.

RABIES AMONG DEER.

THAT all domesticated or semi-domesticated mammals succumb to inoculation with the virus of rabies has long been asserted, and examples of its occurrence have been duly recorded. The possibility, however, of the disease affecting half-wild animals seems to have been lost sight of, and it was therefore with much surprise on the part of the public that the announcement was received last year of the deer in Richmond Park being attacked by the malady.

Apart from the general interest attaching to the welfare of the public using the parks in which these animals are kept, and beyond the special interest felt by the veterinary profession in the clearing up of the diagnosis of this strange and novel condition, the outbreak was of importance as affording a fresh opportunity of investigating the character of the malady under, as it were, new circumstances, and hence we find in the reports of this epizooty recently furnished to the Privy Council by Mr. Cope and Prof. Horsley, many points which fill up certain blanks in our scientific information on the subject.

The prevention of rabies in all animals we have shown before to be the simplest task imaginable for the health authorities of this country to undertake, and nothing illustrates this more clearly than the history of the recent epidemic, which attracted so much notice on account of its excessive mortality, and which terminated by causing the local mischief which forms the ground of this article.

It will be remembered that in 1884 rabies began to increase in the London and home counties districts. No notice being taken of its spread, it soon produced a severe effect, when in 1885 the numerous deaths (twenty-seven) among human beings caused a popular panic, and led the authorities to institute measures for its repression. The authorities in the London district having provided for the merciful extirpation of stray dogs, the familiar vehicle of the disease, secured the non-transmission of the virus by enforcing the use of muzzles. The result of their work during 1886 has been seen during 1887, in the practically total immunity of the population of this great city from this the most justly dreaded of all diseases. Let us not forget to add in passing that as was pointed out at the time of the expiration of the local regulations by those acquainted with the malady, that the measures being but local could only produce a temporary relief from the evil, since the metropolis was continually being infected from districts beyond the reach of the regulations, and that though it could be kept free for a time, yet reintroduction of the virus would certainly occur, and the work would have to be done all over again. This is actually now happening, though not yet officially declared. The disease has reappeared (as it has usually done) in the southern suburbs, and is gradually making its way into the metropolis.

But to return. The epidemic of 1885 terminated in the London district with the infection of the roe deer in Richmond Park, resulting in the extermination of several hundreds of these valuable and pretty animals. From Mr. Cope's interesting report it appears that the first to be seized was a doe which had a suckling fawn, and as we learn from the very valuable evidence of Mr. Sawyer, the head-keeper of the Park, it seems that under these circumstances a doe will attack a dog attempting to worry the herd, as a rabid dog passing through the Park would do. Fortunately in the Richmond case no instance occurred of the transmission of the disease from the deer to man through the dog as in an outbreak recorded in 1856 at Stainborough. Had this happened, the deaths of the deer would not have been attributed to various causes, poisoning, &c., as they now were until the remarkable aggressiveness of the affected animals led to a thorough investigation by the veterinary advisers of the Government. Rabid deer were sent for observation to the Veterinary College, and the symptoms noted. The exact determination yet remained to be made, and, thanks to the recent researches of M. Pasteur, this was now possible. Portions of the central nervous system from these animals were sent to the Brown Institution, and there inoculated by Prof. Horsley into rabbits by the subdural method. These animals died after exhibiting the characteristic symptoms of rabies, and after death the usual *post-mortem* appearances were duly discovered. More infected deer were sent also to the Brown Institution, and the extraordinary changes effected by the disease more closely studied. This kind of deer, naturally gentle and timid, was transformed into a fierce and savage animal, rivalling the rabid horse almost in its attempts to do mischief. The early symptoms, as in all animals, appear to have been indicative of mental hallucination, for the animals would stop feeding, hold up their heads, sniff the air, and then, without the slightest reason, burst into a gallop. When placed in confinement the least noise attracted their attention, and later—*i.e.* on the second and third day—caused them to charge in the direction of the sound. The mental perversion which leads a rabid dog one moment to lick with almost frantic energy a healthy dog placed with it, and then the next moment to violently bite it, finds its parallel in the deer similarly affected, for these animals in a like manner licked their companions, and then ferociously attacked them, seizing them with their jaws (usually about the shoulders) and tearing off hair and pieces of skin. The points thus inoculated with the virus after cicatrization became, as is almost invariably the case, the seat of intense irritation when the disease actively showed itself; hence one of the most prominent signs presented by the animals was that of their rubbing themselves with such force as to make these parts raw. In connection with the differences which are now known to be characteristic of the same disease in different classes of animals, it is interesting to note that in all large animals, whatever be the previous temperament, the course of the malady is closely identical; thus in the horse, the ox, the sheep, the pig, the deer, &c., the illness is rapid, there is great aggressiveness, and yet early paralysis. It is of common knowledge that in the dog these two latter features are sometimes widely separated. The paralysis may set in so soon as to obliterate aggressiveness, and thus a distinct form (dumb) of rabies be produced, though of course the aggressive form of the disease always ends in paralysis if not suddenly arrested by syncope. In the deer the combination of the two symptoms seems to have been very equal. For even when the animal had fallen down from paresis (of the hind-limbs more especially) it would nevertheless spring up and attempt to seize and worry with its teeth every person or object

coming within its reach. The complete metamorphosis of the usual temper of the animal is of course only to be explained by profound mental disturbance, exactly as seen in the human being. We have alluded to the mode of transmission of the disease—viz. through the saliva. This mode was put to direct experiment by an infected animal being placed with a healthy one which had been isolated for some time, and the incubation period was determined in this instance to be nineteen days, the comparative shortness of the period being no doubt due to the very numerous points of inoculation. An interesting and confirmatory circumstance of the reality of this method of transmission was afforded by the fact that so long as the bucks retained their horns they were able to literally stave off infection, but as soon as these natural means of defence fell off at the usual periods, both sexes suffered alike.

The mode of death seems in all cases to have been ultimately cardiac failure, which supervened frequently before the customary coma, the final stage of paralysis, was developed. Relatively, syncope occurred much more frequently than it does in the human subject, and *a fortiori* than it does in the dog, a circumstance explicable by the necessarily extremely fatiguing nature of the fits of excitement to which deer are evidently specially liable in the early development of the disease. According to Prof. Horsley's pathological report, both macroscopic and microscopic appearances of the affected tissues revealed the usual lesions which are symptomatic of rabies. This last fact is a healthy sign of scientific progress, for any layman who has sought to obtain from books or verbal statements made by those justly recognized as being qualified to speak with authority on this subject must have been disappointed with the uncertainty of knowledge which has prevailed respecting the morbid anatomy of rabies up to the present time. The obscurity which existed on this point was aggravated no doubt by the absurd popular superstitions connected with the disease, and by the failure to recognize that it was simply a very severe kind of one of the acute specific maladies. From the latter cause especially has confusion arisen, since it will be found that previous records of the *post-mortem* appearances fallaciously comprehend the examination of animals dying at all possible stages of the malady. But now we know these points accurately; and as in this particular case the subject has been so thoroughly worked up, there will be scarcely any excuse for the disease escaping immediate recognition and adequate treatment.

Here we cannot help pointing out what a very grave injury is inflicted on the public by the vexatious operation of the so-called Vivisection Act, which prevents the veterinary inspector from at once resorting to M. Pasteur's admirably simple and conclusive method of testing the real condition of any animal killed under the suspicion of rabies. Under the present *régime* valuable time is lost, and risk incurred of the inoculative material becoming useless from decomposition, &c., by reason of his being compelled to forward it to some such institution as the Brown for examination. The very valuable observation recently published by M. Pasteur's assistant Dr. Roux, that the immersion of the tissue in a mixture of glycerine and water prevents septic change, but does not mitigate the influence of the virus, to a slight extent obviates part of the difficulties and inconvenience just noted, but the anomaly still remains that, while the immense value of the experimental test has received the full recognition of the recent Committee of the House of Lords, the law does not permit it to be used except in one, or at the outside two places in Great Britain, which have with the usual difficulties and obstruction succeeded in obtaining the necessary permission. No one perhaps supposes that the benefits which science offers to the public will ever be received with anything like adequate acknowledgment of the difficulties, and it may be dangers, which have attended this or that particular discovery. But we think that it cannot be recognized by the mass of the people who actually or theoretically direct the Legislature by their votes, that, while they eagerly reap the benefits of the harvest of science, at the same time they permit that harvest to be choked by the tares of legislative obstruction, and thus very greatly diminish the profits which would otherwise be theirs.

Just as we are much behind other nations in the foundation of technical instruction, so we are being fast outstripped in the provision for means for the scientific investigation of matters which, like the one we are now considering, greatly concern the public welfare. We believe it to be a fact that at the present moment neither of the two great Government Departments which are concerned in the scientific arrest of national disease, viz. the Privy Council and the Local Government Board, have any laboratory whatever at their disposal, and consequently are obliged to seek the necessary accommodation in private institutions; or, to put it in plain language, the Government is not ashamed to get its public work done by the favour of private means. The Berlin Laboratory and the Pasteur Institute should serve as the kind of example which a statesman whose desire for the improvement of the country and the people is not a question of votes but of genuine interest might study with advantage.

Those gentlemen, unfortunately few in number, who represent science at the present moment in Parliament, would have a large field of good work open to them if they attempted to reform this state of affairs by adjusting the advantages and assistance offered by science to the real needs of the nation. At present the actual opinion of the scientific world on any subject of special interest is usually only extracted with difficulty by evidence before a Select Committee. It would be very easy for the scientific members of the House to concentrate their force by previous meeting and organization, and so to give weight to that side in a debate which was truly working for the best solution of any national problem involving health and disease. In former years, the opinion of unscientific persons has been sought on the subject of rabies as being of equal weight with the assured observations of scientific experts. This lamentable state of things has led to the present condition of our legislation against this disease, under which the malady is but temporarily, if readily, stamped out in one district alone; this same district becoming infected again from neighbouring parts of the country as soon as the regulations are withdrawn. There is no doubt from the minutes of the Lords Committee on Rabies, that the Report of that Committee was drafted in this unfortunate manner owing to the influence of Lords Mount-Temple and Onslow, who, in their speeches and writings, have afforded numerous evidences of their complete want of scientific knowledge of the nature of the disease, and who, consequently, have failed to grasp the most obvious way in which it can be extirpated—namely, the universal application of preventive legislation. Mistakes of this kind, it seems to us, would be utterly prevented by combined action of the scientific members of either House, and if, as is sometimes our unfortunate duty, we have to chronicle ill-advised measures of suppositiously scientific officialism, let us hope they will not have passed out into law without a strenuous protest from the *united* voice of "our representatives."

THE COMING OF AGE OF THE "JOURNAL OF ANATOMY AND PHYSIOLOGY."

DURING the past summer there was established (as our readers have been informed), under the title of the "Anatomical Society of Great Britain and Ireland," a new brotherhood of anatomists; and the adoption by

it of the above-named journal as a medium for publication, taken in conjunction with the fact that the same has entered on its twenty-second year, affords a fitting opportunity for briefly reviewing its progress and prospects.

Of the work of the Society to which we have alluded it would be premature to judge. It has been founded in the cause of "those interested in the science of anatomy," and on glancing through its roll of members we see that the comparative and human anatomist are, at last, at work in a common cause. All modern experience shows it to be a truism that the study of human anatomy, if it is to bear good fruit, must be based upon the comparative method. It is well known that essays have long since been made, by certain leaders at home, and by Coues more especially in America, towards the realization of this dream: we will not pause to comment upon the somewhat tardy manner in which these have been received by human anatomists at large. The new Anatomical Society, as its constitution shows, is alive to the truth we have asserted, and, this being so, we shall follow with extreme interest the progress of the new brotherhood, which, if properly ordered, cannot fail to exercise a most beneficial influence upon the healing art.

The journal which the founders of the new Society have selected as their mouth-piece has had, thus far, a successful run. To its pages most of our leading anatomists and physiologists have contributed, and within its covers lie papers which have revolutionized the particular departments of knowledge with which they deal. Fifteen months ago it entered, under a change of publishers, upon a "new series"; and more recently it has, under its extended auspices, as might be expected, shown signs of increase in bulk. Its editors have been ever indefatigable, and most willing to oblige all who have applied to them; but the limit of their generosity has most certainly been reached, and, unless we are sadly mistaken, they will before long find it necessary to reconsider their scheme. In anticipation of this, and in the interests of workers in general, we would advise a more judicious selection and revision of matter tendered for publication than is at present adopted. In the current number we find thirteen papers presented in all—some of great merit, others of a more questionable character. In one of them we read at the outset the remarkable statement that "the minute anatomy of the skin of the horse has never before been described," and at the conclusion the erroneous assertion that "having got perfectly free from the old hair the (hair-) papilla now commences secreting again." On reading this and certain other papers which have been published of late, we cannot close the volumes without being struck with the general looseness and absence of all regard for authority which pervade them. This should not be. To papers such as these the worker turns for originality, or, failing that, for at least a *résumé* of work done up to the time of writing: their multiplication, in the unsatisfactory form to which we now reluctantly call attention, is regrettable, and, in the interests of a literature already overburdened, greatly to be deplored.

By way of further insuring the restriction of the publication within reasonable limits, we would urge the exclusion from the body of each issue of pure compilations and papers wholly controversial—such, for example, as one a short time ago devoted to a consideration of the relations of the Mammalia to the lower Vertebrata, and others which could be named. Productions such as these, containing nothing original, and occasionally but a portion of that which is known on the subjects under review, should be dealt with as supplementary matter. We hear a great deal nowadays, on all hands, about the scant recognition of work done by our countrymen. The retention of papers such as those to which we have alluded, in an authoritative journal like the one before us, cannot fail to call forth the unwelcome "*enthält nichts neues*"; and if it be persisted in, is it not likely that we may yet have to thank ourselves, in a measure, for the supposed want of respect?

Far be it from us to discourage the efforts of individual workers. In calling attention to these defects we merely desire to guard against reproach. If the journal whose interests we are seeking is to continue its useful work done in the past, and to do justice to the best interests of its new supporters in the future, some such deliberate modifications as those to which we have pointed are called for. Far-reaching interests will not excuse inauthoritativeness, and, if the new leaven is to work its best, the rising generation of anatomists will not tolerate inefficiency.

NOTES.

BARON VON SCHWERIN, the Swedish explorer, has presented his whole collection of ethnographical objects, gathered during the last two years' journeys in Africa, to the National Ethnographical Museum at Stockholm. The collection is the largest and most valuable ever presented to this institution by any private person.

ADMIRAL SIR ASTLEY COOPER KEY died suddenly last Saturday. He was in his sixty-seventh year. He had seen much active service, and had held some high appointments, including that of Principal Naval Lord of the Admiralty, and Director of the Royal Naval College, which owed much to his endeavours to apply science to the wants of the Navy.

THE Swedish Government has decided to expend £3000 on a new botanical museum at the Lund University.

THE eighth German Geographentag will be held at Berlin on April 4, 5, and 6.

FROM July 25 to 31 there will be held in Paris, in the rooms of the Medical School, a meeting of the Society for the study of Human and Animal Tuberculosis, under the presidency of Profs. Chauveau and Villemin. Interesting communications and papers are expected.

THE Chair of Psychology to which M. Ribot has been appointed has long existed in the Collège de France, and was not, as has been stated, established by the Paris Municipal Council. This Chair must not be confounded with that of *Philosophie Biologique*, which the Council is creating for Prof. Giard.

A SHORT course of lectures on "The Protection of Buildings from Lightning," by Prof. Oliver J. Lodge, F.R.S., to be delivered under the title of the "Dr. Mann Lectures," as a memorial of the late Dr. Mann, will be begun on Saturday afternoon next, March 10, at the Society of Arts. The course will consist of two lectures, the first of which will take the form of a slight historical sketch, and will call attention to the outstanding questions, difficulties, and points of controversy in connection with lightning-conductors. At the second lecture experimental answers will be given to some of the questions raised, and an endeavour will be made to supply a more complete account of the liability of conductors to side-flash than has yet been attempted. The chair will be taken at 3 o'clock.

LAST Saturday, Sir James Paget delivered an interesting address to the students attending University Extension Lectures in London. His subject was "Scientific Study," and he showed in a remarkably clear and striking way how the study of science develops the power of observation, fosters accuracy of thought, gives men a vivid conception of the difficulty of attaining to a real knowledge of the truth, and makes them familiar with the methods by which they may pass from that which is proved to

the thinking of what is probable. He also offered illustrations of the power of science to minister to the needs of ordinary life, and to satisfy man's "insatiable appetite for the knowledge of wonders." Such addresses as this, delivered by acknowledged masters in their own departments of study, do excellent service to science by bringing prominently before the public the solid advantages which are to be gained by scientific training. They are also made the occasion of some good writing in the daily newspapers. The *Daily News*, for example, had an excellent article on Sir James Paget's address, enforcing the principle that "the study of science goes further than other studies to teach us the simple love of truth for truth's sake."

THE *Japan Weekly Mail* states in connection with the recent publication of the "Life and Letters of Charles Darwin" that the *Beagle*, in which Darwin made his memorable voyage, is now used as a Japanese training-ship. It is stationed at Yokosuka, a naval station in the Bay of Yedo, not far from Yokohama.

THE Directors of the Crystal Palace have arranged that the Photographic Exhibition shall remain open until March 17, a fortnight later than was at first intended. The public interest in this Exhibition is said to have exceeded the most sanguine expectations.

THE Council has reported to the Senate of the University of Cambridge against the admission of women to degrees.

AT the University of Zürich there are at present forty-five female students, twenty-nine of whom study medicine, fourteen philosophy, and two political economy. In 1887 there were 108 female medical students in Paris.

A NEW and most valuable method of determining the molecular weights of non-volatile as well as volatile substances has just been brought into prominence by Prof. Victor Meyer (*Berichte*, 1888, No. 3). The method itself was discovered by M. Raoult, and finally perfected by him in 1886, but up to the present has been but little utilized by chemists. It will be remembered that Prof. Meyer has recently discovered two isomeric series of derivatives of benzil, differing only in the position of the various groups in space. If each couple of isomers possess the same molecular weight, a certain modification of the new Van't Hoff-Wislicenus theory as to the position of atoms in space is rendered necessary; but if the two are polymers, one having a molecular weight n times that of the other, then the theory in its present form will still hold. Hence it was imperative to determine without doubt the molecular weight of some two typical isomers. But the compounds in question are not volatile, so that vapour density determinations were out of the question. In this difficulty Prof. Meyer has tested the discovery of M. Raoult upon a number of compounds of known molecular weights, and found it perfectly reliable and easy of application. The method depends upon the lowering of the solidifying point of a solvent, such as water, benzene, or glacial acetic acid, by the introduction of a given weight of the substance whose molecular weight is to be determined. The amount by which the solidifying point is lowered is connected with the molecular weight M by the following extremely simple formula: $M = T \times \frac{P}{C}$; where C represents the amount by which the point of congelation is lowered, P the weight of anhydrous substance dissolved in 100 grammes of the solvent, and T a constant for the same solvent readily determined from volatile substances whose molecular weights are well known. On applying this law to the case of two isomeric benzil derivatives the molecular weights were found, as expected, to be identical, and not multiples; hence Prof. Meyer is perfectly justified in introducing the necessary modification in the "position in space" theory. Now that this generalization of Raoult is placed upon a secure basis, it takes its well-merited rank along with that of Dulong and Petit as a most valuable means of checking molecular weights, especially in determining which of two or more possible values expresses the truth.

A REPORT on Indian fibres and fibrous substances exhibited at the Colonial Exhibition, 1886, has been published by authority of the Secretary of State for India. It contains the results of a laboratory investigation conducted by C. F. Cross, E. J. Bevan, and C. M. King, in association with E. Joynson; and Dr. George Watt contributes notes of methods of treatment and uses prevalent in India. In issuing the volume, the authors say that perhaps the utmost they can hope to do is to indicate the scope of a more adequate treatment of the subject. They are convinced that when the vegetable fibres come to be recognized as constituting a special field for research, and worthy the attention of those who have command of the necessary resources, there will be a considerable gain to science in the results of the systematic and sustained investigations which will follow.

MESSRS. LONGMANS AND CO. are preparing for publication "The Testing of Materials of Construction," embracing the description of testing machinery and apparatus auxiliary to mechanical testing, and an account of the most important researches on the strength of materials, by William Cawthorne Unwin, F.R.S.; "A Text-book of Elementary Biology," by R. J. Harvey Gibson, Lecturer on Botany in University College, Liverpool; "Dissolution and Evolution and the Science of Medicine," by C. Pitfield Mitchell; and "The Fundamental Principles of Chemistry practically taught, by a New Method," by Robert Galloway, Honorary Member of the Chemical Society of the Lehigh University, U.S.

MESSRS. SWAN SONNENSCHEIN, LOWREY, AND CO. are issuing, in parts, what promises to be a most useful publication—"The Cyclopædia of Education."

A FIFTH edition of Munro and Jamieson's "Pocket-book of Electrical Rules and Tables" has been issued. The first part of this excellent little volume deals with the fundamental principles and measurements of the science; the second part with their applications, including telegraphy, telephony, electric lighting, and the transmission of power by means of electricity. In the new edition many important additions have been made.

WE have received Part I. of "The Characeæ of America," by Dr. T. F. Allen. The author has postponed the publication of the work from time to time in order to accumulate material for a more complete account of the species growing in America. The demand in America for information concerning these plants is, however, so pressing that Dr. Allen has thought it best to issue the first part, which contains introduction, morphology, and classification. The second part will appear in a year or two, and will give descriptions of the species now known to inhabit American waters. The work is illustrated.

THE new number of the Proceedings of the American Philosophical Society (July to December, 1887), contains, among other important papers, a valuable "Contribution to the History of the Vertebrata of the Trias of North America," by E. D. Cope. There are also interesting papers on the question, "Were the Toltecs an Historic Nationality?", and on the ethnology of British Columbia, the former by D. G. Brinton, the latter by F. Boas.

MM. BEAUREGARD AND GALIPPE, of Paris, have issued a second edition of their practical guide to micrographical work. It has been much enlarged.

M. REINWALD, of Paris, has just brought out the first volume of MM. C. Vogt and Yung's "Anatomie comparé pratique."

THE Report on the Administration of the Meteorological Department of the Government of India for the financial year 1886–87 gives interesting details of the work carried on in the various provinces, and of the inspection of the stations. The observatories now number 135; three have been established in the new territory of Upper Burmah, where scarcely anything is yet known about the meteorology. Rainfall is registered at 486 stations, and bright sunshine at six observatories. Ground temperature is recorded at five selected stations, and some of the results are of great interest, showing that the average temperature of the ground in India is about 5° above that of the air; and also that there is a small oscillation of many years' duration, amounting to about 4°, affecting the air temperature and the intensity of solar radiation. Considerable attention is paid to the laws of drought, and the hope is expressed that by degrees they may be established on a sound physical basis. The influence of forests on rainfall has been fully discussed, and the evidence afforded is favourable to the assumption that forests increase the rainfall. The work of marine meteorology also is actively prosecuted; the weather charts of the Bay of Bengal have been lately mentioned (NATURE, December 8, 1887, p. 137). A work on the storms of that district is in course of preparation, and it is proposed to draw up a hand-book on the subject, for the use of seamen.

UNDER the title of "Deutsche ueberseeische meteorologische Beobachtungen," the Hamburg Meteorological Office has commenced a new publication containing observations made under its auspices abroad. The first part contains observations made at six stations in Labrador from September 1883 to December 1884. These stations were equipped in August 1882 as supplementary to the International Polar Expeditions, and, as the missionary observers were willing to continue the observations, and the stations are important owing to the passage of many barometric depressions over Labrador, it has been decided to retain them. The other stations for which observations are published are Hatzfeldhafen (New Guinea) and Walfish Bay (West Coast of Africa). Future parts are to be published as soon as another year's observations are received from Labrador, and will include observations received from other stations in the meantime.

THE Pilot Chart for the North Atlantic Ocean for the month of February draws attention to the great danger to Transatlantic navigation from icebergs and field ice, from the present time and until the end of August. The ice is liable to be encountered off the Grand Banks as far south as 42° N., and between the 42nd and 52nd meridians. It is pointed out that too much reliance should not be placed on the use of the thermometer, and that warning may often be obtained by means of the echo thrown back from the surface of an iceberg when a whistle is sounded, or any sharp noise is made.

THE Chief Signal Officer of the United States has issued a new edition of "Instructions to Observers of the Signal Service" (Washington, 1887, 142 pp. large 8vo). The "Instructions" are most complete, and contain information which will be very useful to observers in all countries, and many points that will be novel to English readers. On the establishment of a station, a local committee of management is formed, the chairman of which corresponds directly with the Signal Office, and a detailed report on the working of the station is furnished each year. All barometrical observations are to be reduced for gravity at lat. 45°, and complete directions are given for removing air from both barometers and thermometers. Instead of the usual drawings of the instruments, detailed plans of all their separate parts are given; by this means observers obtain an accurate knowledge of their construction. The observation of clouds is referred to seven types only. Full directions are given for drawing weather maps from telegraphic reports, and, finally, a good list of works recommended for study, and the necessary tables for reduction, complete the volume.

A REMARKABLE achievement in transportation of live fish a great distance is described by M. Jousset de Bellesme in a recent number of the *Revue Scientifique*. The aquatic fauna of Chili being very poor, a selection of fish, comprising 100 Californian salmon, 40 carp, 20 tench, 20 gudgeon, with a number of eels, barbs, minnows, lotes, &c., were despatched from Paris in September last to stock the waters. The voyage, of about a month, was, of course, a very trying one in this relation, especially as regards variation of temperature. In treatment of the fish care was taken to lessen the activity of their functions by refrigeration and starvation (a carp will live fifty days without food), and a continuous air circulation was kept up in the water (which was not renewed). There was some loss among the salmon, but thirty-nine were successfully installed at Santiago; and the other groups were mostly intact. Only the gudgeons, lotes, and barbs, suffered serious loss. The experiment seems to prove the possibility of carrying alive the most delicate fish from any point of the globe to any other point. It was also ascertained that a temperature of 23° C. is not hurtful to the health of alevins of *Salmo quinat*, as might have been feared. The expense of the transport was considerable, but was willingly borne by the Chilian Government, in view of future advantage to the country.

THE *Zoologist* for March reprints an extraordinary pamphlet, entitled, "An Account of Wolves nurturing Children in their Dens." This pamphlet was printed at Plymouth in 1852, and has long been out of print. On the wrapper of a copy in the Zoological Library of the Natural History Museum at South Kensington there is the following memorandum in the handwriting of the late Colonel Hamilton Smith:—"This account, I am informed by friends, is written by Colonel Sleeman, of the Indian army, the well-known officer who had charge of the Thugg inquiries, and who resided long in the forests of India." The writer records a number of cases of children who are said to have been nurtured by wolves in India. In one instance a large female wolf was seen to leave her den followed by three whelps and a little boy. This happened near Chandour, ten miles from Sultanpoor, in the year 1847. The boy went on all fours, and ran as fast as the whelps could. He was caught with difficulty, and had to be tied, as he was very restive, and struggled hard to rush into holes and dens. When a grown-up person came near him he became alarmed, and tried to steal away. But when a child came near him he rushed at it with a fierce snarl, like that of a dog, and tried to bite it. When cooked meat was put near him he rejected it with disgust; but when raw meat was offered he seized it with avidity, put it on the ground under his hands, like a dog, and ate it with evident pleasure. He would not let anyone come near him while he was eating, but he made no objection to a dog coming and sharing his food with him. The trooper who captured the boy left him in charge of the Rajah of Hasunpoor, who sent him to Captain Nichollets, commanding the first regiment of the Oude Local Infantry at Sultanpoor; and some interesting notes as to the boy's habits are given on this officer's authority. He died in August 1850; and after his death it was remembered that he had never been known to laugh or smile. He used signs when he wanted anything, and very few of them except when hungry, and he then pointed to his mouth. When his food was placed at some distance from him, he would run to it on all fours, like any four-footed animal, but at other times he would walk uprightly occasionally. He shunned human beings, and seemed to care for nothing but eating. If the pamphlet can be proved to be perfectly trustworthy, it certainly deserves to be carefully studied by anthropologists.

THE last issue (Heft 37) of the German Asiatic Society of Japan contains a lengthy paper, with numerous tables of analyses, on the food of the Japanese, the authors being Dr. Kellner and M. Mori. They refer at the outset to the extraordinary differences of opinion amongst various writers as to the exact nature of the staple diet of the Japanese people. One writer says it is almost wholly boiled rice flavoured with small quantities of fish or pickled vegetables; another says that, as far as means allow, it is a mixed, and not a purely vegetable diet, and therefore physiologically ample; a third that it is almost wholly vegetarian; a fourth, that as much animal food is consumed in Japan as in Germany, Austria, France, and the Danubian Principalities; and so on. All the writers here quoted are modern men of science who have resided in Japan, and have therefore had ample opportunities for forming an accurate opinion. As to beef, however (there is no mutton in Japan), there can be no question that its consumption is very small. In 1882 only 36,288 beasts were slaughtered, or about 1 kilogramme of meat per head of the population, and it must be borne in mind that a large consumption takes place at the open ports amongst Europeans, and in the proximity of vessels. The conclusions to which the present writers—one of them, it will be noticed, being a native investigator—come is that the food of the Japanese people varies so considerably that, from a physiological point of view, no single proposition can be laid down respecting it. There are two main groups to be distinguished: in one, the people from poverty are compelled to be vegetarians, and use a diet which leaves much to be desired in its effect in strengthening the body; those in the second group are able to obtain animal food from the sea with some ease, and therefore use a mixed diet, which in kind and quantity appears ample. Between these two extremes we find all kinds of diet. The authors have not only made analyses of the various food-stuffs of Japan, but have investigated in various public institutions, from prisons to schools for army officers, the effect of various classes of food on the labour and weight of different persons.

ON February 10, at 12.40 a.m., a brilliant meteor was seen at Venersborg, in Sweden. It went in a direction from south to north, and was surrounded by an intense blue light. It was seen to fall to the earth some considerable distance off, but no sound could be heard.

DR. ROBERT FRIES, a Swedish botanist, has completed a memoir on the fungus-flora of the south-west coast of Sweden on which he has been engaged for a number of years. It embraces 865 varieties.

PROF. SVEN LOVÉN, the "Nestor of Swedish science," recently completed his seventy-ninth year, when he received numerous congratulations from friends at home and abroad. He is at present engaged in publishing a catalogue by Linnæus of the Lovisa Ulrika Museum in Sweden, which will be accompanied by numerous illustrations and explanatory notes from a modern scientific point of view by Prof. Lovén.

THE report of the Norwegian Association for the Preservation of Archæological Remains for last year shows that thirty-one barrows were opened in 1887 by the Association at Tvetene, in the parish of Brunlanæs, all of which were found to date from the early Iron Age. Some 146 objects of various kinds were found. These objects were added to the Museum of the Christiania University.

THE well-known Norwegian naturalists, M. Michelet and Dr. Bahrt, have introduced a Bill into the Storthing, prohibiting the killing of any birds (except birds of prey, ravens, rooks, and magpies) in the whole of Norway during the period April 1 to August 15, also the taking of eggs or young birds. The chief object of this Bill is to put a stop to the present wanton destruction of birds by foreign "sportsmen."

MR. F. S. WELLS, of Southgate, has sent us four photographs of the lunar eclipse of January 21 last. Considering the small size of the photographs, they are very interesting, and Mr. Wells tells us that they were taken without costly apparatus. In the original negatives the images were merely seven-sixteenths of an inch. Mr. Wells enlarged them five diameters.

MR. R. COPELAND writes to us:—"I have just learnt from Leipzig that Prof. Krehl is the University Librarian at that place, and not Virchl as printed in Dr. Muir's letter on p. 246, and repeated by me on p. 344 of NATURE." Mr. Copeland also mentions that the "Demonstratio eliminationis Cramerianæ" was duly entered under De Prasse by Mr. R. Tucker, Hon. Sec. Mathematical Society, when drawing up the catalogue of the "Mathematical and Scientific Library of the late Charles Babbage" in 1872. This library forms the nucleus of Lord Crawford's collection of scientific books.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Captain R. F. Hibbert; a Common Raccoon (*Procyon lotor*) from North America, presented by Mr. C. J. Urquhart; a —— Civet (*Viverricula* ——) from China, presented by Mr. Percy Montgomery; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Mrs. Mars Buckley; twelve Black-headed Gulls (*Larus ridibundus*), a Common Gull (*Larus canus*), British, presented by Mr. J. G. Barker; five Prince of Wales's Pheasants (*Phasianus principalis* ♂ ♂ ♀ ♀ ♀) from Afghan Turkistan, presented by Major Peacock, R.E.; a Cape Eagle-Owl (*Bubo capensis*), five Angulated Tortoises (*Chersina angulata*), three Areolated Tortoises (*Homopus areolatus*), a Natal Sternothere (*Sternothærus castaneus*), a Smooth Snake (*Homolosoma lutrix*), an Infernal Snake (*Boodon infernalis*), a Rufescent Snake (*Leptodira rufescens*), a Spotted Slowworn (*Acontias meleagris*), five Round-throated Frogs (*Rana fuscigula*), a Narrow-headed Toad (*Bufo angusticeps*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Natal Sternothere (*Sternothærus castaneus*) from South Africa, presented by Colonel J. H. Bowker, F.Z.S.; two Cirl Buntings (*Emberiza cirlus*), British, purchased; a Hog Deer (*Cervus porcinus*), an Eland (*Oreas canna*), a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

TEMPEL'S COMET, 1867 II.—M. Raoul Gautier has published in the Memoirs of the Société de Physique et d'Histoire Naturelle de Genève, vol. xxix. No. 12, a discussion of the orbit of the comet discovered by Herr W. Tempel, at Marseilles, on April 3, 1867, with especial reference to its appearances in 1873 and 1879. There are several points of especial interest about this comet: not only was it an addition to the number of known comets of short period, but it possesses the peculiarity of an elliptic orbit of but slight inclination, and of less eccentricity than that of any other member of the same class. Its spectrum, too, would seem to be unusual, for the imperfect view of it obtained by Dr. Huggins, May 4 and 8, 1867, led him to conclude that the bright bands, which it gave together with a continuous spectrum, were not those of carbon. Its orbit, and especially its period, is also subject to great perturbations from the action of Jupiter, and its perihelion distance was considerably increased between 1873 and 1867 without its aphelion distance being much altered. It had also been identified by M. Winnecke with the comet observed by Goldschmidt at Paris, May 16, 1855, in a search for De Vico's comet, but von Asten's inquiries have shown that the identification was an erroneous one.

M. Gautier—though the perturbations due to Jupiter during the period 1873–79, with which he was principally engaged, have been but small, the two bodies being always distant from each other—has calculated the perturbations after the method of variation of the elements, since this method was most suitable

for the periods 1867–73 and 1879–85, and he wished to connect his calculation with those for the two other periods, which it is his intention to compute, and which he hopes to carry forward so as to furnish positions for the comet for its next return in 1892.

The following are the final results obtained by M. Gautier for the two appearances :—

	Second appearance, 1873. Mean equinox 1873·0.		Third appearance, 1879. Mean equinox 1879·0.		Mean errors common to both systems.
M_0	1873 April 15·0 = −4° 5′ 24″·177	M	1879 April 24·0 = −2° 10′ 2″·454	±	29″·35
μ =	592″·9765465	=	593″·1200165	±	0·000140

log a =	0·5179794	=	0·5179093		
log q =	0·2482605	=	0·2482463		
e =	0·4626205	=	0·4625512		

The time of perihelion passage is given in Berlin mean time.

The comet was not seen in 1885, and there seems distinct evidence, from the greater difficulty of observation in 1873 and more especially in 1879, that it has diminished in brightness at each succeeding return.

COMET 1888 *a* (SAWERTHAL).—The following elements have been computed for this comet by Mr. W. H. Finlay, Royal Observatory, Cape of Good Hope :—

T = 1888 March 17·18 G.M.T.

$$\left.\begin{aligned} \pi - ☊ &= 4^\circ\ 29' \\ ☊ &= 244\ \ 6 \\ \iota &= 43\ 57 \end{aligned}\right\}\ \text{Mean equinox 1888·0.}$$

$$\log q = 9·8354$$

Error of middle observation—

$$\Delta\lambda \cos\beta = -5'' \quad \ldots \quad \Delta\beta = -2''.$$

$$\begin{aligned} x &= [9·8927]\ r \sin(330^\circ\ 30' + v) \\ y &= [0·0000]\ r \sin(240\ \ 7 + v) \\ z &= [9·7954]\ r \sin(329\ 30 + v). \end{aligned}$$

The following ephemeris for Greenwich midnight has been computed by Dr. L. Becker, the perihelion passage having been increased by one day, as suggested by Prof. Krueger :

1888.	R.A. h. m.	Decl. ° ′	Log r.	Log Δ.	Brightness.
March 5	20 33·9	33 9 S.	9·865	9·956	1·5
13	21 3·4	20 29 S.	9·840	9·975	1·6
21	21 30·8	8 31 S.	9·838	0·008	1·4
29	21 57·5	1 58 N.	9·859	0·047	1·0
April 6	22 23·5	10 43 N.	9·898	0·088	0·7

The brightness on February 18 has been taken as unity.

THE TOTAL ECLIPSE OF THE MOON, JANUARY 28.—The following list has been received from the Pulkowa Observatory of the number of occultations observed at those observatories from which reports had been received up to February 17, in addition to those given in NATURE for February 2 (p. 333) :

Pulkowa	50	Padua	4
Tashkent	21	San Fernando	10
Turin	32	Strasburg	10
Belgrade	3	Bordeaux	21
Bothkamp	30	Kiel	36
Geneva	23	Collegio Romano	5
Neuchâtel	6	Wilhelmshaven	2
Kis Kartal	2	Marseilles	39
Paris	12	Liverpool	11
St. Petersburg	2	Bilk	8

At Helsingfors and Algiers they had also been successful.

The weather was cloudy at the following stations : Besançon, Breslau, Charkow, Dorpat, Dresden, Gotha, Gottingen, Hamburg, Jena, Kalocsa, Kasan, Kremzmunster, Leipzig, Munich, Nikolajen, Pola, Prague, Riga, and Upsala. Seventy-five observatories had not reported at the above-mentioned date.

VARIATIONS OF LUNAR HEAT DURING THE ECLIPSE OF THE MOON.—Dr. Boedicker succeeded in making a series of interesting experiments under favourable circumstances of the variations in the amount of heat radiated to us from the moon during the progress of the total eclipse of January 28. The observations were made with a Thompson's galvanometer used in connection with Lord Rosse's 3-foot reflector at Parsonstown, and commenced at 7h. 19m., or 1h. 10m. before the first contact with the earth's penumbra, and continued until 15h. 45m., or 1h. 34m. after the last contact. 638 readings were made in all. The principal deductions drawn from the observations were :—

(1) The heat radiated by the moon commenced to decrease long before the first contact with the penumbra.

(2) Twenty-two minutes before the commencement of totality the heat was reduced to less than 5 per cent. of that which it had been twenty minutes before the first contact with the penumbra.

(3) In spite of this rapid cooling at the approach of totality, the heat after the last contact with the penumbra did not remount immediately to the point where it had been before the first contact.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *MARCH* 11–17.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 11

Sun rises, 6h. 24m. ; souths, 12h. 10m. 1·3s. ; sets, 17h. 57m. : right asc. on meridian, 23h. 28·4m. ; decl. 3° 25′ S. Sidereal Time at Sunset, 5h. 16m.

Moon (New on March 12, 16h.) rises, 6h. 16m. ; souths, 11h. 23m. ; sets, 16h. 39m. : right asc. on meridian, 22h. 41·3m. ; decl. 10° 59′ S.

GEOGRAPHICAL NOTES.

MOUNT RORAIMA, in British Guiana, was ascended for the third time on October 14 last, by Mr. F. Dressel, an English orchid collector. The first ascent, it will be remembered, was by Mr. Im Thurn, in December 1884. The second was in November 1886, by Mr. Cremer, also an orchid collector. Mr. Im Thurn's ascent took place in the beginning of the wet season, when everything was saturated with moisture. Mr. Dressel ascended after continuous dry weather, and found the upper surface comparatively dry, the elevated portions most markedly so; while large areas of the sward-like levels were perfectly desiccated. The water in the various channels was very shallow, and the deep basins or depressions contained but very small quantities, though in no case was any found to be quite dry. Frequently the surface of the water in these shallow basins was more or less covered with a green, apparently a Confervoid, layer. In the pools at the bottom of these wide basins, Mr. Dressel found a considerable quantity of quartz, in the form both of separate crystals, and of aggregated masses, of various and often of large sizes. The presence of such quartz in such positions and under such conditions, *Timehri* points out, is an extremely interesting fact, though our want of knowledge of the petrographic character of the formation of the top of Roraima, beyond the fact of its being sandstone, renders it barren, and one hardly justifying speculation. It will be remembered that on the first ascent no animal life was noticed during the short time spent on the top; and this necessarily denoted the likelihood of the absence or great rarity of birds and insects. During the two or three hours spent on the top by Mr. Dressel, no birds were seen; but a few specimens of butterflies, all of one kind, of a dark brown and nearly black colour, were observed, and two of them were caught, though one alone was sufficiently preserved to show much of its structure. In the shallow basins a few forms of a small black toad with a yellow spot on the throat was also seen, and one was caught, but was accidentally left on the top. A third animal form was found in the moist earth attached to some plants which had been pulled up; from Mr. Dressel's description it is conjectured by *Timehri* to be a Millipede, allied to *Julus*. It is probable enough that a stay of a day or two on the top would well repay the naturalist; and Mr. Dressel thinks it would not be difficult to arrange for such a stay. The fantastic shape into which the sandstone has been fashioned, and the weirdness of the scenes which have been so graphically described by Mr. Im Thurn, affected Mr. Dressel in a similar manner. He mentions that the surface of the rocks present very closely the appearance of granite, owing to weathering; and at first he thought some mistake had been made in describing the formation as sandstone, until he moved away a small rock from its setting, when its real nature was revealed.

Timehri for December last contains a very interesting account by Mr. E. A. Wallace of a visit he paid to the Guahivos, an isolated tribe of Indians, living near the head of the River Meta, a tributary of the Orinoco, in the Republic of Columbia.

AT the last meeting of the Royal Geographical Society Mr. Robert Gordon read a paper on the Ruby Mines near Mogok, Burma. These ruby mines lie about 100 miles N.N.E. of Mandalay. The ruby-bearing region, so far as known, lies within an area ten miles long by five wide, and consists of groups of small valleys nestling beneath the Toung-Meh range, and to the south of it. The Enjouk valley to the north is said to yield rubies and sapphires, but they have not been regularly worked. The valleys arrange themselves into three groups of nearly equal area by the distribution of the watercourses. To the east a few streams unite to form the Yay-Nee, or red water, so called from the washings of red earth from the mines. The most remarkable thing, Mr. Gordon stated, in the Mogok and neighbouring districts, is the distinctness and diversity of races among the peoples in the different communities, who evidently have kept themselves from intermarriage with their neighbours for centuries, and a brief notice of the tribes whose types are found here may not be out of place. In Kathey, as the name implies, the villagers are Katheys, whose ancestors were brought as prisoners from Munnipore very long ago, as they have lost both the Hindoo religion and their own language. In Mandalay, Prome, and Henzadah, where bodies of the same people have been long transplanted, they keep their race and religion pure still. The ethnologist would find matter of intense interest in the interactions of some of these races upon each other, and perhaps the history of these transplanted Katheys would yield the most curious results. When surveying for the railway in the district south of Mandalay, Mr. Gordon found them extensively distributed throughout the country, always living separately in their own villages, and retaining many of their peculiar characteristics, even when they had become thoroughly Burmanized in their speech, religion, and general habits. They are colonies of pure Aryan race, retaining the features and colour and physique of their Indian ancestors, although surrounded for centuries by Turanians of great assimilating power, whose cordial hospitality and tolerance tend to modify and absorb most of the races coming into close contact with them. None of the yellow races of Burma, or Siam, or China, milk their cattle, and it is difficult when travelling in those regions to get a supply of this very useful article. Near Mandalay, and to the south of it, however, the Katheys have accustomed many of the Burmese to the use of milk, and it is perhaps the only part of Burma where it could be got in the country places. In Bama and other villages the people are Paloungs, who keep up intercourse with the tea-growing Paloungs on the hills to the east, and preserve their language, although, like the Katheys, they have become Buddhists. Less is known of the Paloungs than of most of the great tribes bordering on Burma. They differ in speech, and claim to differ in origin, from all their neighbours. They occupy a wedge-shaped territory of mountains and plateau between the Ruby Mines of Burma, the Shans, and China; their principal State being called Toung-baing, which has nominally been subject to Burma, but which, from its inaccessibility, has been practically independent. The region is known to the Burmese as the La-pet Toung, or Tea Mountains, as it is the part from which great supplies of tea in a dry or in a pickled state are brought. The Paloungs who cultivate it appear to be a quiet, unaggressive people; and they do not themselves bring their produce to the Burmese markets, but sell it to trading caravans of Shans and Panthays. In Kyatpyen the people claim to be of pure Burmese stock. They dress, however, in Shan costume of blue or white trousers and jackets, which is very unusual for the Burmese, whose ordinary costume resembles the Scotch kilt. In Mogok the permanent residents are Shans, but Burmanized. Separate communities of pure Chinese and of Mohammedan Chinese are found as permanent or as temporary residents. Beyond these principal peoples, we find in this small locality, attracted by its wealth and its markets, bodies of Mainthas and of Leesaws as temporary visitors. Although the Kachyens are near neighbours to the north, the powerful Shan State of Momeit prevents their irruption to the Ruby Mines. The Mainthas are either Chinese Shans of a different type from the main body, or are hill Chinese from the North-eastern Chinese Shan States. The Leesaws are hill-men of weaker physique, who occupy the mountain regions of Western Yunnan, and are found in isolated communities in the higher parts of the Northern Shan States. They are supposed to be of the same tribal origin as the Burmese; but to have been driven and kept in the more inhospitable hill tracts to the north.

ACCORDING to *Allen's Indian Mail*, Colonel Sartorius, of the 1st Beloochee Regiment, has made an interesting report on his recent journey through the Southern Shan and Red Karen country. At Saga iron ore is found in abundance. Tin is plentiful in Lower Kerennie, and coal at the Lowelon Mountain. Besides these, silver, sulphur, and saltpetre were also found. He describes Rosambhe Lake as being quite as beautiful as the lakes of Cashmere, and the Falls of Kazor, which are 130 feet in height, are perhaps the finest in the East.

OUR ELECTRICAL COLUMN.

LORDS CRAWFORD AND WANTAGE, Sir Coutts Lindsay, and others, have boldly thrown down the gauntlet to the gas people. They have taken ground at Deptford for a central station, and are going to supply electricity to London. They start with 200,000 lamps, and charge at the same rate as gas at 4*s*. 2*d*. per 1000 cubic feet.

THE Meteorological Society are promised a fine display of atmospheric electrical apparatus for exhibition at their meeting on March 20. Lightning protectors of all kinds will be shown.

THE introduction of the terms "magnetic resistance," and "magneto-motive force," as the analogues of electric resistance and electromotive force, with their ratios, magnetic flux and

electric current, is exercising the minds of electricians just now. Mr. Bosanquet has put it very clearly that when there is any opposition to a physical change of such a nature that it is the greater the greater the measure of the cause, and the less the measure of the effect, it is clearly a resistance; and in this sense the quotient of magneto-motive force (ampere-turns among practical men) by magnetic flux per unit area (magnetic induction) is clearly resistance. It must, however, not be forgotten, that magnetic permeability is the analogue of electrostatic capacity, and if we regard iron as the analogue of a dielectric or an insulator, the use of the term is wrong.

THE following relative figures of the cost of the production of 1000 watt-hours, the unit of electrical energy introduced by the Board of Trade, are given by Peukert in the *Centralblatt fur Electrotechnic.*

	s.	d.
Thermo-electric battery (gas)	33	4
Bunsen battery	3	2
Daniell ,, ...	2	2½
Dynamo (gas)	0	6¼
,, (steam)	0	2½

MENGARINI is continuing the work originated by Blaserna, by which the maturing of wine is considerably expedited by the passage of powerful currents through it.

HEIM (Hanover) has recently made some interesting measurements of the intensity of light emitted by various artificial sources of light in daily use:—

Lamps.	Candle-power.	Consumption per Candle per Hour.
Ordinary petroleum	15	3·65 grammes
Argand (gas)	21·9	10·9 litres
Welsbach (gas)	14·4	6·6 ,,
Wenham (gas)	28·4	8·77 ,,
Flat burner (gas)	16·9	14·8 ,,
Pieper arc, 6 mm.	377	·405 watts
Pilsen arc, 10 mm.	1420	·291 ,,
Siemens arc, 14 mm.	3830	·236 ,,
Siemens glow	16	3·25 ,,

VON LANG has measured the counter-electromotive force of an arc lamp, using 5 mm. carbons, and finds it 37 volts, or for Edlund's formula—

$$E = a + blC,$$

where a and b are constants, l the length of the arc, and C the current—

$$a = 35{\cdot}07,\ b = 1{\cdot}32,\ l = 2{\cdot}5 \text{ mm.},\ C = 5 \text{ amperes.}$$

He has found these constants for various other materials. Cross and Shepherd (Boston) had found this back electromotive force to be 39 volts. What is this so-called counter-electromotive force? Surely it is an abuse of terms.

MR. SHELFORD BIDWELL (Royal Society, March 1) is continuing his admirable researches on the changes produced by magnetism in the lineal dimensions of the different magnetic metals. He finds that iron, which first expands with the magnetizing force, soon reaches a maximum point, whence it retracts until it attains its original length; but, on still further increasing the magnetizing force, it contracts until it apparently reaches a minimum point, beyond which his means have not enabled him to proceed. Bismuth appears to continually expand; nickel to continually contract; whilst cobalt contracts, reaches a minimum point, and then expands, approaching its original length. Manganese steel was unaffected. His apparatus was so perfect and sensitive that he could read a variation of one hundred-thousandth of a millimetre.

PROFS. AYRTON AND PERRY have satisfactorily disposed of the question as to whether there is any difference in the light emitted by a glow-lamp when incandesced by alternate or direct currents. They find no difference. The same power (3·39 watts) applied gives the same light (one candle) in each case.

THE PRESIDENT'S ANNUAL ADDRESS TO THE ROYAL MICROSCOPICAL SOCIETY.[1]

RETROSPECT may involve regret, but can scarcely involve anxiety. To one who fully appreciates the actual, and above all the potential, importance of this Society in its bearing upon the general progress of scientific research in every field of physical inquiry, the responsibilities of President will not be lightly, whilst they may certainly be proudly, undertaken.

I think it may be now fairly taken for granted that, as this Society has, from the outset, promoted and pointed to the higher scientific perfection of the microscope, so now, more than ever, it is its special function to place this in the forefront as its *raison d'être*. The microscope has been long enough in the hands of amateur and expert alike to establish itself as an instrument having an application to every actual and conceivable department of human research: and whilst in the earlier days of this Society it was possible for a zealous Fellow to have seen, and been more or less familiar with, all the applications to which it then had been put, it is different to-day. Specialists in the most diverse areas of research are assiduously applying the instrument to their various subjects, and with results that, if we would estimate aright, we must survey with instructed vision the whole ground which advancing science covers.

From this it is manifest that this Society cannot hope to enfold, or at least to organically bind to itself, men whose objects of research are so diverse.

But these are all none the less linked by one inseverable bond; it is the microscope: and whilst, amidst the inconceivable diversity of its applications, it remains manifest that this Society has for its primary object the constant progress of the instrument—whether in its mechanical construction or its optical appliances; whether the improvements shall bear upon the use of high powers or low powers; whether it shall be improvement that shall apply to its commercial employment, its easier professional application, or its most exalted scientific use; so long as this shall be the undoubted aim of the Royal Microscopical Society, its existence may well be the pride of Englishmen, and will commend itself more and more to men of all countries.

This, and this only, can lift such a Society out of what I believe has ceased to be its danger, that of forgetting that in proportion as the optical principles of the microscope are understood, and the theory of microscopical vision is made plain, the value of the instrument over every region to which it can be applied, and in all the varied hands that use it, is increased without definable limit. It is therefore by such means that the true interests of science are promoted.

It is one of the most admirable features of this Society that it has become cosmopolitan in its character in relation to the instrument, and all the ever-improving methods of research employed with it. From meeting to meeting it is not one country, or one continent even, that is represented on our tables. Nay, more, not only are we made familiar with improvements brought from every civilized part of the world, referring alike to the microscope itself and every instrument devised by specialists for its employment in every department of research; but also, by the admirable persistence of Mr. Crisp and Mr. Jno. Mayall, Jun., we are familiarized with every discovery of the old forms of the instrument wherever found or originally employed.

The value all of this cannot be over-estimated, for it will, even where prejudices as to our judgment may exist, gradually make it more and more clear that this Society exists to promote and acknowledge improvements in every constituent of the microscope, come from whatever source they may; and, in connection with this, to promote by demonstrations, exhibitions, and monographs the finest applications of the finest instruments for their respective purposes.

To give all this its highest value, of course, the theoretical side of our instrument must occupy the attention of the most accomplished experts. We may not despair that our somewhat too practical past in this respect may right itself in our own country; but meantime the splendid work of German students and experts is placed by the wise editors of our Journal within the reach of all.

I know of no higher hope for this important Society than that it may continue in ever-increasing strength to promote, criticise, and welcome from every quarter of the world whatever will improve the microscope in itself and in any of its applications, from the most simple to the most complex and important in which its employment is possible.

There are two points of some practical interest to which I desire for a few moments to call your attention. The former has reference to the group of organisms to which I have for so many years directed your attention, viz. the "Monads," which throughout I have called "putrefactive organisms."

There can be no longer any doubt that the destructive process of putrefaction is essentially a process of fermentation.

[1] Delivered by the Rev. Dr. Dallinger, F.R.S., at the annual meeting of the Royal Microscopical Society, February 8, 1888.

The fermentative saprophyte is as absolutely essential to the setting up of destructive rotting or putrescence in a putrescible fluid as the torula is to the setting up of alcoholic fermentation in a saccharine fluid. Make the presence of torulæ impossible, and you exclude with certainty fermentive action.

In precisely the same way, provide a proteinaceous solution, capable of the highest putrescence, but absolutely sterilized, and placed in an optically pure, or absolutely calcined air; and while these conditions are maintained, no matter what length of time may be suffered to elapse, the putrescible fluid will remain absolutely without trace of decay.

But suffer the slightest infection of the protected and pure air to take place, or, from some putrescent source, inoculate your sterilized fluid with the minutest atom, and shortly turbidity, offensive scent, and destructive putrescence ensue.

As in the alcoholic, lactic, or butyric ferments, the process set up is shown to be dependent upon and concurrent with the vegetative processes of the demonstrated organisms characterizing these ferments; so it can be shown with equal clearness and certainty that the entire process of what is known as putrescence is equally and as absolutely dependent on the vital processes of a given and discoverable series of organisms.

Now it is quite customary to treat the fermentive agency in putrefaction as if it were wholly Bacterial, and, indeed, the putrefactive group of Bacteria are now known as Saprophytes, or saprophytic Bacteria, as distinct from morphologically similar, but physiologically dissimilar, forms known as parasitic or pathogenic Bacteria.

It is indeed usually and justly admitted that *B. termo* is the exciting cause of fermentive putrefaction. Cohn has in fact contended that it is the distinctive ferment of all putrefactions, and that it is to decomposing proteinaceous solutions what *Torula cerevisiæ* is to the fermenting fluids containing sugar.

In a sense, this is no doubt strictly true: it is impossible to find a decomposing proteinaceous solution, at any stage, without finding this form in vast abundance.

But it is well to remember that in Nature putrefactive ferments must go on to an extent rarely imitated or followed in the laboratory. As a rule the pabulum in which the saprophytic organisms are provided and "cultured," is infusions, or extracts of meat carefully filtered, and, if vegetable matter is used, extracts of fruit, treated with equal care, and if needful neutralized, are used in a similar way. To these may be added all the forms of gelatine, employed in films, masses, and so forth.

But in following the process of destructive fermentation as it takes place in large masses of tissue, animal or vegetable, but far preferably the former, as they lie in water at a constant temperature of from 60° to 65° F., it will be seen that the fermentive process is the work, not of one organism, nor, judging by the standard of our present knowledge, of one specified class of vegetative forms, but by organisms, which, though related to each other, are in many respects greatly dissimilar, not only morphologically, but also embryologically, and even physiologically.

Moreover, although this is a matter that will want most thorough and efficient inquiry and research to understand properly its conditions, yet it is sufficiently manifest that these organisms succeed each other in a curious and even remarkable manner. Each does a part in the work of fermentive destruction; each aids in splitting up into lower and lower compounds; the elements of which the masses of degrading tissue are composed; while apparently, each set in turn, does by vital action, coupled with excretion, (1) take up the substances necessary for its own growth and multiplication; (2) carry on the fermentive process; and (3) so change the immediate pabulum as to give rise to conditions suitable for its immediate successor. Now the point of special interest is that there is an apparent adaptation in the form, functions, mode of multiplication, and order of succession in these fermentive organisms, deserving of study and fraught with instruction.

Let it be remembered that the aim of Nature in this fermentive action is not the partial splitting of certain organic compounds, and their reconstruction in simpler conditions, but the ultimate setting free, by saprophytic action, of the elements locked up in great masses of organic tissue: the sending back into Nature of the only material of which future organic structures are to be composed.

I have said that there can be no question whatever that *Bacterium termo* is the pioneer of Saprophytes. Exclude *B. termo* (and therefore with it all its congeners) and you can obtain no putrefaction. But wherever, in ordinary circumstances, a decomposable organic mass, say the body of a fish, or a considerable mass of the flesh of a terrestrial animal, is exposed in water at a temperature of 60° to 65° F., *B. termo* rapidly appears, and increases with a simply astounding rapidity. It clothes the tissues like a skin, and diffuses itself throughout the fluid.

The exact chemical changes it thus effects are not at present clearly known; but the fermentive action is manifestly concurrent with its multiplication. It finds its pabulum in the mass it ferments by its vegetative processes. But it also produces a visible change in the enveloping fluid, and noxious gases continuously are thrown off.

In the course of a week or more, dependent on the period of the year, there is, not inevitably, but as a rule, a rapid accession of spiral forms, such as *Spirillum volutans*, *S. undula*, and similar forms, often accompanied by *Bacterium lineola:* and the whole interspersed still with inconceivable multitudes of *B. termo.*

These invest the rotting tissues like an elastic garment, but are always in a state of movement. These, again, manifestly further the destructive ferment, and bring about a softness and flaccidity in the decomposing tissues, while they without doubt, at the same time, have, by their vital activity and possible secretions, affected the condition of the changing organic mass. There can be, so far as my observations go, no certainty as to when, after this, another form of organism will present itself; nor, when it does, which of a limited series it will be. But, in a majority of observed cases, a loosening of the living investment of Bacterial forms takes place, and simultaneously with this, the access of one or two forms of my putrefactive monads. They were amongst the first we worked at; and have been, by means of recent lenses, amongst the last revised. Mr. S. Kent named them *Cercomonas typica*, and *Monas dallingeri* respectively. They are both simple oval forms, but the former has a flagellum at both ends of the longer axis of the body, while the latter has a single flagellum in front.

The principal difference is in their mode of multiplication by fission. The former is in every way like a Bacterium in its mode of self-division. It divides, acquiring for each half a flagellum in division, and then, in its highest vigour, in about four minutes, each half divides again.

The second form does not divide into two, but into many, and thus, although the whole process is slower, develops with greater rapidity. But both ultimately multiply—that is, commence new generations—by the equivalent of a sexual process.

These would average about four times the size of *Bacterium termo:* and when once they gain a place on, and about, the putrefying tissues, their relatively powerful and incessant action, their enormous multitude, and the manner in which they glide over, under, and beside each other, as they invest the fermenting mass, is worthy of close study. It has been the life-history of these organisms, and not their relations as ferments, that has specially occupied my fullest attention; but it would be in a high degree interesting if we could discover, or determine, what beside the vegetative or organic processes of nutrition are being effected by one, or both, of these organisms on the fast-yielding mass. Still more would it be of interest to discover what, if any, changes were wrought in the pabulum, or fluid generally; for after some extended observations I have found that it is only after one or other, or both, of these organisms, have performed their part in the destructive ferment, that subsequent and extremely interesting changes arise.

It is true that in some three or four instances of this saprophytic destruction of organic tissues, I have observed that, after the strong Bacterial investment, there has arisen, not the two forms just named, nor either of them; but one or other of the striking forms now called *Tetramitus rostratus*, and *Polytoma uvella;* but this has been in relatively few instances. The rule is that *Cercomonas typica*, or its congener, precedes other forms, that not only succeed them in promoting, and carrying to a still further point the putrescence of the fermenting substance, but appear to be aided in the accomplishment of this by mechanical means.

By this time the mass of tissue has ceased to cohere. The mass has largely disintegrated, and there appears amongst the countless Bacterial and monad forms, some one, and sometimes even three forms, that whilst they at first swim and gyrate, and glide about the decomposing matter, which is now, much less closely invested by *Cercomonas typica*, or those organisms that may have acted in its place, they also resort to an entirely new mode of movement.

One of these forms is *Heteromita rostrata*, which it will be remembered, in addition to a front flagellum, has also a long fibre, or flagellum-like appendage that gracefully trails as it swims. At certain periods of its life they anchor themselves in countless billions all over the fermenting tissues, and as I have described in the life-history of this form, they coil their anchored fibre, as does a Vorticellan, bringing the body to the level of the point of anchorage, then shoot out the body with lightning-like rapidity, and bring it down like a hammer on some point of the decomposition. It rests here for a second or two, and repeats the process; and this is taking place, by what seems almost like rhythmic movement all over the rotting tissue. The results are scarcely visible in the mass; but if a group of these organisms be watched, attached to a small particle of the fermenting tissue, it will be seen to gradually diminish, and at length to disappear.

Now, there are at least two other similar forms, one of which, *Heteromita uncinata*, is similar in action, and the other of which, *Dallingeria drysdali*, is much more powerful, being possessed of a double anchor, and springing down upon the decadent mass with, relatively, far greater power.

Now, it is under the action of these last forms, that in a period, varying from one month to two or three, the entire substance of the organic tissues disappears, and the decomposition has been designated by me "exhausted"; nothing being left in the vessel but slightly noxious, and pale gray water, charged with carbonic acid; and a fine, buff-coloured impalpable sediment at the bottom.

My purpose is not, by this brief notice, to give an exhaustive, or even a sufficient account, of the progress of fermentive action, by means of saprophytic organisms, on great masses of tissue: my observations have been incidental, but they lead me to the conclusion that the fermentive process is not only not carried through by what are called saprophytic Bacteria, but that a *series* of fermentive organisms arise, which succeed each other, the earlier ones preparing the pabulum or altering the surrounding medium, so as to render it highly favourable to a succeeding form. On the other hand, the succeeding form has a special adaptation for carrying on the fermentive destruction more efficiently from the period at which it arises, and thus ultimately of setting free the chemical elements locked up in dead organic compounds.

That these later organisms are saprophytic, although not Bacterial, there can be no doubt. A set of experiments recorded by me in the Proceedings of this Society some years since would go far to establish this (*Monthly Microscopical Journal*, 1876, p. 288). But it may be readily shown, by extremely simple experiments, that these forms will set up fermentive decomposition rapidly, if introduced in either a desiccated or living condition, or in the spore state, into suitable but sterilized pabulum.

Thus while we have specific ferments which bring about definite and specific results; and while even infusions of proteid substances may be exhaustively fermented by saprophytic Becteria; the most important of all ferments, that by which Natura's dead organic masses are removed, is one which there is evidence to show is brought about by the successive vital activities of a series of adapted organisms, which are for ever at work in every region of the earth.

There is one other matter of some interest and moment, on which I would say a few words. To thoroughly instructed biologists, such words will be quite needless; but, in a Society of this kind, the possibilities that lie in the use of the instrument are associated with the contingency of large error, especially in the biology of the minuter forms of life, unless a well-grounded biological knowledge form the basis of all specific inference, to say nothing of deduction.

I am the more encouraged to speak of the difficulty to which I refer, because I have reason to know that it presents itself again and again in the provincial Societies of the country, and is often adhered to with a tenacity worthy of a better cause. I refer to the danger that always exists, that young or occasional observers are exposed to, amidst the complexities of minute animal and vegetable life, of concluding that they have come upon absolute evidences of the transformation of one minute form into another; that in fact they have demonstrated cases of heterogenesis.

This difficulty is not diminished by the fact that on the shelves of most Microscopical Societies there is to be found some sort of literature written in support of this strange doctrine.

You will pardon me for allusion again to the field of inquiry in which I have spent so many happy hours. It is, as you know, a region of life in which we touch, as it were, the very margin of living things. If Nature were capricious anywhere, we might expect to find her so here. If her methods were in a slovenly or only half-determined condition, we might expect to find it here. But it is not so. Know accurately what you are doing, use the precautions absolutely essential, and through years of the closest observation, it will be seen that the vegetative and vital processes generally, of the very simplest and lowliest life-forms, are as much directed and controlled by immutable laws, as the most complex and elevated.

The life-cycles, accurately known, of monads, repeat themselves as accurately as those of Rotifers or Planarians.

And of course, on the very surface of the matter the question presents itself to the biologist why it should not be so. The irrefragable philosophy of modern biology is that the most complex forms of living creatures have derived their splendid complexity and adaptations from the slow and majestically progressive variation and survival from the simpler and the simplest forms. If, then, the simplest forms of the present and the past were not governed by accurate and unchanging laws of life, how did the rigid certainties that manifestly and admittedly govern the more complex and the most complex come into play?

If our modern philosophy of biology be, as we know it is, true, then it must be very strong evidence indeed that would lead us to conclude that the laws seen to be universal break down and cease accurately to operate, where the objects become microscopic, and our knowledge of them is by no means full, exhaustive, and clear.

Moreover, looked at in the abstract, it is a little difficult to conceive why there should be more uncertainty about the life-processes of a group of lowly living things, than there should be about the behaviour, in reaction, of a given group of molecules.

The triumph of modern knowledge is the certainty which nothing can shake, that Nature's laws are immutable. The stability of her processes, the precision of her action, and the universality of her laws, is the basis of all science; to which biology forms no exception. Once establish, by clear and unmistakable demonstration, the life-history of an organism, and truly some change must have come over Nature as a whole, if that life-history be not the same to-morrow as to-day; and the same to one observer, in the same conditions, as to another.

No amount of paradox would induce us to believe that the combining proportions of hydrogen and oxygen had altered, in a specified experimenter's hands, in synthetically producing water.

We believe that the melting-point of platinum and the freezing-point of mercury are the same as they were a hundred years ago, and as they will be a hundred years hence.

Now, carefully remember that so far as we can see at all, it must be so with life. Life inheres in protoplasm; but just as you cannot get *abstract matter*—that is, matter with no properties or modes of motion—so you cannot get *abstract* protoplasm. Every piece of living protoplasm we see has a history: it is the inheritor of countless millions of years. Its properties have been determined by its history. It is the protoplasm of some definite form of life which has inherited its specific history. It can be no more false to that inheritance than an atom of oxygen can be false to its properties.

All this, of course, within the lines of the great secular processes of the Darwinian laws; which, by the way, could not operate at all if caprice formed any part of the activities of Nature.

But let me give a practical instance of how, what appears like fact, may over-ride philosophy, if an incident, or even a group of incidents, *per se* are to control our judgment.

Eighteen years ago I was paying much attention to Vorticellæ. I was observing with some pertinacity *Vorticella convallaria*; for one of the calices in a group under observation, was in a strange and semi-encysted state, while the remainder were in full normal activity.

I watched with great interest and care, and have in my folio still the drawings made at the time. The stalk carrying this individual calyx fell upon the branch of vegetable matter to which the Vorticellan was attached, and the calyx became perfectly globular; and at length there emerged from it a small form with which, in this condition, I was quite unfamiliar: it was small, tortoise-like in form, and crept over the branch on setae or hair-like pedicels; but, carefully followed, I found it soon swam, and at length got the long neck-like appendage of *Amphileptus anser!*

Here then was the cup or calyx of a definite Vorticellan form, changing into (?) an absolutely different Infusorian, viz. *Amphileptus anser!*

Now I simply reported the *fact* to the Liverpool Microscopical Society, with no attempt at inference; but two years after I was able to explain the mystery, for, finding in the same pond both *V. convallaria* and *A. anser*, I carefully watched their movements, and saw the *Amphileptus* seize and struggle with a calyx of *convallaria*, and absolutely become encysted upon it, with the results that I had reported two years before.

And there can be no doubt but this is the key to the cases that come to us again and again of minute forms suddenly changing into forms wholly unlike. It is happily amongst the virtues of the man of science to "rejoice in the truth," even though it be found at his expense; and true workers, earnest seekers for Nature's methods, in the obscurest fields of her action, will not murmur that this source of danger to younger microscopists has been pointed out, or recalled to them.

And now I bid you as your President farewell. It has been all pleasure to me to serve you. It has enlarged my friendships and my interests; and although my work has linked me with the Society for many years, I have derived much profit from this more organic union with it; and it is a source of encouragement to me, and will, I am sure, be to you, that, after having done with simple pleasure what I could, I am to be succeeded in this place of honour by so distinguished a student of the phenomena of minute life as Dr. Hudson. I can but wish him as happy a tenure of office as mine has been.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. x. No. 2 (Baltimore, January 1888).—In the opening paper (pp. 99–130), entitled "Soluble Quintic Equations with Commensurable Coefficients," G. P. Young develops at some length the application of his general method, described in vol. vi., to the solution of twenty quintic equations, such as $x^5 - 10x^3 - 20x^2 - 1505x - 7412 = 0$.—Mr. D. Barcroft discusses (pp. 131–40) forms of non-singular quintic curves. The subject is profusely illustrated by drawings of 47 curves on twelve large pages (interpolated between pp. 140 and 141).—F. Morley (pp. 141–48) writes on critic centres in cubics.—The expression of syzygies among perpetuants by means of partitions, by Captain P. A. MacMahon, R.A. (pp. 149–68), is a very interesting addition to the author's previous papers on the subject.—The number concludes with three short papers: "Démonstration directe de la formule Jacobienne de la transformation cubique," by the Abbé Faà de Bruno; note on geometric inferences from algebraic symmetry, by F. Morley; and "Surfaces telles que l'origine se projette sur chaque normale au milieu des centres de courbure principaux" (pp. 175–86), by P. Appell.

Rivista Scientifico-Industriale, January 31.—On chemical valency, by Prof. Fr. Mangini. The probable cause of valency, that is, the varying proportions with which the atoms of the simple bodies combine with hydrogen, or its equivalent chlorine, to form molecules, is here attributed to the varying degrees of motion assumed to be pre-existent and inherent in the atoms themselves. A numerical coincidence is pointed out between the acoustic, luminous, and chemical phenomena, seven being the number of the chief musical notes, of the chief colours in the spectrum, and, as is now generally admitted, of the chemical valencies. It is further to be noted that the temperature required to produce the spectral lines varies with the valencies of the different elements. Thus, a much higher temperature is required for the polyvalent than for the monovalent alkalines, and in all these phenomena a connection is seen to exist between the heat required to show the spectral lines and the quantivalence of the atoms. Another nexus is found between the allotropic state and the number of vibrations needed to produce the spectroscopic phenomena. This highly suggestive paper will be continued in a future number of the *Rivista*.

Bulletins de la Société d'Anthropologie de Paris, tome x. fasc. 3 (Paris, 1887).—On the various methods of measuring the thorax, by Dr. E. Maurel. The writer, in enumerating the various instruments in use for this purpose, gives the preference to those designed by MM. Woillez, Niely, and Fourmentin, by which a graphic representation of the dimensions of the chest is obtained; although he claims to have improved upon their design in an instrument to which he has given the name stethograph.—On a Breton amulet, called "Kistin Spagn," by M. Bonnemère. Under this name the people of Locmariaque treasure a seed, probably a cashew nut, or, according to some, the seed of the mahogany-tree, which is brought home by Breton sailors. The nut is carefully scraped and boiled in new milk, when it is supposed to be a sovereign remedy against intestinal disorders. By some of the peasant women, however, the nut is pierced and worn on a chain, with their keys, scissors, &c., as an amulet. Singularly enough, it is found that even in Paris these nuts are believed to be specifics against various diseases, more especially the gout, three or four when carried in the trousers pocket being regarded as capable of warding off this malady.—On calves born with so-called bull-dog heads, by M. Dareste. Animals of this description were at one time characterized in South America as constituting a distinct race, but the gradual diminution in their numbers since the cattle of the pampas have acquired a marketable value leads to the inference that they are being killed when first dropped, in order to eliminate deformed animals from the herds, and this opinion of the deformity of the so-called "natos-calves" is confirmed by the presence of other abnormalities in all the animals of this description which have been examined in Europe.—On the colour of the hair and eyes in Limagne, near the Monts-de-Dôme, by Dr. Pommerol. These observations refer to 200 individuals, and appear to indicate that, taken generally, one-fourth of the population have light hair, and three-fourths dark hair, while light and dark eyes are equally frequent.—On the worship of Taranis in popular traditions of Auvergne, by Dr. Pommerol. The writer believes that under this name we have the Gallic representative of the supreme god of the heavens, and wielder of thunder and storms; and that the custom still prevalent in France of building an uncut stone into the gable or roof-top of a house, or hammering into the newly finished walls an irregularly formed metal, wooden, or stone cross, or mallet, to keep bad luck from the building, is a survival of the ancient usage of averting evil by the help of emblems connected with the worship of the supreme gods, as Baal's stone, Jupiter's thunderbolt, or Thor's hammer.—Circumcision in its social and religious significance, by M. Lafargue. The fact that this rite was practised among the Egyptians long before its adoption by the Hebrews has led to the inference that its practice was due to hygienic considerations only. But the author believes that we have here merely one of the numerous forms of mutilations submitted to by primæval men with a view of propitiating their deities, and of which we have such varied and striking evidence among different peoples, as the Assyrians and Aztecs, as well as among the black races; while survivals of similar faith in the efficacy of voluntarily inflicted suffering and mutilation are to be traced in the mythology of the Greeks and Romans.—On the influence of their surrounding medium on the peoples of Central Asia, by M. de Ujfalvy. Referring to the services recently rendered to science by Richthofen in unravelling the tissue of misconceptions in regard to the geognosy of Central Asia, due to the theories of Humboldt, Klaproth, and others, the writer considers the influence which the soil and their surroundings have had on the inhabitants of the four distinct zones into which the first-named of these *savants* has subdivided the Asiatic continent. Thus, while the central zone, by the general levelling of the surface through the chemical disintegration of the rocks, and the absence of streams to enrich the soil, compels men to follow a nomadic, or pastoral, rather than a settled life, the peripheral zone abounds in rich and fertile lands, yielding abundant opportunities for the exercise of human industry, and a corresponding advance in mental and social development. The intermediate zones correspond ethnographically with the transitional character of their geognostic features. Next to the extraordinary influence of the varied configurations of Asia on the destinies of its inhabitants, M. de Ujfalvy points out the importance of loess formations as factors in determining the spread and establishment of civilization. This part of the subject is treated at great length, and deserves the careful attention of the palæologist no less than the student of ethnography, seeing that the loess constitutes an important agent in the preservation of the animal and industrial remains of prehistoric ages.—On the nervous system, considered from a physico-chemical point of view, by Dr. Fauvelle. Here the nervous system of man is regarded as a physical apparatus, presenting certain analogies with an electric pile.—Anthropology, and philology, with reference to the

Philippines, by M. O. Beauregard. This is a lengthy treatise on the products, language, sociology, and history of the islands, based chiefly on Spanish authorities.—Report, by M. Topinard, of the excavation of the Neolithic grotto of Feigneux (Oise), in which was found a skull that had been trepanned both before and after death. These finds were specially rich, including four skulls which bore traces of having been compressed; and, considered generally, this deposit may be regarded as a pendant to that of Orrouy.—(1) On a burial ground of the Stone Age at Crécy-en-Brie; (2) on cut flints in the alluvial sand below Paris; and (3) on a prehistoric work-place at Fontenay-aux-Roses, by M. Thieullen. The writer draws attention to the frequency with which the larger debris of cut flints are found near water, and always in localities favourable to the existence of prehistoric man, while from the character of the great ossuaries, in which, as at Crécy-en-Brie, the remains of men and women of all ages, and children, are found, he believes we may assume that the men of the period lived in family rather than in tribal association.—A study of the brain of Bertillon, by MM. Chudzinski and Manouvrier. A *résumé* of the results of this carefully conducted cerebral analysis, which are here given in detail, shows generally, *inter alia*, a large development of the anterior portion of the brain in all directions; a relatively inferior development in point of size in the temporal lobes, and in the cerebellum; and great ramification in the fossæ.

THE *Izvestia* of the Russian Geographical Society (xxiii. part 5) contains, besides Dr. Bunge's preliminary report about his expedition to the New Siberia Islands, a lecture on the problems of scientific geography by Dr. Petri, who was appointed in October last Professor of Geography and Anthropology at the St. Petersburg University; a paper by M. Rovinsky on the beliefs of the Montenegrins; M. Nikolsky's sketch of fishing on Lake Aral, a valuable contribution to the knowledge of the fishes inhabiting Lake Aral, and especially the lower Amu-daria, their habits, and the modes of fishing; and notes by General Stebnitsky on recent pendulum observations, on M. Boguslavsky's work on the Volga, and on W. J. Havenga's map of Sumatra.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 2.—"On Tidal Currents in the Open Ocean." By J. Y. Buchanan, F.R.S.

This paper gives details of some current observations which I made in the open ocean north of the Canary Islands in October 1883 in the course of the surveying expedition preliminary to the laying of a telegraph cable between these islands and the mainland of Spain. This expedition consisted of two steamers, the *Dacia* and the *International*, belonging to the India-rubber, Gutta-percha, and Telegraph Works Company (Limited), of Silvertown. The chief scientific results gained during it were the confirmation of the view—which was suggested by the density and temperature of the bottom water observed in this part of the Atlantic during the cruise of the *Challenger*—that the overflow of warm concentrated sea-water from the Mediterranean at the bottom of the Straits of Gibraltar was the cause of the abnormally high density and temperature of the bottom water in this part of the ocean, and the preparation of a complete survey of the bed of the ocean in this district. During the progress of the work several very remarkable "oceanic shoals" were discovered and surveyed, notably the "Coral Patch" in lat. 34° 57′ N., long. 11° 57′ W., with a depth of 400 to 500 fathoms, and the "Dacia Bank," in lat. 31° 9′ N., long. 13° 34′ W., with a minimum depth of 49 fathoms. In sounding over both of these banks conclusive evidence was obtained of the existence of actual vertical precipices in some positions on their flanks; and from the very great average steepness all round, it is rendered in every way probable that, if they were laid dry, they would form mountain peaks as precipitous and inaccessible as any to be found on land. The dredging on the Coral Patch showed it to consist of deep-sea corals, principally *Lophohelia prolifera*, growing with the utmost luxuriance and attached to dead stems of the same species, already getting coated with peroxide of manganese.

For the purposes of the survey of the "Dacia Bank" a buoy was anchored on its edge, and on the afternoon of October 21 I spent some hours in a boat made fast to it, and observed the current in strength and direction. The following is a summary of the results:—

Hour p.m.	2.15	2.40	3.30	4.6
Direction (true) ...	N. 11° E.	N. 41° E.	N. 56° E.	N. 101° E.
Rate (knots per hour)	0·47	0·30	0·26	0·30

It will be seen from these observations that in two hours the current had shifted its direction through 90°, and had passed through a minimum velocity of 0·26 per hour without there having been any period of "slack water." The observations are too few in number to make it worth while submitting them to analysis; but a little study of them will show that they indicate a current which is the resultant of a continuous current and a periodic one. A constant current running south-east by east, combined with a tidal current running north-north-west and south-south-east, the maximum velocity of which, in either direction, is twice that of the permanent current, would give a resultant agreeing fairly with that observed.

No measurements were made of the under current, but, by sinking a tow-net made fast to a sounding-line, it was seen to be running at a depth of 75 fathoms in the same direction as the surface current and apparently with much the same velocity. In the channels between the Canary Islands, where even on the shallowest ridges there is over 1000 fathoms of water, the tidal current reaches to the very bottom, and its scouring action is shown by the nature of the bottom. To seaward, in 1800 or 2000 fathoms, the bottom is a fine Globigerina ooze, which gets coarser and sandier as the water shoals in the channels, till on the summit ridge there is generally no loose deposit at all, and the bottom is rock or coral coated with black oxide of manganese. Round the western end of Teneriffe the tide runs violently, causing rips and overfalls. Much rocky ground is met with in the North Atlantic in depths of 1300 and 1400 fathoms, especially on the ridge which appears to extend through the whole length of that ocean. It is not unlikely that the summit edge of this ridge may be swept clean through the greater part of its length, and it must be remembered that the removal of sediment from one part of the ocean bottom means its deposit in greater abundance in others, especially in hollows in the neighbourhood of the ridge. Hence a sounding in "ooze" or "mud" in one position furnishes no argument against the trustworthiness of another sounding in the vicinity and in equally deep water on "rock" or "hard ground."

It is evident, then, that the power of shoals to transform the tidal wave into tidal currents furnishes a natural agency which tends to limit the indefinite shoaling of the water by the continual deposition of loose sediment. On the other hand, these currents, in sweeping clean the rocky eminences at the bottom of the ocean, prepare a lodging-place for deep-sea corals, and assist in bringing food to them when settled, thus enabling them to build up their pillar-like banks, of which a very fine example is furnished by the "Coral Patch" above referred to. There can be little doubt that it is reducing more or less rapidly the depth of the water above it. The "Dacia Bank" and the "Seine Bank" are examples where limiting conditions, probably of temperature, appear to have been reached. The water may be too warm for the deep-sea species; and not warm enough for the tropical, *par excellence*, reef-building species.

A remarkable cluster of banks resembling those above described occurs off the Brazilian coast, between the Agulhas reef and the islands of Trinidad and Martin Vaz Some of them are named, as the Jaseur, the Montague, and the Victoria banks; with from 25 to 30 fathoms, and completely surrounded by deep water. Further north is the dangerous Rocas, lying close to the route of steamers from North America and Europe to South American ports. Further south, again, are two suggestive soundings, one of 19 fathoms, in lat. 32° 40′ S., long. 47° 0′ W., marked "Nelson, 1859," and the other of 72 fathoms, in lat. 37° 50′ S., long. 49° 50′ W., marked "Sutlej, 1863," in the chart. Seamen are not usually mistaken as to whether they have or have not found bottom in depths such as 19 or 72 fathoms, and there is little doubt that careful search would reveal the existence of shoals in these localities. But the search must be diligent and methodical, always following the lead of the soundings as they shoal. The careful and detailed study of these oceanic shoals or embryo islands is of great importance for oceanographical science, and it would not be easy to find more interesting work for the marine surveyor.

March 1.—"On the Changes produced by Magnetization in the Dimensions of Rings and Rods of Iron and of some other Metals." By Shelford Bidwell, F.R.S.

Linnean Society, February 16.—W. Carruthers, F.R.S., President, in the chair.—Mr. Spencer Moore exhibited, and made some remarks upon, specimens illustrative of the *Palmella* state *Draparnaldia glomerata*.—Mr. D. Morris (Royal Gardens, Kew) exhibited a specimen of wood of *Hieronyma alchornioides* received from Trinidad, showing in its fissures mineral deposits, which on chemical analysis proved to be calcic carbonate. For comparison, Mr. Morris also exhibited and made some observations upon some deposits of calcic phosphate in teak. Some of these (described by Sir Fred. Abel, Quart. Journ. Chem. Soc. xv. 91), are 6 feet in length, 6 inches in breadth, and from $\frac{1}{8}$ inch to $\frac{3}{8}$ inch in thickness. Deposits in bamboo known as *tabasheer* (silicate) were shown, as also pearls (carbonate of lime) from cocoanuts, received from Dr. Sydney T. Hickson (see NATURE, vol. xxxvi. p. 157). All these specimens were from the Museum of Economic Botany of Kew.—Dr. Burn Murdock exhibited and offered remarks upon the intra-marginal (so-called) veins in the section *Areolata* of the genus *Erythroxylon*, of which *E. coca* is the most familiar species. These lines are due to a thickening of the parenchymatous tissue which takes place in the bud stage, and are in no way connected with the venation of the leaf.—Mr. G. F. Sherwood exhibited a collection of photographs taken in Samoa, illustrating the scenery and people, together with a number of necklets formed with strings of various bright-coloured seeds.—The first paper of the evening was read by Mr. H. N. Ridley, on self-fertilization and cleistogamy in orchids. Three common methods of self-fertilization were explained: (1) by the breaking up of the pollen mass, and falling of the dust either directly upon the stigma, or into the lips whence it comes into contact with the stigma; (2) by the falling of the pollen masses as a whole from the clinandrum into the stigma; and (3) by the falling forward of the pollinia from the clinandrum, or the anther cap, the caudicle and gland remaining attached to the column. An interesting discussion followed, in which Prof. Marshall Ward, the Rev. G. Henslow, and Mr. A. W. Bennett took part.—A paper was then read by Dr. John Rae, F.R.S., entitled "Notes on some of the Birds and Mammals of Hudson's Bay Territory." Dr. Rae, whose long residence in Northern and Arctic America enabled him to speak authoritatively from personal observation, gave an interesting account of the migration of the Canada goose, snow goose, and blue-winged goose, and of the habits of the American hare and lemming. He particularly referred to the belief entertained by some of the Indian tribes he had met with, and to which he himself gave credence, that certain species of small birds are assisted on their migrations by being carried on the backs of the Canada geese. Mr. J. E. Harting, in criticising this paper, gave an exposition of the views held by leading ornithologists on the subject of the American Canada and snow geese, their relationship and nomenclature, and pointed out that the story of small birds being carried by larger ones is not confined to North America, but is current in South-Eastern Europe, Palestine, and Arabia, where trustworthy evidence has been obtained that wagtails and other small birds travel on the backs of cranes. He added that one instance was known to him of such an occurrence in England, a short-eared owl having been seen to arrive on the north coast of Yorkshire carrying on its back a golden-crested wren, which was secured by the observer.

Chemical Society, February 16.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Chemical investigation of Wackenroder's solution, and explanation of the formation of its constituents, by Prof. Debus, F.R.S. Wackenroder's solution is obtained by passing hydrogen sulphide into an aqueous solution of sulphur dioxide until the latter is decomposed. It has been considered to contain sulphur in suspension and pentathionic acid in solution, although neither the acid nor its salts have been prepared pure, and, in consequence, Spring has denied the existence of the acid, regarding it as a solution of sulphur in tetrathionic acid. The author finds that Wackenroder's solution contains: (1) sulphur in suspension in very minute drops, (2) a new allotropic modification of sulphur, (δ), in simple solution, and in the colloidal condition, (3) traces of trithionic acid, (4) tetrathionic acid, (5) pentathionic acid, and (6) a polythionic acid containing more sulphur than the penta- acid, probably hexathionic acid. Pure potassium and copper pentathionates were prepared, and the reactions of the polythionates studied, among the most interesting of which are the spontaneous changes in aqueous solution shown by the equations—

$$(a)\ K_2S_5O_6 = K_2S_4O_6 + S\,;\ (b)\ 2K_2S_4O_6 = K_2S_3O_6 + K_2S_5O_6\,;$$
$$(c)\ 2K_2S_3O_6 = K_2S_4O_6 + K_2SO_4 + SO_2\,;\ (d)\ 3K_2S_3O_6 = K_2S_5O_6 + 2K_2SO_4 + 2SO_2\,;$$

the reactions (*a*) and (*b*) occurring in either direction with equal facility. The final products of the action of hydrogen sulphide on tetra- and penta-thionic acids are water and sulphur. The polythionic acids can also be obtained by the action of sulphur dioxide on potassium thiosulphate or on the chlorides of sulphur. The concluding portion of the paper was devoted to a discussion of the formulæ of the polythionates.—Potilizin's law of the mutual displacement of chlorine and bromine, by Prof. Thorpe, F.R.S., and Mr. J. W. Rodger. On heating bromine with an equivalent quantity of an anhydrous metallic chloride in a sealed glass tube, free from air, to the temperature of the melting-point of zinc, Potilizin found that the amount of chlorine displaced by bromine was greater the higher the atomic weight of the metal in the chloride; and further, that, if A be the atomic weight of the metal, p the percentage of chlorine displaced from its chloride when treated as above, and E its valency, the formula $\frac{A}{pE^2}$ = a constant held good in the case of fourteen chlorides. To test the validity of this law, the authors heated the chlorides of sodium, potassium, silver, strontium, barium and lead with bromine at 350°–450°, and found that, with the exception of silver chloride, in which the deviation was not so marked, the amount of chlorine displaced was considerably less than that required by Potilizin's law, and in all cases stood in no definite relation either to the duration of heating or to the atomic weight of the metal of the chloride used, although most chlorine was displaced from the chloride of highest molecular weight when several were heated simultaneously. These experiments therefore disprove the validity of Potilizin's law.—A gasometric method of determining nitrous acid, by Dr. P. F. Frankland. Based on the interaction of urea and nitrous acid.—The action of some specific micro-organisms on nitric acid, by the same. The author has investigated the behaviour, when grown in nutritive solutions containing nitrates, of a number of micro-organisms obtained from air and water, and cultivated in a state of purity. Of thirty-two different forms so examined, sixteen or seventeen, and particularly *Bacillus ramosus* and *B. pestifer*, were found to reduce the nitrate to nitrite more or less completely, whilst the remainder were quite destitute of this power. The behaviour of the organisms was not altered in this respect by excluding air from the solutions in which they were cultivated.—The action of phosphorus pentachloride on salicylaldehyde, by Mr. C. M. Stuart.—Some interactions of nitrogen chlorophosphuret, by Mr. W. Couldridge.—Action of alcohols on ethereal salts in presence of small quantities of sodic alkylate, by Prof. Purdie and Mr. W. Marshall.—Note on the densities of cerium sulphate solutions, by Dr. B. Brauner. The values of the densities of solutions of the anhydrous and of the hydrated salt are identical for solutions of equal concentration.

ERRATUM.—P. 406, second column, line 9 (from top), *for* $v = (n^2 - 1)(n^2 + 2)$ *read* $v = (n^2 - 1)/(n^2 + 2)$.

Physical Society, February 25.—Prof. Reinold, F.R.S., President, in the chair.—The following papers were read:—Note on the efficiency of incandescent lamps with direct and alternating currents, by Prof. W. E. Ayrton, F.R.S., and Prof. J. Perry, F.R.S. This relates to the question whether the "efficiency" (candles per watt) is greater or less for alternating than for direct currents. Experiments made by Messrs. Shepherd and Wheatley, two of the students at the Central Institution (to whom the authors express their thanks for the valuable assistance rendered) show that no appreciable difference can be detected when the lamp is at the same candle-power. In performing the experiments, three-way switches in connection with Gramme and Ferranti machines were arranged so that the current through the lamp could be quickly changed from direct to alternating, or *vice versâ*, adjustable resistances having been previously placed in the two circuits to give equal readings on a Cardew voltmeter placed as a shunt to the lamp. The currents were measured by a reflecting dynamometer wound with fine wire in order to make the error, due to unequal current density over the section, negligible. The problem has also been investigated from

theoretical considerations, but the results as yet deduced would not lead the authors to anticipate the equal efficiency found experimentally. An interesting discussion followed, in which Mr. Swinburne, Prof. S. P. Thompson, Mr. Boys, and the authors took part.—Observations of the height, length, and velocity of ocean waves, by the Hon. Ralph Abercromby. Several sets of observations were made by the author in the South Pacific in 1885. The heights were measured by a sensitive ameroid, and the length and velocity by a chronograph, assuming the length and speed of the vessel to be known. The largest waves observed in a heavy sea gave a height of 46 feet, length 765 feet, velocity 47 miles per hour, and time period of 16·5 secs. Great discrepancies exist between the results of different observers, which the author believes to be chiefly due to the comparative rarity of well-defined simple waves. Replying to a question from Mr. Baily, the author said the effect on the barometer of the difference of wind pressure on the two sides of a wave was negligible.—On the temperature at which nickel begins suddenly to lose its magnetic properties, by Mr. Herbert Tomlinson. Different authorities give different values, ranging from about 300° to 400° C. In investigating the subject the author found that the said temperature depends on the magnetizing force used; *e.g.* with magnetizing forces of 5, 99, and 182 units, the temperatures at which the permeability attained its maxima were 287° C., 248° C., and 242° C., and those corresponding to permeability = 0 were 333°, 392°, and 412° respectively. From the above results it will be seen that for small magnetizing forces the change of permeability from maximum to 0 is much more sudden than for the greater forces. As in iron, the permeability decreases as the magnetizing force increases. An experiment was shown in which a nickel plated brass wire was heated to dull redness whilst suspended between the poles of an electro-magnet, and allowed to cool. When the critical temperature was attained, the wire was suddenly attracted to one or other of the poles. In reply to Mr. Shelford Bidwell, the author stated that the changes in permeability due to ordinary atmospheric changes of temperature were considerable, when small magnetizing forces were used.—Experiments on electrolysis, by Mr. W. W. Haldane Gee, Mr. H. Holden, and Mr. C. H. Lees. Whilst studying some electrolytic polarization phenomena with palladium electrodes in dilute sulphuric acid (pure), a dense liquid was seen *after reversing the current* to flow downwards in streaks from the anode. The paper is devoted to the investigation of the character of the liquid streaks, and the authors conclude that the streaks are of concentrated sulphuric acid, formed by the union of the hydrogen (occluded by the electrode whilst serving as cathode) with the SO_4 liberated at the same electrode when the current is reversed. Similar streaks were found with phosphoric acid, &c. In their next paper the authors hope to describe some experiments in which these and similar effects become of great importance in changing the resistances of electrolytes.

Zoological Society, February 21.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. A. Thomson exhibited a series of insects reared in the insect-house in the Society's Gardens during the past year, and read a report on the subject.—Prof. G. B. Howes read a note on the azygos veins of the Anurous Amphibia. The author described an individual specimen of *Rana temporaria*, in which the azygos vein (prerenal portion of the posterior cardinal) had been retained on one side, its relations differing in important details from that observed by Hochstetter in *Bombinator*. By way of supplementing that author's work, he had examined examples of a few genera not dealt with by Hochstetter. He recorded the presence of these veins in the only specimen of *Discoglossus* dissected, and in one of five individuals of *Alytes obstetricans*—facts which lent additional support to the views of Cope and Boulenger of the lowly affinities of the Discoglossidæ. He had failed to detect these vessels in the *Aglossa*; while he regarded their total absence in *Pelobates* and *Pelodytes* as fresh evidence of the Pelobatoid rather than the Discoglossid affinities of the last-named genus.—Mr. A. Smith-Woodward read the second part of his palæontological contributions to Selachian morphology.—Mr. Oldfield Thomas gave an account of the mammals obtained by Mr. G. F. Gaumer on Cozumel and Ruatan Islands, Gulf of Honduras.—A second paper by Mr. Thomas contained the description of a new and interesting annectent genus of Muridæ, based on a specimen which had been in the Paris Museum for some years. This was supplemented with remarks on the relation of the Old and New World members of the family.—Dr. G. H. Fowler exhibited and made some remarks on a new *Pennatula* from the Bahamas, the most interesting feature of which was the presence of immature antozooids at the dorsal end of the leaves, devoid of tentacles, but possessing a well-marked syphonoglyphe on the stomatidæum which disappears with the increasing age of the polyp. The species was proposed to be named *Pennatula bellissima*.

Royal Meteorological Society, February 15.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Electrical and meteorological observations on the Peak of Teneriffe, by the Hon. Ralph Abercromby. The author made a trip to the Island of Teneriffe in October 1887, for the purpose of making some electrical and meteorological observations, and now gives some of the results which he obtained, which may be summarized as follows:—The electrical condition of the Peak of Teneriffe was found to be the same as in every other part of the world. The potential was moderately positive, from 100 to 150 volts, at 5 feet 5 inches from the ground, even at considerable altitudes; but the tension rose to 549 volts on the summit of the Peak, 12,200 feet, and to 247 volts on the top of the rock of Gayga, 7100 feet. A large number of halos were seen associated with local showers and cloud masses. The necessary ice-dust appeared to be formed by rising currents. The shadow of the Peak was seen projected against the sky at sunset. The idea of a south-west current flowing directly over the north-east Trade was found to be erroneous. There was always a regular vertical succession of air currents in intermediate directions at different levels from the surface upwards, so that the air was always circulating on a complicated screw system.—Rainfall of South Africa, 1842–1886, by Mr. W. B. Tripp. The author gives the rainfall statistics from all those stations situated in South Africa which possess records of ten complete years and upwards. He remarks upon the chronological succession of wet and dry years, and the consecutive years above and below the mean; and also describes the seasonal distribution of monthly maxima, and the extent over which monthly rains prevail. He concludes by comparing the curves of rainfall with those of sunspot energy.—Some methods of cloud measurements, by Mr. Nils Ekholm. As exact cloud measurements afford almost the only easily available means of determining motions in the upper regions of the atmosphere, the author describes some methods which seem to him likely to give the best results. He also details the plans adopted at the Swedish Polar Station, Cap Thorsden, in Spitzbergen, and at the Upsala Observatory, for determining the direction and angular velocity of the clouds, and for making direct measurements of the height and absolute motions of the clouds.

EDINBURGH.

Royal Society, January 30.—The Rev. Prof. Flint, D.D., Vice-President, in the chair.—Prof. Nicholson read a paper on the causes of movements in general prices.—Prof. J. B. Haycraft and Dr. E. W. Carlier gave a demonstration of a method by which human blood may be withdrawn from the body and its fluidity preserved. Castor-oil is the medium in which the blood is suspended. The finger from which the blood is obtained is greased and plunged in the oil before the puncture is made, every precaution being taken to prevent contact of the blood with the air or with solid matter. In this way the blood may be preserved in a fluid state for a considerable time. As the drops of blood settle slowly in the oil, the corpuscles are seen to fall to the lower part of the drops, while the clear plasma remains above. Prof. Haycraft and Dr. Carlier believe that the human blood plasma has never before been demonstrated in an unaltered condition except in microscopic quantity. Coagulation eventually occurs, because the blood necessarily comes in contact with the sides of the wound made in the finger.—Mr. D. B. Dott read a paper, written by himself in conjunction with Dr. Ralph Stockman, describing experiments which show that the ordinarily accepted formula of morphine is the correct one.—Mr. Robert Kidston read the first part of a paper on the fossil flora of the Staffordshire coal-fields, and also read a note on *Neuropteris plicata*, Sternb., and *Neuropteris rectinervis*, Kidston.—Mr. John Aitken communicated a note on a monochromatic rainbow seen at sunset.—Prof. Haycraft read a note on a "scratching centre" found in the spinal chord of some vertebrates.—Prof. Tait communicated an answer to Prof. Boltzman's strictures, which appeared in the *Sitzungsberichte* of the Vienna Academy, on his investigations on the kinetic theory of gases. This has been sent to the *Philosophical Magazine*.

PARIS.

Academy of Sciences, February 27.—M. Janssen in the chair.—On the doctrine of the probability of error; the law of Gauss, by M. J. Bertrand. It is shown that the law of Gauss, based on the postulate, "The mean of the results of any number of measurements is the most probable value deducible from those measurements," is incapable of rigorous demonstration.—Artificial production of rhombohedric crystals of rubies, by MM. E. Fremy and A. Verneuil. Specimens were shown of these crystals produced by the method described at the meeting of March 14, 1887. These are very different from the rubies obtained by the authors in 1877, which were produced in a vitreous vein from which they were detached with great difficulty. The present gems are on the contrary produced in a porous and friable vein, where they occur in clusters of crystals in a state of great purity, and from which they may be easily removed. To effect this it suffices to throw the product of calcination into a flask of water and shake it violently. Then the vein being light remains in suspension in the water, while the heavier rubies are at once precipitated to the bottom. The gems are always rhombohedric, and in every respect comparable to the natural stones. They have the same colour and hardness, easily scratch topaz, become black when heated, regaining their beautiful pink tint when cooled, have a diamond-like brilliance, and perfectly regular crystalline form. The paper was followed by some remarks by M. Des Cloiseaux, to whom the specimens had been submitted for a thorough crystallographic examination. —On some general conditions under which nitrogen is fixed by vegetable soil, by M. Berthelot. The author had already established by a long series of experiments that certain argillaceous earths and certain sands have the property of fixing atmospheric nitrogen and enriching themselves by a slow and progressive process with organic nitrous substances obtained directly or indirectly from living organisms. Since then he has prosecuted the study of this interesting phenomenon, and here resumes the results of his further researches. Some experiments are also described on the transformation of the nitrates in the soil into nitrous combinations of organic character. His observations tend to the general conclusion that the earth should not be regarded as an inert mineral body, stable and invariable in its composition until disturbed by the process of vegetation, but as a body filled with living beings, and whose chemical composition and abundance of nitrogen vary and oscillate with the conditions determining the vitality of those beings.—On a method of quantitative analysis of chloroform, and on the solubility of this body in water, by MM. G. Chancel and F. Parmentier. Priority of discovery is claimed by the authors for this process, which, in a recent communication to the Academy, M. L. de Saint-Martin describes as new.—The Neolithic epoch at Champigny, by M. Emile Rivière. The results are described of the researches that have been carried on since 1867, by MM. Le Roy des Closages, Carbonnier, and the author, at the Neolithic station near the village of Champigny in the Department of the Seine. Here have been found numerous flint implements, scrapers, arrow-heads, polished hatchets, knives, besides four grind-stones and much coarse pottery curiously ornamented, all in association with the bones of the horse, pig, deer, roebuck, and ox. The material of some of the implements points at long migrations, or else a widespread intercourse with more or less remote tribes, the rocks used in their fabrication occurring in the region stretching from Belgium to Chiavenna in the Italian Alps.—Elements and ephemeris of the planet 272, by M. Charlois. These elements are the result of three observations made at the Observatory of Nice on February 4, 11, and 18.—Permanent deformation and thermodynamics (continued), by M. Marcel Brillouin. The chief feature of the present study is the determination of the consequences of the axiom of Clausius.—Experimental researches on the variations produced by a shock in the magnetic condition of a steel bar, by M. G. Berson. It is shown generally that the shocks or impacts given to steel bars have the effect of facilitating the disposition of the molecules in a given direction under the action of the stimulating forces, by diminishing for a very brief interval the molecular friction known as coercing force.—On the laws of chemical equilibrium, by M. H. Le Chatelier. This is a reply to a recent communication from M. Duhem claiming priority in connection with a law of thermo-chemistry lately enounced by the author.—Action of aniline on epichlorhydrine, by M. Ad. Fauconnier. Continuing the researches of M. Hörmann, the author has succeeded in obtaining one of that chemist's anticipated bases, which results from the combination of two molecules of aniline with one of epichlorhydrine. The mode of preparation and properties of this body are described.—On the respiration of corn yeast at various temperatures, by MM. Gréhant and Quinquaud. Continuing the classical studies of MM. Pasteur and Schützenberger, the authors have carried out a series of experiments to measure the volume of oxygen absorbed and of carbonic acid produced by yeast living at first in distilled water in the absence of sugar and in contact with a determined volume of air. They find that the relation $\frac{CO_2}{O}$ is variable with the temperature, so that the isolated yeast-cells would appear to behave differently from the fungi and tissues lacking chlorophyll, which give a constant relation $\frac{CO_2}{O}$ under all temperatures for the same individuals of the same species.

Astronomical Society, February 1.—M. Flammarion, President, in the chair.—M. Flammarion expressed his admiration of what he had seen at the Nice Observatory on a recent visit. In the great equatorial (30 inches aperture), the Orion nebula is splendid, stars of the sixteenth magnitude seem bright, and double stars from 0"·1 to 0"·3 apart are discovered.—M. Flammarion observed the lunar eclipse on January 28 at Nice. The moon remained easily visible during totality, and of a bright copper hue. The Nice Observatory is 375 metres above the level of the Mediterranean Sea. In the finder of the great equatorial the shadow was fringed with a transparent border about 2′ in breadth. MM. Henry Brothers and M. Trouvelot remarked the contrast this eclipse presented with that of October 1884, in which the moon nearly disappeared. M. Detaille said that he had been struck by the very fine colour of the moon; the earth's shadow, though ill-defined on the edge, was quite circular.—MM. Henry showed a photograph of the Pleiades taken with their 34-centimetre object-glass, and an exposure of four hours. The negative included stars down to the seventeenth magnitude. Much new nebulous matter is discovered in this photograph. One of the bright stars is enveloped in a dense nebula hitherto unseen. Several singular long thin streaks of nebulous matter extend in some cases from star to star to a considerable length.—M. Berteaux, geographical editor, presented the Society with a new map of the moon by M. C. Gaudibert, the well-known selenographer. This map has been made from M. Gaudibert's observations and revisals; it has been drawn by M. Tenet, and reproduced by heliography. The diameter of the disk is 64 centimetres.

BERLIN.

Physical Society, February 3.—Prof. von Helmholtz, President, in the chair.—Prof. Paul du Bois Reymond spoke on the difficulty of forming any conception of force acting across an intervening space. From among the various instances of such forces the speaker selected gravity for a thorough discussion. He explained the six properties characteristic of this force, pointing out that only two of them—viz. the proportionality to the mass, and the law of inverse squares of the distances—can be proved experimentally, while some of its other properties, as, for instance, the independence of gravity from the condition of motion of the mass, are much doubted by many observers. Prof. du Bois Reymond then discussed the ever-recurring endeavours in past times to arrive at some mechanical construction for gravity, endeavours which were in all cases unsatisfactory, since they were always dependent either on the fundamental properties of matter, which are themselves incomprehensible, or upon physical phenomena whose basis was still undetermined. Just as in the case of many problems the experiments for whose solution have been repeated until their inaccuracy was clearly proved, so also in the case of gravity has a mechanical conception been repeatedly sought for: hence it becomes necessary to show that gravity is beyond our comprehension, and the speaker proceeded to do this by showing that Lesage's theory of the impact action of the atoms of ether, which has been so long and persistently believed, while it explains the law of inverse squares does not explain the proportionality to the mass, and in certain special cases leads to perfectly impossible results. Gravity is therefore incomprehensible, and Newton's view that it is something inherently present in all matter is correct, since it is by means of this force alone that matter is made evident to us; indeed, as far as the matter itself is concerned, it may be entirely left out of account.—Prof. Helmholtz then explained how he is in the habit of treating the subject of gravity in his lectures. He represents it as being that

law of Nature, established by experience, that every body when in the neighbourhood of another body is subject to an acceleration which is proportional to its mass, and diminishes in the ratio of the inverse square of the distance between them. Such a law of Nature as this, established as it is on the basis of experience, is on the whole not unsatisfactory.—The same speaker then briefly communicated the results of two researches which he had brought before the Academy of Sciences on the previous day. Of these one is due to Prof Kundt, and has reference to the refractive power of metals. He has succeeded in constructing transparent prisms of metals, and thus determining their refractive index. The other, due to Prof. Hertz, has for its subject the rate of propagation of electro-dynamic action. By an extremely ingenious method, which the speaker explained, and which has been used by Prof. Hertz, in many of his previous researches, for the measurement of electrical vibrations, he has succeeded in proving that electricity is propagated along a metallic wire at the rate of 200,000 kilometres per second, and that electro-dynamic action passes through dielectrics with the velocity of light. These experiments thus provide the experimental confirmation of the Faraday-Maxwell theory of electro-dynamic action.

Meteorological Society, February 7.—Dr. Vettin, President, in the chair.—Lieut. Gross gave an account of a balloon voyage which he made on January 21, and described, while presenting the curves he had obtained, his meteorological observations made during this voyage with wet and dry bulb thermometers. One point of great interest which he described was that the balloon remained constantly at the upper surface of the layer of clouds which it was traversing, so that while the body of the balloon was above the clouds the car was completely immersed in the latter, notwithstanding that ballast was frequently thrown out.—Dr. Hellmann produced the curves of temperature for Northern Italy for the month of January, which showed that the cold in this region had been much more intense than in Berlin: the minimum temperature at Alessandria was – 16·5° C.—Prof. Schwalbe spoke on the subject of earthquakes in their relationship to meteorological and cosmic phenomena. He proved, on the basis of a study of the literature of this subject extending over many years, that all sorts of meteorological phenomena, such as temperature, atmospheric pressure, wind, moisture, rain, dryness, atmospheric electricity, clouds, and even optical phenomena, have been referred to earthquakes, either as accompaniments or the outcome or the cause of the same. If the statistics of earthquakes are alone considered, or more especially if microseismic observations are taken into account, the above relationship admits of being readily established; but it breaks down completely if it is worked out in a really scientific way throughout the whole of any one or a series of years. The same remark holds good with respect of those cosmic relationships which have been supposed to exist by various writers, such as that the attraction of the moon and the sun is a cause of earthquakes; this view has recently been held by Falb, and although it is in complete antagonism to the results of careful scientific investigation it has nevertheless been largely accepted by laymen. Just as the whole of Falb's views admit readily of being disproved, so also do his prognostications of earthquakes. According to Falb, each lunar quarter-day may be considered to be essentially connected with the occurrence of an earthquake which may take place either five days sooner or three days later than this time; but, notwithstanding the concession of these wide limits as to time, it has not been found that these periods are always accompanied by an earthquake.

Stockholm.

Royal Academy of Sciences, February 8.—Baron A. E. Nordenskiöld gave an account of a work he is now editing, entitled "Atlas, containing maps (copies) printed during the fifteenth and sixteenth centuries."—On the Aralo-Caspian Sea and the glaciation of the North of Europe, by Dr. H. Sjögren.—On the compression of the crust of the earth under the atmospheric pressure, by the same.—On the method used in computations concerning a certain Life Assurance Company, by Prof. Mittag-Leffler.—On the probability of divergence occurring in employing the hitherto usual methods to represent planetary pertubations analytically, by Prof. Gyldén.—On the Bacteria of the swine-plague, by Dr. E. Selander.—On the structure of Champia and Lomentaria, by Prof. Agardh.—On a series, by Dr. Lindman.—Contributions to the knowledge of the reactions of the plato-oxalate, by Dr. Söderbaum.—On the action of chloron on α- and β-naphthol, by Prof. Cleve.—On two β-amido-naphthalin-sulphon acids, by G. Forsling.—On the action of the metaphosphoric acid on di- and tri-oxides, by K. J. Johansson.—Contributions to the knowledge of carbo-hydrates; No. 2, on graminine, by Drs. Ekstrand and Johansson.—Contributions to the theory of the undulatory movement in a gaseous medium (continuation), by Prof. Bäcklund.—On the rhombic porphyry from the valley of Brumun in Norway, by H. Bäckström.—The form of the crystals, and the optical constants of hydro-carbostyrile, by the same.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Hand-book of Perspective: H. A. James (Chapman and Hall).—Elementary Hydrostatics: S. B. Mukerjee (Thacker).—Chambers's Encyclopædia, New Edition, vol. i. (Chambers).—The Flora of West Yorkshire: F. A. Lees (Reeve).—The Fisheries and Fishery Industries of the United States; Section 2, Geographical Review: G. B. Goode (Washington).—The Religious Sentiments of the Human Mind: D. G. Thompson (Longmans).—Incwadi Yami: J. W. Matthews (Low).—History of Portugal; E. McMurdo (Low).—Geometry in Space: edited by R. C. J. Nixon (Clarendon Press).—The World to Come: J. W. Reynolds (K. Paul).—Flora of the Hawaiian Islands: W. Hildebrand (Williams and Norgate).—Facts about Ireland: A. B. MacDowall (Stanford).—Everybody's Pocket Cyclopædia (Saxon).—On Cold as a Cause of Disease: W. H. Ransom (Williams and Norgate).—Bulletin de l'Académie Royale des Sciences de Belgique, No. 12 (Bruxelles).—Geological Magazine, March (Trübner).—Catalog der Conchylien-Sammlung, Sechste Lieferung (Paetel, Berlin).—Memoirs of the Boston Society of Natural History, vol. iv. LIFE CONTINGENCIES.

Institute of Actuaries' Text-book of the Principles of Interest, Life Annuities and Assurances, and their Practical Application. Part II. Life Contingencies (including Life Annuities and Assurances). By George King. (London: C. and E. Layton, 1887).

SOME years ago the Council of the Institute of Actuaries came to the conclusion that the students of actuarial science were subjected to great inconvenience and loss of time in consequence of the number of different books and scientific papers to be consulted in acquiring a knowledge of the subject. Persons actively engaged in the work, and wishing to refresh their memory as to the best methods of solving some special question, frequently felt the same sort of inconvenience. The Council, with that consideration for the students which has always been characteristic of them, resolved to provide what was wanted. They accordingly authorized the compilation and publication—the cost to be borne by the Institute—of a "Text-book of the Principles of Interest, Life Annuities and Assurances, and their Practical Application." The first volume, entitled Part I., and treating of the principles of interest (including annuities-certain), has been before the public since 1882. The second part, which is concerned with "Life Contingencies," has now been issued. The editing or authorship of this portion of the text-book was intrusted to Mr. George King, the Actuary of the Atlas Insurance Company, and formerly of the Alliance, whose practical acquaintance with assurance calculations, well-known devotion to his work, and experience as a lecturer at the Institute, qualified him, in a high degree, for undertaking the task.

In the opening chapters of the present volume, the author deals with the ordinary mortality table, its construction from different kinds of data, and its varied application by the actuary and the statist, including the determination of the probable numbers dying or surviving in a community, or in an annuity or other society. Such a table, showing out of a certain number of persons born how many attain to each year of age, may obviously be formed from records of the duration of life in a great number of individual cases; always provided the cases constitute a fair selection. Here, however, arises great practical difficulty, and mortality tables are, in consequence, usually constructed from observations yielding the probability of living one year at each year of age. This is so important a fact, at least to students commencing the study, that we should have been glad if the "elementary illustrations" given by the author had included a numerical illustration in brief detail reproducing the process underlying one or other of the standard tables. The author has proceeded wisely, we think, in first collecting the elementary formulæ of the doctrine of chances, and then showing how these may be applied to the numbers of the mortality table in order to solve the many and important questions arising in connection with single or joint lives. He points out two fallacies which it is desirable the public should recognize as such. This is one:—

"It will be found . . . that the higher the age from which we count, the greater will be the average age at death. Thus, at age 10, the average age at death is 60·257 years; at age 20, it is 62·101; at age 30, it is 64·726; and at age 60, it is 73·808. . . . It is frequently stated by shallow reasoners that some professions, such as that of the lawyer, must be conducive to longevity . . . because the average age at death of the members of that profession is much higher than that of the general population. But the general population starts from age 0; and starting from age 0 the average age at death, if the mortality were to follow the table, would be only 47·785 years, whereas . . . a lawyer does not enter the profession until he reaches manhood; and usually it is not until many years later that he attains sufficient eminence for his death to be commented upon. Therefore, even if the rate of mortality among lawyers be not more favourable than among the general population, the average age at death of those whose deaths attract notice must be greater."

Much attention is given in this portion of the book to attempts which have been made to embody the *law of mortality* in a mathematical formula which should readily lend itself to the purposes of calculation. Two such attempts are introduced to our notice: the hypothesis of De Moivre, and the hypothesis of Gompertz. De Moivre, in his treatise on "Annuities on Lives," published in 1725, made the assumption, now well known, that, out of eighty-six births, one person dies every year until they are all extinct. Gompertz, in a paper contributed to the Royal Society in 1825, just a century later, observed: "It is possible that death may be the consequence of two generally co-existing causes: the one, chance, witbout previous disposition to death or deterioration; the other, a deterioration, or increased inability to withstand destruction." It would appear, however, that he did not pursue this twofold notion to its conclusion, but contented himself with investigating the effect of supposing "the average exhaustion of a man's power to avoid death to be such that at the end of equal infinitely small intervals of time he lost equal portions of his remaining power to oppose destruction which he had at the commencement of these intervals." The words now quoted, taken alone, perhaps do not give a very precise idea of what was intended, but they really cover the assumption that the force of mortality increases in geometrical progression, and may be represented, as Mr. King says, by Bc^x, where B and c are constants, and x the age. From this, the equivalent of the differential coefficient of the log of the number living, we find the number living at age x may be expressed in the form $k(g)^{c^x}$. By judiciously choosing values for the constants k, g, and c, the results approximate more or less closely to fact for a greater or smaller extent of life, but it was left to Mr. Makeham, the present Actuary to the Church of England Assurance Company, to perfect the formula, and render it an exponent of the effect of the two co-existing causes of death originally contemplated by Gompertz. The final shape of the formula then became $ks^x(g)^{c^x}$, wherein a fourth constant, s, is introduced. In this shape, although there still remains a difficulty with the youngest ages of life, the formula has been used for adjusting crude observations

and simplifying calculations involving contingencies depending on several lives. The hypothesis of Gompertz, as formulated by Makeham, is, no doubt, useful for graduating certain tables, and for dealing with some of the more complex problems of life contingencies, but we doubt whether a disproportionate consideration is not given to it and to its application. In so far as it presents itself to us as the most successful effort yet made to fasten down the law of mortality, it has, no doubt, a charm and a fascination for everyone, and especially the mathematician; but, keeping in view the limited use made of it for the ordinary purposes of assurance work, and that even for graduating it is only one of several methods in vogue, we are inclined to think a less elaborate treatment would have been more commensurate with the proper scope of a text-book and book for general reference.

The next, and of course the main, portion of the volume is concerned with the great class of questions involving the consideration of interest when combined with life contingencies; that is to say, with annuities and assurances, whether on single or joint lives, and whether absolute or contingent; with advowsons, next presentations, fines for the renewal of leases on lives; also with life interests and reversions, and the values of life policies. Explanations and demonstrations are given at length, and some of them are exceptionally good. We may note that, in the chapter on annuities and assurances, the author says: "It has been common, in treatises on life annuities, to deal with annuities and assurances separately, but the two classes of benefits are so intimately connected that they ought always to be taken together." We are not quite sure that we have caught exactly the nature of the objection entertained by the author to the common method of dealing with the two kinds of benefit. We take it the intimate connection alluded to implies that both things are built up of the elementary forms of which $v^n l_{x+n}$ is the type, and proceed on parallel lines, and not that the results for the one should be obtained by giving an algebraic twist to the results deduced by a direct process for the other. We do not infer from his words, or gather from his book, that he would not exhibit the present value of an assurance by direct reference to the present value of £1 to be received by each of the persons alive at age $x + n$, rather than obtain it by an indirect process of reasoning, such, for instance, as this:—"If here be an annuity on (x) payable at the end of each year on which he enters, and another annuity payable at the end of each year which he completes, it is evident that the difference between the two is the value of £1 payable at the end of that year on which (x) enters, but which he does not complete; that is, the value of £1 payable at the end of the year of the death of (x), or, in other words, the value of an assurance on (x). Now $v(1 + a_x)$ is evidently the value of the first-named annuity, and, deducting from this the value of the ordinary annuity, a_x, we have the value of the assurance, $v(1 + a_x) - a_x$." The building up of a formula by premising its verbal interpretation is often an admirable example of ingenuity, but this process can never be allowed to displace the established course of mathematical reasoning.

In this, the staple portion of his work, Mr. King manifests his extensive acquaintance with the subject, or, rather, subjects. With a great quantity of matter at his command, he has used the pruning-knife very sparingly, possibly too sparingly. All the usual formulæ are given for precise calculation, and a number of approximative processes are developed where an exact calculation would be too cumbrous for actual use. It is worth suggesting for consideration whether a collection of questions to be worked out by students might not with advantage be inserted in a future edition of the book. There are many precedents for such a course in connection with text-books, and a goodly supply of questions is already at hand in the examination-papers set at the Institute in past years.

There is a third portion of the work, occupying some seventy pages, in which finite differences, interpolation, and summation are treated with more fullness than branches of pure mathematics would seem to be entitled to in a volume professedly assigned to life contingencies. Indeed, the author admits in his preface that these subjects were not within the scope of the text-book as originally planned. No doubt we have placed before us propositions which are specially applicable to actuarial needs, arranged and demonstrated with Mr. King's usual ability; but it seems to us they would have been more conveniently published in some other connection than the present. A knowledge of these things in a duly regulated course of study would naturally precede the consideration of their application.

The text of the work is supplemented by a collection of interesting tables, commencing with a table of mortality based on a combination of data for young and mature lives, and intended to show the mortality of healthy male life from birth to extreme old age. We must not fail to mention that the collection embraces complete tables for finding the value of joint-life annuities up to four lives inclusive.

Looking at the work as a whole, we find the various subjects are cleverly handled, the propositions appear one after the other in well-ordered succession, the demonstrations are well chosen, and the wording is clear and effective. Altogether Mr. King has done his work diligently and with good judgment, and has placed all future students of the Institute under a debt of obligation to himself and to the Council.

ROSENBUSCH'S "PETROGRAPHY."

II.

Mikroskopische Physiographie der massigen Gesteine. Von H. Rosenbusch. II. Abtheilung. Zweite gänzlich umgearbeitete Auflage. (Stuttgart, 1887.)

IN a notice (NATURE, vol. xxxv. p. 482) of the first part of the present work, we showed that the author, adopting a natural system of classification which gives the first place to field-evidence, divides the eruptive rocks into three great groups, viz. (1) the *Plutonic* rocks; (2) the *Dyke* rocks (*Ganggesteine*); and (3) the *Volcanic* or *Effusive* rocks. Unable to free himself entirely from the idea that geological age ought to be an essential factor in rock-classification, he subdivides the third group into a *palæo-volcanic* and a *neo-volcanic* series. It is the treatment of the neo-volcanic series which constitutes the bulk of this, the second and final part of the book.

The neo-volcanic rocks, which are stated to be essentially confined to Tertiary or post-Tertiary times, occur, for the most part, as lava-streams and sheets, and are often accompanied by tuffs. They are classified by Prof. Rosenbusch as follows :—

(*a*) Family of the Liparites and Pantellerites (equivalents, on the one hand, of the palæo-volcanic quartz-porphyries, on the other, of the granitic plutonic rocks).

(*b*) Family of the Trachytes and basic Pantellerites (equivalents of the palæo-volcanic quartzless porphyries, and of the plutonic syenites).

(*c*) Family of the Phonolites and Leucitophyres (equivalents of the plutonic elæolite-syenites).

(*d* and *e*) Family of the Dacites and Andesites (equivalents of the porphyrites and diorites).

(*f*) Family of the Basalts (equivalents of the melaphyres and certain augite-porphyrites in the palæo-volcanic series; and of the gabbros and diabases among the plutonic rocks).

(*g*) Family of the Tephrites (equivalents of the theralites, *i.e.* plagioclase-nepheline rocks of the plutonic series).

From this synopsis the merits of the new classification may be appreciated. No classification that taxonomic ingenuity may devise will wholly satisfy the desires of the sanguine petrologist. Rocks, however much they may be characterized by a certain amount of geological uniformity persistent over large areas (which have aptly been termed "petrographical provinces"), are still, it must be remembered, mere mineral aggregates; and the amount of possible variation, dependent on differences in chemical constitution, and varying conditions of consolidation, is enormous. Rock-types, which may be clearly defined and sharply separated on paper, will, in the field, often be found passing over into one another by gradations so imperceptible that the petrographer must regard as hopeless any attempt to draw a hard and fast line between them.

A weak point in Prof. Rosenbusch's classification seems to us his fundamental separation of the "dyke-rocks" (*Ganggesteine*) from the plutonic and volcanic series (*Tiefen- und Ergussgesteine.*) Both plutonic bosses and volcanic sheets must necessarily be accompanied by dykes or pipes through which the eruption took place, and into the rocks composing which they pass by imperceptible gradations. The author, indeed, calls attention himself to this fact (on pp. 6 and 522), and proposes to include under the head of "*Ganggesteine*" only those rocks which occur *solely* in the form of dykes and are unaccompanied by tuffs. Still, rocks so nearly allied as these must necessarily be to the dykes and volcanic pipes and necks in immediate connection with the centre of eruption, should not, we think, be so widely separated from them. On the other hand, we find placed in this group rocks, such as granite-porphyry, which are known to occur in bosses, as, for instance, at Shap and at Dartmoor.

As to the question of age, it is so far satisfactory that the author has gone a step in what is surely the right direction, in eliminating this factor from the consideration of the plutonic rocks. With regard to the advisability of retaining the separation into an older and a younger series of the volcanic rocks, Prof. Rosenbusch refrains from expressing an opinion (p. xi. of preface.) In connection with this question, we must draw attention to one point. The structure characteristic of the dolerites (diabases of the Germans) in which allotriomorphic masses of augite are penetrated by idiomorphic crystals and microlites of felspar, and which is known as *ophitic structure*, occurs nowhere in more typical development than in the dolerites of the Western Isles of Scotland (described and figured by Judd) and of Iceland (Bréon), a statement that anybody who has seen rock-sections from these localities will support. Yet these rocks, apparently because they are of Tertiary age, are placed by Prof. Rosenbusch (pp. 725 and 733) with the basalts, and are described as possessing "*intersertal structure*," a structure characterized, according to the definition given on p. 504, by the presence of a hypocrystalline interstitial substance (mesostasis) wedged in between the felspars. That some of the rocks in question contain small wedge-shaped portions and films of glassy interstitial substance nobody will deny; but that many of them are perfectly holocrystalline and truly ophitic is equally beyond question.

Besides "intersertal structure" we notice two other structural terms used now for the first time, viz. "*pilotaxitic*" and "*hyalopilitic*." The former is applied to a holocrystalline structure, especially characteristic of certain porphyrites and basalts, in which the ground mass consists essentially of slender laths and microlites of felspar in felted aggregation, and often exhibits fluxion-phenomena. The addition of films of glass produces "*hyalopilitic*" structure.

New rock-names are *Tholeiite* (p. 504) and *Alnöite* (p. 805). The former is given to a variety of augite-porphyrite with typical "intersertal structure." Certain North of England dykes (the Hett dyke, Tynemouth dyke, and Hebburn dyke) described by Teall, are referred to this group. Several of the English, Scotch, and Irish traps, described by Allport and Hull, are, according to the author, olivine-tholeiites (p. 515). The word "*Alnöite*" is applied by Prof. Rosenbusch to a subdivision of the melilite-rocks, hitherto classed with the melilite-basalts, but differing from the latter by their occurrence in the form of dykes and their near relation to the elæolite-syenites.

Interesting to English readers are the remarks contained on pp. 417, 418. In referring to the Cambrian quartz-felsites and felsites of Wales, which have been described by Messrs. Bonney, Cole, and Rutley, Prof. Rosenbusch compliments these authors on not having overlooked the influence of dynamic metamorphism in developing their present character. He then goes on to say that he has been led, partly by Prof. Bonney's descriptions, partly by the examination of sections, to the belief that two distinct classes of rocks are here associated, viz. metamorphosed eruptive rocks (schistose porphyries), and metamorphosed slates and tuffs (porphyroïdes). A comparative study of these rocks in connection with the "*Lenne-porphyren*" and the porphyroïdes of the Thüringer Wald would, the author thinks, be productive of interesting results. Many of these rocks (*e.g.* from between Llanberis and Cwm-y-Glo, north-west of Cwm-y-Glo, Llyn Padarn, near Llanberis; also the nodular felsites from Conway Falls, and the rock from Digoed) ought, judging from the frequent occurrence of striated and microperthitic felspars,

rather to be referred to the quartz-keratophyres than to the quartz-porphyries (p. 418).

We are glad to see that olivine is no longer regarded by the author as an essential constituent of basalt. This rock-name is thus made to gain considerably in significance, since it now embraces all (neo-)volcanic rocks of *basic* composition which essentially contain plagioclase and augite, whether they occur as lava-sheet or dyke. The *acid* plagioclase-augite rocks, on the other hand, whether with or without olivine, are referred to the andesites.

In connection with the basalts, it may be of interest to point out how considerable an alteration in the minor subdivisions of a rock-group has been produced by modern microscopic research. The old familiar grouping of the basalts, according to their granular texture, as dolerite, anamesite, and basalt, has been superseded. The modern petrographer distinguishes, with Prof. Rosenbusch, between the following structural varieties, which may coexist with any granular dimension: (1) "hypidiomorphic granular," (2) "intersertal," (3) "holocrystalline-porphyritic," (4) "hypocrystalline-porphyritic," and (5) "vitrophyric."

Welcome additions to the book are an appendix to the invaluable literature-index of Vol. I., bringing it up to the present date; and a useful index of localities, compiled by Dr. H. B. Patton. The book is well got up, well printed, and remarkably free from typographical errors.

F. H. HATCH.

A TREATISE ON CHEMISTRY.

A Treatise on Chemistry. By Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives; or, Organic Chemistry. Part IV. (London: Macmillan and Co., 1888.)

THE present instalment of this well-known work deals with those benzenoid compounds containing respectively seven and eight atoms of carbon.

The excellent features referred to in our notices of the previous parts are preserved in this new section. The historical portions are especially valuable. Most text-books of organic chemistry restrict themselves to giving an account of the existing state of the science; but in the present work the description of every important compound, or group of compounds, is prefaced by an historical review of the various investigations which have led up, step by step, to the views now held. To students of organic chemistry, who, in ninety-nine cases out of a hundred, never see the older memoirs (and, if they did, would probably only be bewildered by the obsolete nomenclature and formulæ), these historical introductions are a great boon. As instances of this interesting mode of treatment, we may cite the historical introductions to the subjects of *toluene*, of the *nitrotoluenes*, and of *creosote*—with the account, in the latter case, of the confusion between creosote and phenol, and of the way in which this confusion was eventually cleared up. In this connection we may call the attention of our spelling reformers among English chemists to the passage (p. 33) quoted from Reichenbach's original memoir in which he first coins the word "creosote." The etymological knowledge of the average English chemist (when it exists at all) is little—and dangerous. He has learned that there is such a word as κρέας, and rashly opining that he is at liberty to derive an English word from a Greek nominative, he changes Reichenbach's spelling to "cre*a*sote"—a corrupt form which, as "creasotum," has passed into the Pharmacopœia, embalmed in the choicest apothecaries' Latin. One regrets that the zeal of the reformer was not tempered by the knowledge that Reichenbach derives the word from the contracted genitive, κρέως.[1]

The descriptive portion of the work is full and accurate. The only case that we have noticed in which the information is not up to date is in the account of the *benzaldehydines* (pp. 141 and 142), which are represented as ordinary condensation-compounds of ortho-diamines with benzaldehyde; whereas Hinsberg showed, about a year and a half ago, that they are in reality benzylated anhydro-bases. The name "Nevile" is also throughout erroneously given as "Neville."

OUR BOOK SHELF.

A Text-book of Organic Materia Medica. By Robert Bentley, M.R.C.S., F.L.S. Cr. 8vo. pp. 415. (London: Longmans, Green, and Co., 1887.)

IT is a difficult matter to produce a text-book of materia medica which shall answer the requirements of the student in these days. No subject is less clearly defined either by teachers or by the authorities at Examining Boards. Prof. Bentley indicates this difficulty in his introduction, where he first defines "materia medica" and the allied words "pharmacology" and "therapeutics," and then confesses that our first English authority in this department of science, Dr. Lauder Brunton, has used some of the terms in a different sense. There is one advantage, however, in this difference of view—namely, a variety in the treatment of the subject; and we have to thank Prof. Bentley for having produced a work which departs in many directions from the somewhat stereotyped arrangement of English works on materia medica.

As might have been expected from the accomplished Professor of Botany in King's College, the work is mainly devoted to a careful description of the characters of medicinal plants and their products. The arrangement of the plants is founded, so far as the Phanerogamia are concerned, upon that adopted by Bentham and Hooker in their "Genera Plantarum." The descriptions are given very fully, so as to enable the student to recognize the drugs with facility and certainty, and thus at the same time readily to detect any adulteration. The author is right when he expresses his belief that in the latter respect the book will be especially valuable to the pharmacist. To the medical student and to the medical practitioner adulteration is no longer a subject of direct interest. The day has gone by when crude drugs came into the dispensary of the doctor, who now buys all the preparations ready made; and the Examining Bodies, aware of this, have relieved medical students of the laborious subject of drug adulteration, and now require of them the recognition of but a few of the most important specimens. No doubt the book will find its largest circle of readers amongst young men preparing for the examinations of the Pharmaceutical Society.

In our opinion it would have been better to give the strength as well as the dose of the more important preparations, such as those of opium.

The sections on the chemical composition of drugs have

[1] "Of course the reformer may write "creatosote" if he chooses; but "creasote" is inadmissible.

been carefully brought up to the level of recent researches. The methods of the separation of active principles, such as morphine and atropine, from the crude substances, and their reactions, are not given.

Prof. Bentley does not undertake to give more than the most general indication of the action of the remedies he has so fully described. All that is said of rhubarb, for instance, under the heading of medicinal action, is that "it possesses tonic and slightly astringent properties, and in large doses it acts as a purgative." This is a very good system for pharmaceutical students, and according to some authorities for medical students also at the commencement of their career. But it manifestly encourages learning by rote. What impression of definiteness or value does the word "tonic," for example, represent in the mind of the juvenile reader? Of course none.

Again, whilst we acknowledge that Prof. Bentley has on the whole confined himself to an account of the actions of the various drugs on the healthy organism, we must object to the heading "Medicinal Properties," which is put before the paragraphs descriptive of these. A drug has an action quite apart from the circumstance that it may be employed as a "medicine," *i.e.* in relation to the treatment of disease.

The book contains a number of beautiful illustrations of plants and drugs. It is remarkably free from typographical errors, and the style of its production reflects credit on the publishers.

Catalogue of the Fossil Mammalia in the British Museum (*Natural History*). Part V., containing the Group Tillodontia, the Orders Sirenia, Cetacea, Edentata, Marsupialia, Monotremata; and a Supplement. By Richard Lydekker, B.A., &c. (London: Printed by order of the Trustees, 1887.)

WITH this part Mr. Lydekker completes his laborious and very meritorious work of cataloguing the large collections of Mammalian fossil remains in the British Museum.

The named species are 719 in number, and are arranged under 301 generic and 100 family headings, 106 out of this total being regarded as not to be distinguished from existing forms.

Rich as is the collection in the British Museum, it is very far from including all the known existing fossil forms of Mammalia; but, failing any treatise on such, this work will be of the greatest assistance to all workers in this field. Though at the commencement of his Catalogue Mr. Lydekker did not give descriptions of all the forms detailed, yet, as it proceeded, he somewhat altered his method, giving some of the more important distinctive characters, and so the value of the work to the student has been increased.

A volume of this nature is not capable of being described in any detail, and it will suffice to add that it will be quite a necessary book of reference in the library of a biologist.

Lehrbuch der Histologie. Von Dr. Philipp Stohr, a. o. Professor der Anatomie zu Wurzburg. (Jena: Gustav Fischer, 1887.)

THIS is an excellent little treatise on the same lines as Ranvier's larger "Traité Technique d'Histologie" and Prof. Schäfer's smaller "Essentials of Histology." The various tissues are systematically described with clear and well selected wood-cut illustrations; and after each section of the systematic description a full and careful account is given of the best methods of preparation, which will enable the student to verify the descriptive account. The microscopic structure of the chief organs is treated in the same way. The directions as to *technique* are not merely those suitable for an elementary student, but such as will be useful to one who is advancing in the direction of original research. The figures are, with the exception of a few diagrams, actual representations of what the student should be able to obtain by the particular mode of preparation recommended. An introductory chapter treats of the arrangement of the laboratory, and the apparatus and reagents necessary.

E. R. L.

A Treatise on Photography. By Captain Abney, R.E., F.R.S. (London: Longmans, Green, and Co., 1888.)

THE appearance of a fifth edition of this well-known book is sufficient proof of its popularity, and no trouble seems to have been spared by the author to make this issue a success. The volume has been thoroughly revised, and much new matter added. The author gives the results of his researches, communicated to the Royal Society, on the "Effect of the Spectrum on the Haloid Salts of Silver;" concluding with a chapter on celestial photography, and photography with the microscope.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coral Formations.

I HAVE read Captain Wharton's paper on "Coral Formations" (p. 393), and the letters of Mr. John Murray and Mr. G. C. Bourne in your issue of March 1.

There is, doubtless, room for difference of opinion as to this important and many-sided question, but I think the balance of evidence is in favour of Mr. Murray's view as to the formation of lagoons.

In this connection the fact that carbonate of lime is soluble in water had been practically overlooked, and its increased solubility in sea-water seems to have been unnoticed before Mr. Murray formulated his views as to their formation. The active life in coral reefs is practically outwards (assuming a shape similar to fairy rings on grass), leaving the central portion more or less dead, or with wide spaces of coral sand and only scattered patches of living animals. The organic matter in this dead coral, by its oxidation, produces carbonic acid, which dissolving in the sea-water exalts its solvent action on the carbonate of lime, now more or less in an amorphous condition.

Reducing such a question to figures has a great advantage, and is often the only way of arriving at a safe conclusion. With assistance derived from the Scottish Marine Station, I have lately been conducting some experiments on the solubility of carbonate of lime in sea-water, the results of which may interest the readers of NATURE at the present time.

The experiments were conducted with sea-water of specific gravity 1·0265 (obtained from the German Ocean 20 miles from land), and at temperatures of from 70° F. to 80° F., which reefs require. The corals used were several species of *Porites*.

Dead or rotten coral exposed to sea-water under these circumstances is soluble to the extent of 5 to 20 ounces per ton.

Take now a reef with a lagoon already formed, half a mile in diameter. This will give an area of about 600,000 square yards, and supposing the water to be 3 feet deep and only one-sixth part of this to be in actual contact with the dead coral, we have 100,000 tons exerting its solvent action. This would give, were the sixth part of the lagoon water to be expelled and replaced with fresh sea-water at each tide, and taking the solvent action at only 10 ounces to each ton, an amount of carbonate of lime removed equal to about 3000 tons each year.

I do not insist that such an amount of carbonate of lime *must* year by year be removed from the lagoon, but I think these experiments show that the carbonate of lime so removed may easily exceed any additions to the lagoon by secretions of

animals living in it, or by coral sand carried into it by wind and waves from the outer edge in the same space of time, and therefore I think the balance of evidence is in favour of Mr. Murray's explanation of lagoon formation.

Could the experiment be made, it would be a matter of extreme interest to know if, and in what proportion, carbonate of lime really exists in lagoon waters, as also the proportion in the waters outside the reef, where new coral formation is actively at work.

It is quite reasonable to suppose that the dead coral so dissolved in the formation of lagoons is carried out as material for fresh coral growths. ROBERT IRVINE.

Royston, Edinburgh, March 6.

IN reference to the interesting discussion on coral formations which has recently appeared in NATURE, a few words from the chemist's point of view may not be out of place.

For some time past I have been endeavouring to satisfy myself regarding the solubility of calcium carbonate in sea-water, and with this end in view I immersed weighed pieces of dead coral (dried at 212° F. till constant) in sea-water. These were protected by suspending them under glass bells floated in about 18 inches of water, and allowed to remain at rest for a known length of time. The following are the results obtained:—

First Experiment.—Oculina varicosa, from St. Thomas, West Indies, weight 16·3164 grammes, with a surface of, roughly, 8 square inches, lost by solution in twenty days, 0·0748 gramme.

Second Experiment.—Madrepora scabrosa, from Levuka, Fiji, weight 21·8540 grammes, surface of 16 square inches, lost 0·1497 gramme in thirty days.

Third Experiment.—Montipora foliosa, Amboyna, weight 15·3334 grammes, surface of 15 square inches, lost 0·1223 gramme in forty-six days.

Every care was taken that the corals should not be subjected to the action of other than convection currents. The temperature ranged between 30° and 40° F. Specific gravity of the water found less than 1·026.

Mr. W. G. Reid, in a paper communicated to the Royal Society of Edinburgh, showed that the solubility of carbonate of calcium increased with pressure; and when determining the percentage of $CaCO_3$ in certain soundings I found that the greater the depth the less carbonate derived from surface shells was present, while it is a well-known fact that in the red clay or other deep-sea deposits, $CaCO_3$ almost completely, if not entirely disappears, as has frequently been pointed out by Mr. Murray.

From the above considerations there can be little doubt that there is considerable action going on in the waters of the ocean.

Take, for instance, a circular lagoon four miles in diameter; this would give a superficial area of 12½ square miles. Taking the results obtained in Experiment 1, and applying them to this imaginary case, then in twenty days, in absolutely still water, there would be dissolved 464 tons of $CaCO_3$, equal to 8472 tons in a year. If the specific gravity of carbonate of calcium be taken at 2·65, this amount would give a thickness of half an inch covering the whole area of the lagoon. In other words, at the same rate it would require about a century to deepen the lagoon one fathom.

These results must be, however, very much under-stated, as the temperature in the coral regions is about twice what I could obtain; the sea-water is denser; there is the action of carbonic acid gas, CO_2, which is constantly being generated by decomposing organic matters, especially in these warm areas, and all which would increase materially the solubility. Moreover, there are the tides and currents continually replacing, or rather mixing with, the denser waters.

The coral animals in the lagoon are, however, constantly laying down new material in the shape of $CaCO_3$, assimilated either directly from the sea or through the medium of other organisms upon which they feed, or both combined. Now it depends upon the excess of the one process over the other whether there be an increase or decrease in the depth of the lagoon.

Growth is restricted mainly in reefs to the outer periphery, leaving large spaces of coral sand in the interior to be freely acted upon. In this way the coral formation increases outwards, while there is a deepening of the interior, albeit this deepening is very small. JAMES G. ROSS.

14 Argyle Place, Edinburgh, March 10.

CAPTAIN WHARTON in his interesting paper satisfactorily explains a condition of reef-growth previously little known and but imperfectly understood. I was pleased to learn that Mr. Bourne's long-expected account of Diego Garcia will soon be published. His remarks concerning the *directing* influence of currents agree closely with those of Semper ("Animal Life," vol. xxxi. Internat. Sci. Ser. p. 228). Of the importance of this agency there can, I think, be no doubt; but solution is also an important agency within the lagoon, and one more capable of actual demonstration than the directing force of the currents. But amongst the supporters of the *anti-subsidence* theory of Murray there is a difference of opinion as to the relative importance to be attached to solution; and we cannot accept the name of "theory of solution" for the new view if it is intended to exclude the other agencies that previously cause the death of the coral, such as the repressive influence of sand, the diminished food-supply, the tidal scour, &c. With this exclusive meaning, the name "theory of solution" would contradict itself, and we should be regarding the problem in much the same light as if we were solely to contemplate the mystery of our own existence from the point of view of the undertaker.

The development of the new theory should be borne in mind. Chamisso, seventy years ago, advanced the view that an atoll owes its form to the growth of the corals at the margin and to the repressive influence of the reef-debris in the interior; but this view gave no satisfactory explanation of the foundation of such a coral reef, and Darwin was driven to his theory of subsidence. The great defect in the view of Chamisso was, however, removed by Murray, who supplied the *foundation* of an atoll without employing subsidence; and investigations in the Florida Sea and in the Western Pacific have confirmed his conclusions. The *forms* of reefs he attributed to well-known physical causes; but Semper and Agassiz have dwelt upon the importance of other agencies, and in our present state of knowledge it will be wisest to combine in one view the several agencies enumerated by these three naturalists as producing the different forms of coral reefs. On the outer side of a reef we have the directing influence of the currents, the increased food-supply, the action of the breakers, &c. In the interior of a reef we have the repressive influence of sand and sediment, the boring of the numerous organisms that find a home on each coral block, the solvent agency of the carbonic acid in the sea-water, and the tidal scour. These are all real agencies, and we only differ as to the relative importance we attach to each. Future investigations will probably add others to the list, besides ascertaining the mode and degree of action of each cause.

March 10. H. B. GUPPY.

Reason and Language.

THE kindness of Prof. Max Müller's reply I recognize with pleasure but without surprise, since those who know him know him to be as remarkable for his courtesy as his great learning.

In answer to his first question, I must say that I made a point of attending his Royal Institution lecture on the day his "Science and Thought" was published, and was greatly disappointed that illness hindered my attending the others. But I immediately obtained his book, and applied myself to understand what seemed to me its essence, though I have not read it from cover to cover. Should I have to review it, of course I shall conscientiously peruse the whole of it.

Before replying further, it may be well to restate my position as follows.

Man is an intellectual being able to apprehend certain things directly and others indirectly. Normally, his conceptions clothe themselves in vocal sounds, and get so intimately connected therewith, that the "word" becomes practically a single thing composed of a mental and an oral element. But these elements are not *identical*, and the *verbum mentale* is anterior and superior to the *verbum oris* which it should govern and direct. Abnormally, conceptions do not clothe themselves in oral expressions at all, but only in manual or other bodily signs, and this shows that concepts may be expressed (however imperfectly), in the language of gesture without speech. One consequence of these relations is that neither the utterance of sounds (articulate or inarticulate) nor bodily movements could have generated the intellect and reason of man, and Noiré's hypothesis falls to the ground. On the other hand, beings essentially intellectual, but as yet without language, would immediately clothe their

nascent concepts in some forms of bodily expression by means of which they would quickly understand one another.

As to the expressions "reason" and "reckoning," I would observe that a study of an organism's embryonic development is a most valuable clue to its nature, and no doubt a similar utility attends historical investigations in Prof. Max Müller's science. Nevertheless, we cannot understand the nature of an animal or plant by a mere knowledge of an early stage of its existence; an acquaintance with the outcome of its development is even more important. Similarly, I venture to presume, the ultimate meaning of a word is at least as much its true meaning as is some archaic signification which may have grown obsolete. The word "spirit," if it once meant only the breath, means more now—as we see from the Professor's first letter. Similarly, if "reason," in its Latin form, once only meant "reckoning," that is no "reason" why it should only mean reckoning now. Here it would seem as if we had an instance of the *verbum mentale* having acted upon and modified the *verbum oris*. I cannot but regard the representation that affirmative and negative propositions are mere cases of addition and subtraction as an incorrect and misleading representation, save when they refer to mathematical conceptions. I am compelled also to object to another of the Professor's assertions. He says:—"There is a wide difference between our apprehending our own activity and apprehending that A is A. Apprehending our own activity is inevitable, apprehending that A is A is voluntary." It is true there is a great difference between these apprehensions, though they both agree in being instances of apprehensions which are not inferences, and as such I adduced them (NATURE, February 16, p. 364). Nevertheless in my judgment the difference between them is not the difference which the Professor states. Both are alike voluntary, regarded as deliberate reflex cognitions, and both are alike inevitable, regarded as indeliberate, direct perceptions. The labourer inevitably perceives that his spade is what it is, though the nature of that perception remains unnoticed, just as he inevitably perceives his own continuous being when he in no way adverts to that fact.

I must further protest against the assertion that the idea "therefore" is "present in the simplest acts of cognition"—that every perception of an object is an inference. This I regard as one of the fundamental errors which underlie all the madness of idealism. Akin thereto is the notion that a philosopher who desires to speak with the very strictest accuracy ought, instead of using "the big I," to say, "a succession of states of consciousness." To me it is certain that even one state of consciousness (to say nothing of "a series") is no more immediately intued by us than is the substantial ego; each being cognized only by a reflex act. What I intue is my "self action," in which intuition both the "ego" and the "states" are implicitly contained, and so can be explicitly recognized by reflection. I was myself long in bondage to these two errors, from which it cost me severe mental labour to escape by working my way through philosophical subjectivism. These questions I cannot here go any further into, and I only mention them in consequence of Prof. Max Müller's remarks. I will, however, in turn, refer him to my "Nature and Thought," as well as to a larger work which I trust may before long be published, and which, I venture to hope, he will do me the honour to look at.

My object in calling attention to the fact that one word may have several meanings, and several words one meaning, was to show that there could not be "identity" between thought and language. This point the Professor seems practically to concede, since he now only calls them "inseparable, and in one sense identical." I do not understand degrees of identity. No mere closeness of resemblance or connection can make two things absolutely identical. I did not, however, content myself with denying this "identity" on account of polyongeny and homonymy; I also referred to common experience (which shows us that men do not invent concepts for preformed words, but the reverse), and I appealed to certain facts of consciousness. To my assertions about consciousness the Professor replies: "The object of all scientific inquiry is the general and not the individual." But this is a quite inadequate reply, since our knowledge of general laws is based on our knowledge of individual facts, and if only one man could fly, that single fact would be enough to refute the assertion that flight is impossible to man.

With respect to evolution, I never said that Prof. Max Müller misunderstood "natural selection," but only that he misrepresented it—of course unintentionally. It is of the essence of natural selection not to affirm teleology as formerly understood, although, of course, it can say nothing (for the whole of physical science can say nothing) about a primordial teleology at the foundation of the entire cosmos. I, in common with the Professor, look forward to "the ultimate triumph of reason and right," but my confidence is not due to any "faith" I have in "Nature" or anything else. I profoundly distrust "faith" as an ultimate basis for any judgment; I regard my conviction as a dictum of pure reason—the certain and evident teaching of that science which underlies and gives validity to every other. I therefore agree with Prof. Max Müller in regarding it as a lesson which "true philosophy teaches us."

ST. GEORGE MIVART.

Oil on Troubled Waters.

IT may interest some of the readers of Captain Wharton's paper on this subject to have their attention called to a curious narrative in Bede, illustrative of the power of oil over troubled waters. When a certain presbyter, Utta, was sent from the North of England by Oswiu to fetch his bride from Kent, he applied to Aidan, the greatest teacher of his day, for his blessing. Aidan gave him not merely his blessing, but some consecrated oil, and told him that on his way back from Kent by sea he would encounter a storm, and thereupon he was to pour the oil on the sea, which would immediately become calm. It happened as St. Aidan had foretold. Utta and his fair charge were duly overtaken by a fearful tempest; the waves were breaking over the ship, when Utta bethought himself of Aidan and his oil. "Assumpta ampulla, misit de oleo in pontum, et statim, ut prædictum erat, suo quievit a fervore" ("Historia Ecclesiastica," lib. iii. cap 15). Aidan had been brought up at the monastery of Iona. Did the boatmen of the Western Islands in the seventh century know of this use of oil? and did Aidan bring the knowledge from thence that saved from shipwreck Utta and the bride Eanfleda?

EDW. FRY.

Were the Elephant and Mastodon contemporary in Europe?

ONE of the most effective services which NATURE does for the cause of science is to enable students who live far apart to exchange ideas in its correspondence columns. May I be allowed to ask a question of some interest, perhaps, to others besides myself? It is a singular fact that we probably know less of the *sub-aërial* conditions prevailing in so-called Pliocene times than we do of those of most geological horizons. The marine Mollusca of this age have been preserved in large numbers and in many places, but the remains of the land fauna are singularly sporadic and broken.

I know of no fragment of a land surface of this age which exists in Britain. In the Crags we have a very puzzling medley of mammalian bones and marine shells mixed heterogeneously, and pointing unmistakably to the beds having been rearranged, and, as the French say, *remanié*.

Unfortunately the Pliocene period has been largely defined on the evidence of these very unsatisfactory beds—unsatisfactory not merely because *it is certain* that the remains of land and marine animals are confusedly mixed up in them, but also because *it is exceedingly probable* that the debris of two geological stages have been mixed together also.

It seems clear to me that, if the Pliocene age is to be clearly defined, we must not rely upon the evidence of the English Crags for defining it, but go elsewhere—namely, to France, Italy, &c.

It is very well known that nowhere in France has the mastodon, which is generally accepted as a very typical Pliocene mammal, been found in the same beds with the elephant. In the English Crags, no doubt the older type of elephant (the *E. meridionalis*) and possibly also molars of the later forms (*E. antiquus* and *E. primigenius*) have occurred with mastodon remains and the remains of other so-called Pliocene beasts; but the mixed character of these deposits puts them out of court, and we are bound to follow the evidence of the French beds, which occur *in situ* and unmixed, if we are to be assured of our position.

My purpose in writing is to ask whether the Italian evidence is the same as the French. Unfortunately the Italian beds do not seem to me to have been studied with the minute care which they deserve. No doubt enormous numbers of mastodon remains and also of remains of *E. meridionalis* occur close together in Italian deposits, but so far as I know the question has not been critically tested as to whether they occur in the *same* beds

or not. Prof. Capellini, of whom I asked the question at the meeting of the British Association at Manchester, could not answer me. *Primâ facie* we should certainly expect the Italian evidence to support the French, but this is by no means the conclusion to be drawn from text-books, in which it is generally taken for granted that in Italy the elephant and mastodon have been found at the same horizon.

The question is one of very great interest and importance, and an answer to it would be especially valuable to me. Perhaps some of your readers may have the means of answering it.

HENRY H. HOWORTH.

21 Earl's Court Square, February 28.

True Average of Observations?

I HAVE long been dissatisfied with the method of taking the arithmetic mean as the most probable value of a *comparatively few* direct observations of a quantity. This is certainly the legitimate result of the theory of probability, or "method of least squares," when one knows nothing to guide one in giving more weight to one than to another observation.

But without knowing anything of the conditions under which the observations were made, or, otherwise, no choice among them being possible by considering these conditions, still, when one comes to compare the results among themselves, this comparison seems to me to afford means of judging between them. Thus, if all the results are plotted on sectional paper, they are found to be grouped closely together at one place and to be scattered wide apart at others. Now the most probable result (whatever be the right method of finding it) lies certainly somewhere about the place of close grouping; and it seems fair to consider those results that come near this place as the *better ones*, and to allow to them *more weight* than to the others in calculating the mean.

If the observations were extremely numerous, there can be no objection to taking the arithmetic mean as the true probable value. But one has usually to content one's self with a few only, and in order to get a better approximation in this case I have constructed the following formula. I would be glad if some of your correspondents will express their opinions as to its legitimacy. In a case of this kind one ought not to trust entirely to one's own judgment; one should submit one's own judgment to be checked by that of several others.

The method I propose is as follows.

First fix upper and lower limits outside which the true value cannot possibly lie, and reject absolutely all measurements outside these limits. The result will not be appreciably affected by taking these limits a little higher or lower, and it is better to err in taking them too wide apart than *vice versâ*. One usually has, or ought to have, a general notion of the quantity sought for, sufficient to determine these limits; but if this be not so, they may be determined by adding to and substracting from the arithmetic mean what is thought to be the maximum possible error.

Let x_1, x_2, x_3, &c., be the *excesses* of the various measurements above the lower of the above possible limits. Let x_0 be the *excess* above the same limit of the as yet unknown most probable value as determined by the formula below.

Attach to each x the weight $\left\{1 - \left(\frac{x - x_0}{x_0}\right)^2\right\}$, *and take as x_0 the mean of the x's with these weights attached.*

Note that equal weights are given to measurements equally above and below x_0. Also to an x coinciding with the lower possible limit, a weight zero is given. Zero weight is also given to an x as much above x_0 as the lower possible limit is below it.

The rule results in the following formula:—

$$\text{Weight for } x = 1 - \left(\frac{x - x_0}{x_0}\right)^2 = \frac{2x_0x - x^2}{x_0^2},$$

$$x \times \text{weight} = \frac{2x_0x^2 - x^3}{x_0^2}.$$

Therefore, the mean equals—

$$x_0 = \frac{2x_0\Sigma x^2 - \Sigma x^3}{2x_0\Sigma x - \Sigma x^2}.$$

This is a quadratic for x_0, the solution of which is—

$$x_0 = \frac{3}{4}\frac{\Sigma x^2}{\Sigma x}\left\{1 + \sqrt{1 - \frac{8}{9}\frac{\Sigma x \Sigma x^3}{(\Sigma x^2)^2}}\right\}.$$

Of course the labour of finding this mean is greater than that of finding the arithmetic mean; it involves summing the first, second, and third powers. But the method is only intended to be used when the number of values to be dealt with is not large, and with the help of a table of squares, cubes, and square roots, the work is not really very laborious.

It is easy to prove that this result is identical with the arithmetic mean in the following three cases: (1) all the x's equal; (2) the x's all equidistant, *i.e.* forming an arithmetic progression; (3) the x's infinitely numerous.

The practical meaning of the rule may perhaps be made clearer by the annexed table, giving the weights attachable to various values of x where x_0 is taken equal to unity.

x	1 or	·9 1·1	·8 1·2	·7 1·3	·6 1·4	·5 1·5	·4 1·6	·3 1·7	·2 1·8	·1 1·9	0 2
$1 - \left(\frac{x - x_0}{x_0}\right)^2$	1	·99	·96	·91	·84	·75	·64	·51	·36	·19	0

The following is a numerical example:—

x	x^2	x^3
1·73	2·993	5·178
·89	·792	·705
·42	·176	·074
1·21	1·464	1·7715
1·17	1·369	1·6016
$\Sigma x = 5·42$	$\Sigma x^2 = 6·794$	$\Sigma x^3 = 9·330$

$$\sqrt{1 - \frac{8}{9}\frac{\Sigma x \Sigma x^3}{(\Sigma x^2)^2}} = ·162 \text{ and } x_0 = 1·0925.$$

The arithmetic mean or $\frac{\Sigma x}{5} = 1·084$.

Mason College, February 4. ROBERT H. SMITH.

Crepuscular Rays in China.

IMMEDIATELY after sunset enormous rays of light are frequently seen spreading from the part of the horizon where the sun has disappeared, and also—though somewhat fainter—from the opposite part of the horizon. Sometimes the rays stret ch right across the sky, and when strongly developed they appear first in the east, and then in the west, and resemble auroral rays, glowing in a yellow or red colour, while the sky between the rays is deep blue or greenish. They appear to be caused by invisible cirro-stratus clouds high up in the air. This phenomenon is never seen in England, or at any rate it is by no means so conspicuous as here. Ancient Greek mariners may have had their imagination impressed by a similar phenomenon, ῥοδοδάκτυλος ἠώς being so frequently mentioned in Homer.

Crepuscular rays at sunrise or sunset are seen at all seasons in Southern China, but they are most frequent at the height of the typhoon season, and most intense just before typhoons, which latter are indicated beforehand by crepuscular rays as well as by halos.

The following table exhibits the number of evenings when strong crepuscular rays were registered in each month of the past three years, and also the mean monthly frequency of the strongly developed phenomenon:—

	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
1885	—	—	3	2	4	3	—	—
1886	—	1	1	1	3	7	—	1
1887	1	—	—	2	3	—	—	—
Mean	0·3	0·3	1·3	1·7	3·3	3·3	0·0	0·3

W. DOBERCK.

Hong Kong Observatory, December 31, 1887.

"An Unusual Rainbow."

I READ with interest a letter with the above heading in NATURE (vol. xxxvi. p. 581) from Mr. S. A. Hill of Allahabad, India, of date September 18, 1887. He describes a brilliant rainbow which he saw after the sun had set, and states that such a phenomenon "must be of rare occurrence," and that he had "never before seen anything similar, nor read anywhere a description of a rainbow after sunset." I had not read his letter when, on the

evening of the 1st inst. I observed a similar rainbow. I saw it first at 7h. 25m. p.m., the registered time of sunset here for that day. It lasted for nearly fifteen minutes. The western horizon was cloudy, and the sunset a fine one. The bow was exceedingly brilliant, and as far as I could judge, a perfect semicircle, the ends of the arc being about 4° above the horizon. There was a secondary bow equally perfect, and of remarkable brightness; the brilliant glow below the primary, and the marked dulness between it and the secondary, added to the beauty of the sight. After reading Mr. Hill's letter, I published my observations in a letter to the *Argus*, that others might confirm or correct them. I have received six replies, all in accord with my observations. One of my correspondents informed me that he had, some years ago, seen a lunar rainbow formed just before the moon had risen. H. M. ANDREW.

The University, Melbourne, January 26.

The Nest of the Flamingo.

IN an interesting article by Mr. Bowdler Sharpe, entitled "Ornithology at South Kensington," published in the December number of the *English Illustrated Magazine*, there is a description and figure of the flamingo's nest, and an opinion is expressed that the previously-held ideas about the nest being tall, and the female sitting upon it in a straddling manner, might now be considered as exploded.

I have seen numbers of these tall nests in the shallow pans of water—or "vleys," as they are locally called—in Bushmanland, Cape Colony, particularly at Klaver Vley. These quaint nests were built in the water where it was a few inches deep, and at a considerable distance from the shore. They were conical in form, about 18 inches high, and 6 inches in diameter at the top, with a shallow basin-like cavity for the eggs; built, so far as I can recollect, of slimy mud. To perform the office of incubation, the bird must have straddled over the nest. The species no doubt differs from the one described in the article. There should be no difficulty in securing specimens of these nests. Possibly the object aimed at in building the nests in the water is to secure them against some enemy, and the height of the nest, besides conveniencing the long-legged owner, provides for the rising of the water-level. E. J. DUNN.

Pakington Street, Kew, near Melbourne.

Dynamical Units and Nomenclature.

IN his review of Prof. MacGregor's "Kinematics and Dynamics," on page 361, Prof. Greenhill tilts a lance against those whom he terms mathematical precisionists. I do not know this book, and I hold no brief in its defence; but as I owe to these precisionists whatever clear ideas I have on mechanics, I feel bound to enter into the lists on their behalf, little as they need my aid.

Both the precisionists and practical men start with the same two dynamical quantities, which they respectively call *mass* and *force*, *weight* and *force*; of these they select arbitrary units, and respectively name them *pound* and *pound-weight*, *weight-of-a-pound* and *force-of-a-pound* (or *pound-weight* and *pound-force*).

To the single word *pound* the practical man does not, so far as I know, attach any single definite idea, and he cannot, therefore, use this word singly without introducing possible confusion; for it characterizes matter and force equally, and yet *is* neither. On this view Prof. Greenhill's own expression "the attraction of the earth on a pound," should for accuracy and consistency be "the attraction of the earth on the weight of a pound (*or* on a pound-weight)."

To the precisionist a pound *is* a certain mass, just as a foot *is* a certain length, so that the practical man's "weight of a pound" is simply the "pound" of the precisionist, who would no more dream of 'distinguishing' it as "the mass of a pound" than of distinguishing a foot as "the length of a foot."

The attraction of the earth on a certain amount of matter is called "the force of 10 pounds" by practical men, and "the weight of 10 pounds" by precisionists: these are purely *definitions*, so that the phrases are absolutely equivalent. If, then, in the specification of a force produced otherwise than by the attraction of the earth a precisionist is required to speak of it as "a force equal to the weight of 10 pounds," the practical man must follow suit with "a force equal to the force of 10 pounds." These expressions stand, or rather fall, together, and the consistent precisionist would specify the force as "10 pounds-weight" merely.

If, however, a *body*, such as a brickbat or the iron block supplied with a balance and called a "pound weight," is to be introduced into the specification, a precisionist would very properly say "a force equal to the weight of 10 brickbats or of 10 pound-weights"; and the *complete* idea hereby conveyed cannot be expressed by the practical man otherwise than by "the attraction of the earth on 10 brickbats or on 10 pound-weights."

In no way, then, is "a force equal to the weight of a mass of 10 pound-weights," the precisionist equivalent of the practical "force of 10 pounds," nor is it even consonant with precisionist nomenclature.

Since, therefore, the precisionist uses *mass*, *force*, *pound*, *pound-weight*, as the exact equivalents of the practical man's *weight*, *force*, *weight-of-a-pound*, *force-of-a-pound*, the advantage does not seem to lie on the side of the latter, more especially when he is untrue to himself in loosely using the word "weight" as often in the sense of "force" as according to his definition.

But so far both practical men and precisionists labour under the immense disadvantage of dealing with a variable force-unit which can be made precise only by a specification of place; and it is greatly to the credit of the latter that they have introduced a simple invariable force-unit by which all forces, whether due to gravitation or other physical action, may be expressed absolutely in a form which allows of direct comparison between them. With this unit ma is the correct measure of a force, and when Prof. Greenhill speaks of "the mathematician straining after the equation $F = ma$, when using the gravitation unit of force," I utterly fail to understand what is meant, considering that this expression of a force necessarily implies an *absolute* force-unit; and I further feel strongly tempted to deny that either for this unintelligible operation or for any other the precisionist ever uses g pounds as a mass-unit, though, if he ever does use a variable mass-unit in measuring the invariable mass of a body, he is surely countenanced by the practical man who does not hesitate to use a variable force-unit in measuring the invariable force exerted by a given spring compressed to a given extent. I might further add that the precisionist *never* measures the weight of a body in "pounds," even if he denotes it by w, and that, if he does sometimes denote this variable force by the same number irrespective of place, it is only when using the practical man's variable force-unit.

With regard to confusion arising from the use of the equation $w = mg$ any more than from the use of the equation $w = m$, this would be to me inconceivable, did I not notice that Prof. Greenhill uses the phrase "if the equation $w = mg$ is supposed to be used with absolute units." Does there indeed exist a single man who thinks that this equation can be used with other than absolute units? If such there be, to him certainly will confusion be not only possible, but probable too, and deservedly so; but to others there can surely be no more confusion in expressing a (precisionist) weight as m or mg indifferently than in expressing an angle as θ or $180\,\theta/\pi$, it being of course premised that the proper unit—(*precisionist*) *pound-weight* or *poundal*, *radian* or *degree*—is named.

Further, how it can be a solecism to measure pressure in poundals per square foot any more than in pounds-weight per square inch—which latter is the precisionist equivalent of what an engineer would loosely and most inaccurately call "pounds"—I am at a loss to understand, since pressure is the measure of the distribution of force over area, and a poundal is as much a force as "the force of a pound," and very much more definite. And how the expression of the (precisionist) weight of a body in poundals rather than in pounds-weight is a solecism also demands explanation.

Lastly, I must seriously protest against the suggestion that a precisionist should ever ask for, or want to buy, "half a poundal of tea": what he wants is the tea itself, the substance of it and not the earth's action upon it, and very rightly and properly he asks for "half a pound," which the consistent practical man would have to term "the weight of half a pound."

In the above I am not concerned to defend the practice of those mathematicians who select fantastic units of mass or force as a foundation for some puzzling questions of no utility whatever: I have merely attempted to define the position of the physicist or precisionist, and to rebut *seriatim* the charges brought against him in Prof. Greenhill's criticism.

February 27. ROBERT E. BAYNES.

Too many Decimal Places.

A COMMUNICATION in NATURE of January 26 (p. 294) ends with the sweeping suggestion "that, as a rule, only experimentalists are capable of judging the limits of accuracy of experiment, and that they may be trusted to save themselves trouble where trouble may be saved without sacrificing accuracy."

On the contrary, is it not true that experimenters, as a class, have shown a marked tendency to give unnecessary trouble, both to themselves and to those who utilize their re-ults, by using too many significant figures in their numerical work? The strictures of mathematicians have done much to check this tendency. But can it yet be claimed that their habits need no critical inspection in this respect? Not being prepared to bring forward statistics, I can only make this remark in the form of a query, which applies to the general statement quoted, rather than to the merits of the special discussion which gave rise to it. In vol. lxi. (1871) of the Journal of the Franklin Institute, Prof. Pickering has shown by graphical methods how greatly Regnault's coefficients may be simplified. J. RAYNER EDMANDS.

"The Teaching of Elementary Chemistry."

IN NATURE of February 23 (p. 389), an anonymous correspondent, signing himself "Z.," draws attention to what he calls "a few highly misleading passages in the two books reviewed under the above heading in NATURE of January 19."

In the name of the authors of these books, I challenge "Z." to make good his statement that the passage which he quotes from p. 65 of the "Elementary Chemistry," concerning the reaction between sodium and water, is "highly misleading." We assert that the sentence is not misleading. The second statement quoted by "Z." is not quite correct: chlorine monoxide is prepared by passing dry chlorine over yellow mercuric oxide, which has been previously dried at 300°-400°, at the ordinary temperature, not over heated mercuric oxide, as stated on p. 116 of the "Elementary Chemistry." We thank "Z." for the correction. But, inasmuch as the result of passing chlorine over yellow mercuric oxide dried at about 100° is to evolve oxygen without forming chlorine monoxide, the correction does not affect the argument, and it may still be justly said that in making chlorine monoxide "we carry out a reaction in which oxygen is produced in presence of chlorine." The supposed contradiction found by "Z." between the directions given in the "Practical Chemistry" to the student who is burning a weighed quantity of magnesium—not to remove the lid of the crucible lest some of the magnesia should be "volatilized and lost"—and the statement in the "Elementary Chemistry," that "no compound of magnesium has been gasified," rests upon a verbal quibble. *Volatilized* and *gasified* have not precisely the same connotation. I confidently assert that no student is in danger of being misled by either of the statements which "Z." has quoted.

"Z." states that the results of an experiment on the reaction between potash and iodine, described on p. 63 of the "Practical Chemistry," contradict the sentence on p. 62 of the same book concerning the similarities between the chemical properties of chlorine, bromine, and iodine. I reply that "Z." has here shown himself to be unacquainted with the methods of chemical classification; and also that he has taken the word *similar* to mean the same as *identical*.

If "Z." will bring forward proofs that the statements he has quoted are "highly misleading," and will sign his name to the letter in which he states these proofs, I am ready to argue each point with him in detail. But, if "Z" continues to charge the authors of the books he has deigned to notice with making misleading statements, while he himself remains anonymous, I shall decline to take any notice of his communications.

THE DISPERSION OF SEEDS AND PLANTS.

IN a recent number of NATURE (vol. xxxv. p. 151) I mentioned instances which had come under my observation, in which birds had taken an active part in the dispersion of seeds and plants. Since then I have come across further notes bearing upon the subject which is one of considerable interest and importance, as it throws a direct light upon some at least of the agencies whereby plant life has been distributed over the surface of the globe. Although birds, from their greater adaptability to rapid and extensive locomotion, are more concerned than any other animals in the dispersion of plants, they are by no means alone in this work.

It may seem strange, at first sight, to assert that cattle have been the means of distributing the seeds of certain plants from one country to another, but a statement is made by Grisebach[1] respecting *Pithecolobium Saman* (N.O. Leguminosæ), a large tree native of Tropical America, now naturalized in Jamaica, that the "seeds were formerly brought over from the continent [of America] by cattle." This statement has been carefully examined, and it is fully borne out by facts. Formerly, Jamaica, like Trinidad at present, was dependent for cattle on Venezuela. The food of the animals during their voyage consisted amongst other things of the pulpy legumes of *Pithecolobium Saman*. The seeds being very hard were uninjured by the process of mastication and digestion, and they were dejected by the animals in the pastures, where they germinated and grew up into large trees. In this instance the seeds were carried across the sea a distance of about a thousand miles, and there is no doubt that the cattle were directly concerned in their introduction. Indeed, without them the seeds, even if accidentally introduced amongst the fodder, would not have been placed under such circumstances as would have enabled them to give rise to plants. In the first place, by being passed through the animals the seeds were softened and the period of germination hastened. In the second place, being embedded in the droppings of the animals the seeds had a suitable medium to protect and promote germination; and this medium enabled the young plants to withstand the season of drought which is incidental to almost every tropical country. In this instance we have cattle not only the means of introducing the seeds of a valuable tree, but also involuntarily instrumental in establishing the tree in a new country, and providing shelter, shade, and food for their progeny. Those acquainted with the guango or rain-tree, as this *Pithecolobium* is locally called, will fully realize its value as a shade and food-tree for cattle, and they will also appreciate the singular concourse of circumstances by means of which such a tree was introduced to a new country by the very animals which required it most.

It is possible there may be some who will doubt the possibility of seeds retaining the power of germination after undergoing the processes of mastication and digestion, and especially in the special case of ruminating animals. There is, however, very clear evidence on the subject. It is a common occurrence in India to utilize the services of goats to hasten the germination of the seeds of the common *Acacia arabica*, known as the babul. This tree belongs to the same natural order as the *Pithecolobium*, and grows in the poorest and driest soils of India. The babul seeds will not germinate readily in the hot weather, and it is the regular habit, in order to save a season, for a person desirous of a crop of seedlings to make a bargain with a herdsman or a neighbour who possesses a flock of goats to quarter them for some days in a small inclosure in which they are fed on babul leaves and pods. The droppings of the animals contain a certain number of seeds which are uninjured, and these now readily germinate, and give rise to plants the same

[1] "Flora, British West India Islands," p. 225.

season. I am informed by Dr. Watt that in India "several other plants are treated in the same way." The seeds of the several species of cultivated Guava are hard and do not easily germinate. These, however, are said to germinate more freely and readily when they are picked up in night soil.

While on this subject I would mention that when at St. Helena in 1883 I expressed some surprise that no attempt was made to utilize "urban" manure in the neighbourhood of Jamestown, when the land was so impoverished and yielded such poor crops. I was met by the fact that if such manure was largely used the land would become overrun with plants of the prickly pear, *Opuntia Ficus-indica*, the fruit of which is largely consumed by the inhabitants. There is little doubt that the seeds of this plant, like those of the Guava, and I suspect also species of *Passiflora*, which are swallowed whole, are capable of germination after they have passed through the human body. Another instance occurs to me where the use of manure has been the means of distributing an undesirable plant on cultivated lands. In many tropical countries a grass known as Para, Mauritius, or Scotch grass, and sometimes as water grass (*Panicum barbinode*), has been introduced from Brazil, and highly esteemed for its rapid growth and nourishing properties. It grows well in moist situations, on the banks of streams, and even in soils so swampy as to be suitable for nothing else. In such situations it spreads rapidly and yields abundant food for cattle and horses. Nothing, however, could be worse than this grass for cultivated areas, where the land is required to be kept free from weeds, and where crops of sugar-cane, coffee, tea, and cacao are raised. It has been found that where animals are fed on this grass the joints even after passing through the animals have been known to grow. Hence the manure, if freshly used, has been the means of establishing the plant over wide areas.

In a recent work Mr. Ball has drawn attention to numerous introduced plants which are met with in South America. He naturally mentions the cardoon, the wild state of the common artichoke, which is now more common in temperate South America than it is anywhere in its native home in the Mediterranean region. Darwin [1] doubts whether any case exists on record of an invasion on so grand a scale. Several hundred square miles are covered with this introduced plant, which has over-run all members of the aboriginal flora. The introduction of the cardoon appears to have been effected directly by man for the purpose of contributing to the food supply of cattle; but as regards another widely-spread plant the mode of its introduction is not clearly known.

Mr. Ball states:—"As to many of these [introduced South American plants] it appears to me probable that their diffusion is due more to the aid of animals than the direct intervention of man. This is specially true of the little immigrant which has gone farthest in colonizing this part of the earth—the common stork's-bill (*Erodium cicutarium*), which has made itself equally at home in the upper zone of the Peruvian Andes, in the low country of Central Chili, and in the plains of North Patagonia. Its extension seems to keep pace with the spread of domestic animals, and as far as I have been able to ascertain it is nowhere common except in districts now or formerly pastured by horned cattle. It is singular that the same plant should have failed to extend itself in North America, being apparently confined to a few localities. It is now common in the Northern Island of New Zealand, but has not extended to South Africa, where two other European species of the same genus are established." [2]

Erodium as a genus is separated from the true Geraniums amongst other reasons on account of the tails of the carpels being bearded and spirally twisted on the inside. It is possible that these characteristics have enabled the seeds to attach themselves to the legs and bodies of cattle and so effected their distribution over wide areas in such situations as are favourable to their growth.

In the Island of Jamaica we have a remarkable instance of the naturalization and wide distribution of an introduced plant in the case of the Indian mango. In an official Report, published in 1885, I stated that to the mango, possibly more than any tree in the island, is due the reforesting of the denuded areas in the lower hills; and as in consequence of the changes taking place in the climate members of the indigenous flora are unable to maintain their ground, it is fortunate the island possesses in a vigorous and hardy exotic like the mango the means of counteracting the baneful effects of deforestation. It specially affects land thrown out of cultivation, and the sides of roads and streams where its seeds are cast aside by man and animals. It practically re-clothes the hills and lower slopes with forest, and it enables the land to recuperate its powers under its abundant shade-giving foliage.[1] It is strange that in Ceylon, which is so much nearer the home of the species, the mango does not spread by self-sown seedlings. This corroborates Mr. Ball's statement with regard to *Erodium cicutarium*. The latter is widely spread in South America, but only sparingly found in other countries under apparently exactly corresponding conditions. We cannot say why such anomalies exist. They do exist, however, and offer problems which can only be solved by a closer study of the conditions of plant life, and the interdependence of plants and animals acting and reacting one upon the other.

The orange-tree was introduced to Jamaica more than a hundred years ago. It is now found practically wild over the settled parts of the island, and the fruit is exported to the value of nearly £50,000 per annum. Up to quite recently very few trees were planted. Nearly the whole were sown by the agency of frugivorous birds, who carried the seeds from place to place and dropped them in native gardens, coffee plantations, sugar estates, and grass lands. In such localities the orange-trees grew and flourished, and now a demand has arisen for the fruit in the United States an important industry has been established, the active agents in which have been birds. The agency of birds in the distribution of the seeds of plants is too large a subject to be discussed at length here. A valuable contribution of facts in this direction has lately been made by Dr. Guppy in his important work on the Solomon Islands. As the most recent addition to our knowledge of what takes place in oceanic islands at the present time it deserves careful attention. It will suffice only to quote one or two sentences:—"Whilst through the agency of the winds and currents the waves have stocked the islet with its marginal vegetation, the fruit-pigeons have been unconsciously stocking its interior with huge trees, that have sprung from the fruits and seeds they have transported in their crops from the neighbouring coasts and islets. The soft and often fleshy fruits on which the fruit-pigeons subsist belong to numerous species of trees. Some of them are as large even as a hen's egg, as in the case of those of the species of *Canarium* ('Ka-i'), which have a pulpy exterior that is alone digested and retained by the pigeon. Amongst other fruits and seeds on which these pigeons subsist, and which they must transport from one locality to another, are those of a species of *Elæocarpus* ('toa'), a species of laurel (*Litsea*), a nutmeg, (*Myristica*), an *Achras*, one or more species of *Areca* (palm), and probably a species (of another palm) *Kentia*."

ON THE APPEARANCES PRESENTED BY THE SATELLITES OF JUPITER DURING TRANSIT.

A PAPER was read by Mr. Edmund J. Spitta, at the November meeting of the Royal Astronomical Society, of especial interest to those who have devoted their attention to Jovian phenomena. As the paper itself is a long one, being the result of over four years' work, we must refer our readers for details to the paper itself; but, speaking briefly, the author observes that since the discovery of the satellites by Galileo in 1610, astronomers have been puzzled by their discordant appearances during transit, but more especially by the fact that these phenomena do not apply equally to all the satellites, or even in some instances to the same satellite in two successive revolutions. It appears that notably the fourth—the farthest from its primary—as it approaches the disk of Jupiter, becomes rapidly and increasingly fainter until it arrives at contact. When once on the limb it shines with a moderate brilliancy for about ten or fifteen minutes, then becomes suddenly lost to view for another period of about the same duration, and lastly reappears, but as a dark spot which grows darker and darker until it equals the blackness of its own shadow on the planet. The appearance presented by the second satellite, however, is entirely different, for it seems never to have been seen otherwise than pure white during transit; whereas the first and third differ yet again from the preceding two. The former is sometimes a steel-gray, and at others a little darker, whereas the latter has been seen perfectly white, and yet so black as to be mistaken for the fourth; both appearances having been witnessed by Maraldi as far back as 1707, and that too in successive revolutions.

The author seems to have spent some years in examining these phenomena on all possible occasions, and under different conditions, such as before, during, and after opposition; and to have collected all published and unpublished observations; and also to have devised an occulting eye-piece—movable shutters in the focus of a Ramsden eye-piece—for the express purpose of shutting off the light of Jupiter; but, to use his own words, "without adding to the pre-existing knowledge of the subject."

The fact of having witnessed, when on the banks of the Rhine in 1886, the transit of a brilliantly illuminated ship's lantern as a dark spot on the disk of the rising full moon, suggested the carrying out of a series of experiments to ascertain the proportions of light which two bodies must possess, so that the smaller should appear gray or black when superimposed on the larger; and it was hoped that if the facts and figures thus experimentally obtained corresponded with the albedos of the satellites themselves as compared with Jupiter, it would not be unreasonable to suspect that the abnormal appearances presented by the satellites depended on functional idiosyncrasies of the eye itself, rather than upon physical peculiarities of the Jovian system.

Space will not allow a description of the experiments, which were somewhat numerous, the photometer employed being an adaptation of that arranged by Prof. Pritchard, of Oxford; but, speaking in short, small disks of different tintings of Indian ink, representing the satellites, were superimposed on larger ones of various sizes of pure white cardboard, and it was found that, with certain restrictions, the difference of albedo (a term expressing "the relative capacity for reflection of diffused light from equal areas") between the smaller and the larger caused the gray and black appearances, and that they were not due to any difference in the *quantity* of light reflected from either. For a moon to appear gray or black, a difference of albedo was required of 0·42 in the first case, and of 0·87 in the second, whilst moons of a superior albedo remained white during transit.

Further, the effect of one moon approaching another, was gone into, and the fading of the smaller was likewise found to be in direct proportion to the relation its albedo bore to that of the greater, and was in no way connected with the *amount* of light reflected by either. The effects in the appearance of the same little moons when in transit over different portions of a sphere were also studied, and, strange as it may seem, *the whole of the phenomena of the dark transit were thus accidentally reproduced*, and this caused much surprise, seeing it was brought about by such simple means. The concluding experiments consisted in photometrically ascertaining, for the first time, the reflective ability of different portions of an unpolished sphere; and the results obtained are set forth in the following abridged table; column 1 giving the exact angle of the observation, and column 2 the resulting albedo.

30°	...	...	·735
40	...	...	·500
50	...	...	·367
60	...	...	·323
65	...	...	·261
70	...	...	·172
75	...	...	·133
80	...	...	·080
83	...	...	·049
86 30′	...	...	·027

A large number of facts and figures having been ascertained, attention was then directed to obtaining the relative albedos of the real satellites themselves as compared with Jupiter. The reduction of the observations was attended with several difficulties, each of which had to be dealt with; but one of them especially deserves a passing mention, and it is this, viz. that the eye does not seem to be impressed in the photometer with the light coming from an object of sensible area, such as Jupiter, to the same extent as it is from a point of light such as is shown by the satellites. A suggestion from Capt. Abney, however, relieved the difficulty, and, this systematic error removed, the results came out in an extremely satisfactory manner, for it was then found that the albedos of the satellites corresponded very approximately with the requirements of the experiments, as the following abridged table shows; in column 1 is shown the number of the satellite, in column 2 its difference in magnitude with that of Jupiter, and in column 3 the resulting albedo.

I.	...	8·12	...	·656
II.	...	8·40	...	·715
III.	...	7·88	...	·405
IV.	...	8·73	...	·266

Thus is it shown to be more than probable that the reason the fourth satellite is uniformly black during transit, when it has passed its period of disappearance, is owing to its albedo being so low as to grant the difference between it and the background necessary for a body to appear black when superimposed on another as ascertained by the experiments. Its preliminary whiteness and disappearance are also shown to be a question of relative albedo, for they are due to the fact that a sphere at its limb and edges loses so much in reflective ability, that up to that moment, the satellite possesses sufficient albedo (as compared with the background in that situation) to maintain its whiteness. So too with the second satellite: its albedo proves to be so high that it is capable of preserving its brilliancy throughout the entire transit. The third and first satellites evidently possess sides of differing albedo, one high enough to maintain a brighter aspect than the other, or even, as in the case of the third, to make it appear white when one side is presented to the earth, and dark when the other. In conclusion, to quote from the original paper, "it is not unreasonable to conclude that these anomalous phenomena are due to functional idiosyncrasies in the eye itself, rather than to physical peculiarities of the Jovian system."

THE MONSOONS.[1]

EVERY School Board pupil who reads a shilling primer of physical geography knows that the monsoons are periodical winds which blow over the Indian Ocean at different seasons of the year; but very few, even among regular meteorologists, are fully aware of the interesting but complex nature of the details of these phases of atmospheric circulation.

The two publications which are the subject of this notice contain a vast amount of information and research connected with these winds. The charts of the Bay of Bengal consist of a series of maps of mean pressure, resultant wind, and ocean currents for every month of the year; with a page of descriptive letter-press for each. They were compiled by Mr. W. L. Dallas, and are published in the inconvenient size of 23 by 18 inches.

The memoir on the winds of the Arabian Sea is a long and exhaustive report by the same author, with a critical and theoretical discussion of the results obtained all over the North Indian Ocean. This is published in a large quarto form, and contains small-scale charts of mean pressure, and of both wind force and direction, for every month of the year; while similar maps of temperature and vapour-tension are given for the months of April, May, and June only.

Space will permit us to notice only the extreme conditions which characterize the months of January and July, or the most pronounced periods of the north-east and south-west monsoons respectively. It will be well to take the north-east monsoon first, as it is much the simpler of the two. One of the most important results of Indian research has been to modify the crude idea that the north-east monsoon blows directly all the way from the great Siberian winter anticyclone down to the equator. Now it has been shown that there is in the month of January a small anticyclone over the Punjab, and an area of high pressure over the Persian Gulf.

This fact is of far more than local importance. The typical distribution of pressure over the globe consists of an equatorial belt of low pressure, with a belt of anticyclones on either side, about the line of the two tropics. Heretofore we have been constrained to look on the Siberian anticyclone—centered near the Arctic Circle—as the representative of the tropical belt of high pressure, but now there is the strongest presumption that these smaller anticyclones are the true, but diminutive, equivalents of the tropical belt.

There is a curious irregularity in the sweep of the isobars and winds over India towards the equator. The charts indicate a local depression all along the west coast of India, and a slight general protrusion of pressure over the Bay of Bengal. This latter is important, as we shall have to refer to the converse condition in the opposite monsoon.

The conditions of the south-west monsoon are a good deal more complicated, for in July we have to explain the following relations of pressure and wind. A belt of high pressure runs along the twentieth degree of south latitude almost from Australia to long. 70° E.; but then the isobars mount up to the equator along the coast of Africa. An irregular area of low pressure lies over Scinde, but the baric slopes all round are by no means symmetrical. The most noticeable irregularity is an area of relatively low pressure over the south-west of the Bay of Bengal, so that the mean isobar of 29·80 which runs towards the north-east from Africa to near Bombay, bends then to the south-east until it arrives near Trincomalee, in Ceylon, when it turns again to the north-east. The wind conforms partially to this distribution of pressure. South of the Line the south-east trade blows with great uniformity, crosses the equator with a regular sweep into the Arabian Sea, turning first to the south-west, and eventually to the west, between Karachi and Bombay. But in the Bay of Bengal the situation is rather different. The depression, before noted, is associated with a west-north-west wind over Southern India, but a light westerly current and rainy weather prevails all over the south of the Bay, from the latitude of Ceylon, down to the equator, while a strong south-west monsoon blows all up the Bay itself. Hence a ship going up to Calcutta will find the south-east trade replaced by light irregular winds between south and west, with much rain, from the equator to about 10° N., before she encounters the fresh south-west monsoon in the upper part of the Bay.

Mr. Dallas gives many interesting details in this memoir, such as a discussion of the so-called "soft place" in the monsoon between Bombay and Aden. This is a region described in the East Indian sailing directories as lying along, or about, the ninth parallel in the Arabian Sea; but the present series of observations afford very little evidence of the existence of this tract of quiet conditions.

The author seems to find some difficulty in explaining the cold air found along the African coast during the height of the monsoon, but this is almost certainly due to the cold water which wells up from below, as the hot surface water is driven to the north-east. The weather shore of a tropical coast in a steady atmospheric current is always cold for the same reason.

Mr. H. F. Blanford has worked out the precipitation of the south-west monsoon in his great memoirs on "Indian Rainfall," and has brought out most clearly a great meteorological principle. He finds that even with the saturated atmosphere of the Indian Ocean—air that contains nearly twelve grains of water in a cubic foot, as compared to about six grains in our own climate—no great precipitation takes place without dynamical cooling. That is to say, unless the air is forced upwards by local obstacles, &c., and so cooled by expansion, no great rainfall can occur.

But the great question, about which there is still some doubt, is the precise relation of the south-west monsoon to the south-east trade. Dové started the theory that the south-east trade turns to south-west after crossing the equator, owing to the influence of the earth's rotation; and there can be little doubt that in the Arabian Sea the trade wind does sweep directly across the Line and grow into the monsoon.

But in the Bay of Bengal, Mr. Blanford finds that the south-west monsoon is not linked up habitually with the south-east trade, though it is so occasionally; and he considers that the monsoon is drawn from a reservoir of air over the equatorial zone fed by the south-east trades, but that it is not the south-east trade simply diverted from its ordinary course.

This opinion is based on the following facts, brought out by the charts under review, for—

(1) The south-east trades are strong, but the winds are light and variable from the equator to 10° N., above which fresh winds are again developed. There is, then, some hitch in the sweep of the south-east current across the equator.

(2) The winds just north of the line are nearly from the west, while they flow from south-west at the top of the Bay. Theoretically the wind should get more and more westerly the further north we go.

(3) The south-east trade is tolerably dry; the equatorial belt of westerly winds is very wet and squally; while the precipitation of the south-west monsoon is not very great out at sea.

Though these facts undoubtedly indicate some irregularity in the flow of the south-east trade across the

[1] "Weather Charts of the Bay of Bengal and adjacent Sea north of the Equator." Issued by the Meteorological Department of the Government of India. (Calcutta, 1887.)
"On the Winds of the Arabian Sea and Northern Indian Ocean." By W. L. Dallas, late of the Meteorological Office, London. Published by the Meteorological Department of the Government of India. (Calcutta, 1887.)

Line, still we are constrained to think that the south-west monsoon is still part of the same system. If the monsoon was independent of the trade, there must be a belt of high pressure between the two; and of this there is absolutely no trace.

We must therefore look to some explanation other than the conception of an independent circulatory system over the Bay of Bengal; but materials are at present wanting to form a definite conclusion on the point at issue. There are two ways by which the question could be settled.

A few sets of observations of cloud-motion on ships coming up the Bay from southward, would almost infallibly give decisive results. If the upper clouds over the west winds, just north of the Line, come from the south or south-east, the surface wind has been drawn across the equator; but if, on the contrary, the clouds drive more and more from the north of west the higher they are, then the circulation over the Bay of Bengal is not fed directly by currents which have crossed the line.

A set of daily weather charts for the whole Indian Ocean would also clear away many doubts. When differences of pressure are small, and winds are variable, charts of mean monthly isobars, and of resultant winds, are very delusive; for the average relation of pressure, wind, and weather, may be quite different from that on any actual day.

The materials at present available point unmistakably to some connection between the anomalous wind and weather in the southern portion of the Bay, and the local area of low pressure over Southern India. It is very conceivable that the whole width of the south-east trade does not cross the equator with an unbroken front; but that for some reason or other a great local eddy may be developed in the Bay of Bengal. No river ever flows regularly, but is broken up into ripples and backwaters; and though there are many differences between the flow of water and of air, still there are certain properties common to the motion of every fluid.

Very few English meteorologists care much for theoretical discussions of air motion; but the Indian workers use mathematics freely in their investigations. Mr. Dallas calculates the flow of a current of air from 10° S. latitude to 10° N., according to the formula given by Mohn and Gulberg. He takes a gradient directed N. 30° E., across the Arabian Sea, and notes the difference both of force and direction between the observed and calculated winds. No doubt there is a certain accordance between the results so obtained; but still there are errors, which, taken with other things, suggest that the theory is still imperfect.

According to the formula—a modification of Ferrel's theory—when air flows northwards down a gradient, the angle between the wind and the gradient should decrease as we approach the equator, disappear altogether on the line, and then gradually increase as we proceed further north. But in practice the trade keeps steadily in the south-east from about 20° S. almost to the equator, then turns rather suddenly to south-west, and the monsoon advances steadily in that direction from about 5° to 20° N. In the opposite monsoon, the north-east winds run steadily from about 20° N. down to the line, and then turn rapidly to north-west.

It is well known in our own latitudes that, though the wind rotates in contrary directions round cyclones and anticyclones, the sweep of the wind is usually less than the curvature of the isobars would suggest. For instance, if an anticyclone lies to the north of Great Britain, all the winds will often be from about north-east instead of sweeping gradually from north-east through east to south-east. This and many other similar observations point to a north-east and south-west set of the winds all over the northern hemisphere, which has not yet been accounted for by any theory.

In conclusion, we may remark how thoroughly the author has discussed the subjects of his memoirs; though some will doubtless differ considerably from him in the theoretical portion of his work. India presents a field for research unique from that in any other part of the world; and those who are acquainted with the magnificent equipment, order, routine, and system of inspection inaugurated by Mr. Blanford, will feel confident that every year will add to our knowledge of a region that presents the most fascinating problems to the student of atmospheric dynamics. RALPH ABERCROMBY.

NO. 2 MUSEUM, KEW.

THE Museum of Monocotyledonous Products in the Royal Gardens, Kew, better known, perhaps, as No. 2 Museum, which was recently closed for rearrangement, has been again opened to the public. The entire collection has been classified according to the plan of the "Genera Plantarum," so that the whole of the collections contained in Museums Nos. 1 and 2 are now arranged according to the system adopted by Bentham and Hooker.

A new room which was added to the Museum a few years since has now been utilized; this has given space that was much needed for the proper display of the products of such important natural orders as *Scitamineæ*, *Bromeliaceæ*, *Amaryllideæ*, *Liliaceæ*, *Palmeæ*, *Aroideæ*, *Cyperaceæ*, and *Graminaceæ*. In the first named order, a large number of valuable economic plants are included, such as ginger, turmeric, cardamoms, arrowroot, bananas, and others; while in *Liliaceæ* we find sarsaparilla, asparagus, onions, squills, medicinal aloes, and New Zealand hemp. All these have had much more space given to them than hitherto, and the fine collection of native New Zealand garments made of the indigenous hemp (*Phormium tenax*), which are rapidly becoming scarce, are now opened out and fully shown. A very large increase of space has been given to the *Palmeæ*, and as it is one of the most important orders to mankind generally, especially in tropical countries, it was but fitting that this unique collection of palm products should be fully displayed. In such a series as that at Kew it is difficult to particularize any one exhibit as more important than another, but we may draw attention to the fine set of specimens illustrating the coco de mer, or double cocoa-nut of the Seychelles (*Lodoicea sechellarum*). This comprises a fine series of fruits, including a model of the fruit in which the nut is inclosed, made and presented by the late General Gordon, of the so-called double or usual form, as well as quadruple, sextuple, and others, besides seeds showing the mode of germination, very fine male spadices, and carved shells. The series of products of Palmyra palm (*Borassus flabelliformis*) is also a very complete one, comprising sections of the trunk, both longitudinal and transverse, toddy collecting apparatus and various manufactures from the leaves.

In the *Gramineæ*, which was very much crowded throughout, a large increase of space has enabled the interesting collections of maize, sorghums, sugar-cane products, rice, and the numerous grains of India, to be easily examined, while in the *Cyperaceæ* the Indian mats from the culms of *Cyperus Pangorei* and *C. tegetum* and other products of the order have been opened out, and now form a striking series.

APPARATUS FOR EXPERIMENTS AT A HIGH TEMPERATURE, IN GAS UNDER HIGH PRESSURE.[1]

A DIFFICULTY often experienced in laboratories is how to raise a body to a high temperature while surrounded by a gaseous atmosphere under considerable pressure.

[1] Translated from *La Nature*, February 11, 1888.

The apparatus which I constructed several years ago makes it possible to bring bodies to a temperature approaching that of the fusion of platinum, whilst maintaining them in a gaseous atmosphere, of which the nature and pressure may be varied at will.

This apparatus (Fig. 2) is composed of a mass of steel

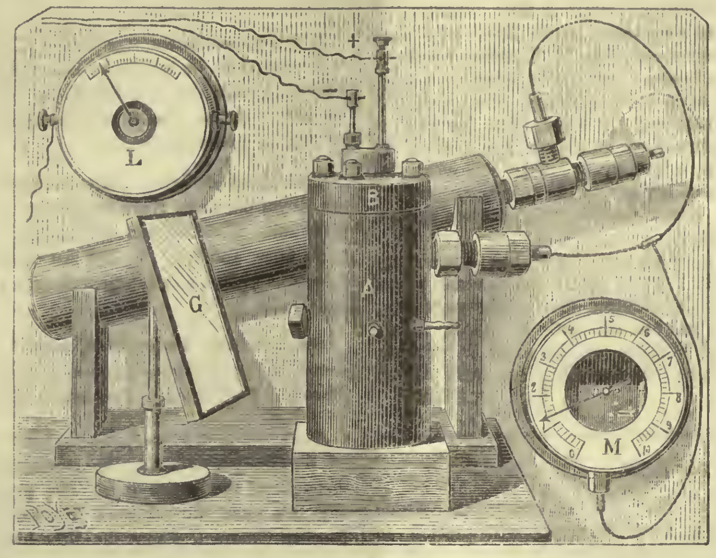

FIG. 1.—Apparatus of M. Cailletet. A, mass of steel with cylindrical bore, with its stopcock B (see the details in Fig. 2); G, mirror permitting the reaction to be seen; M, manometer; L, amperemeter.

A, in which there has been hollowed out a cylindrical space of about a quarter of a litre capacity. This species of test-tube may be closed by means of a metallic stop-

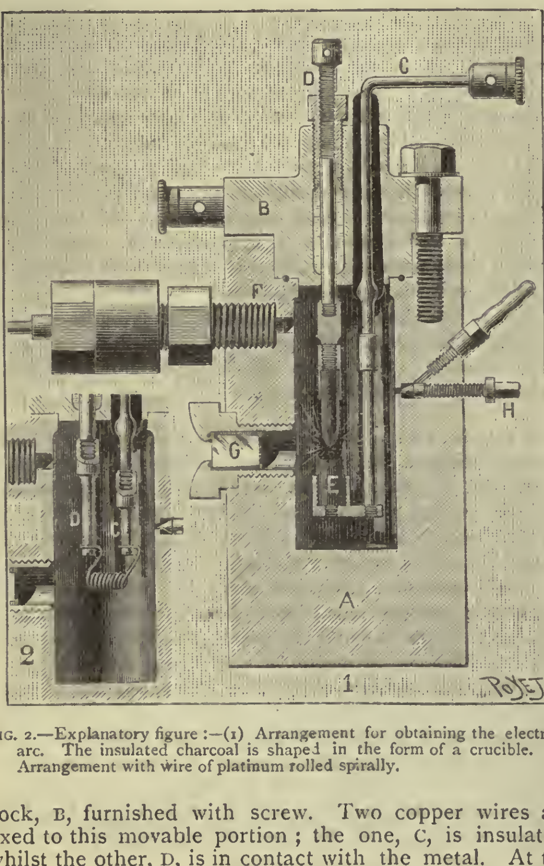

FIG. 2.—Explanatory figure:—(1) Arrangement for obtaining the electrical arc. The insulated charcoal is shaped in the form of a crucible. (2) Arrangement with wire of platinum rolled spirally.

cock, B, furnished with screw. Two copper wires are fixed to this movable portion; the one, C, is insulated, whilst the other, D, is in contact with the metal. At the ends of these two wires there is fixed, according to the requirements of the experiment, either a sheet of platinum moulded into the form of a crucible, or a wire of platinum rolled spirally, a kind of receptacle for the body experimented on, and which is brought to the desired temperature by the passage of an electric current. Two or three accumulators are sufficient for these experiments. A fragment of gold, placed in the spiral, melts in a few seconds. When it is desired to maintain the temperature long, the exhausted accumulators are replaced by others in readiness, simply by use of a commutator. The high temperature developed by the electric arc may also be turned to account; in that case two charcoal rods are arranged, of which one, movable, is fixed to the extremity of a screw, D, capable of being adjusted from the outside in order to place it in communication with the other charcoal rod, E, insulated and shaped in the form of a crucible.

The block of steel is pierced by an orifice, F, connected by a metallic capillary tube with the reservoir which contains the compressed gas. A window furnished with a thick glass, G, allows the phases of the experiment to be followed by looking in an inclined mirror, so as to be secure from all danger in case of the glass breaking. Lastly, the gases contained in the apparatus may be collected, by means of a stopcock at the screw H, in cases where it is desirable to analyze them.

The gas used for the experiments is compressed previously in a holder by means of the mercurial pump, a description of which I have already published; it is also easy to employ the carbonic and sulphuric acid furnished by commerce.

A metallic manometer fixed to the apparatus renders it possible to ascertain that the pressure of the gases exercises an energetic cooling influence upon the bodies which are heated by the electric current.

Thus, the current which causes the fusion of the wire or sheet of platinum produces only a sombre red temperature when the pressure is sufficiently great. I have been able to lessen this cause of cooling, by placing the body on which I was experimenting in a small test-tube, which resists the motion of the gases, and which is not repre-

sented in the figure. I have repeated, with this apparatus, the classical experiment of Hall on carbonate of lime. A fragment of chalk, heated in a spiral of platinum, diminishes sensibly in volume, while it is being changed into a hard body of a brownish-yellow colour, which dissolves slowly in acids, at the same time liberating carbonic acid. Also, our fellow-worker, M. Debray, has long since shown that Iceland spar can be carried to a high temperature in carbonic acid without being changed, and without losing its transparency. I have also found that a crystal of spar transformed to chalk on the surface by the action of heat under ordinary pressure recovers the lost carbonic acid, but not its primitive transparency; I have not been able to effect fusion of the spar in the course of my experiments.

To sum up, the apparatus which I have the honour to make known, and which I have used for several years past, in experiments upon the electric light under pressure, researches which I have carried on with M. Violle in his laboratory at the Normal School, will be able to render, I hope, numerous services to chemists as well as to mineralogists.

L. CAILLETET.

NOTES.

AT the Bath meeting of the British Association, which will begin on September 5, Prof. Schuster will preside in Section A (Mathematics and Physics); Prof. Tilden in Section B (Chemistry); Prof. Boyd Dawkins in Section C (Geology); Mr. Thiselton Dyer in Section D (Biology); Colonel Sir C. W. Wilson in Section E (Geography); Lord Bramwell in Section F (Economic Science and Statistics); Mr. W. H. Preece in Section G (Mechanical Science); and General Pitt-Rivers in Section H (Anthropology).

THE Croonian Lecture of the Royal Society will, at the request of the Council, be delivered this year by Prof. W. Kühne, of Heidelberg. As is well known, Prof. Kühne has for many years devoted attention to the endings of nerves in muscle, and in the Croonian Lecture he proposes to dwell on the light thrown on the nature of muscular contraction and nervous action by the study of these nerve-endings. Since the rooms of the Royal Society are not well adapted for showing illustrations to large audiences, the lecture, which will be largely illustrated, will be delivered, by the permission of the Managers of the Royal Institution, in the lecture theatre of the Royal Institution. The date fixed is Monday, May 28, at 9 p.m.

IN reply to a question put by Lord Herschell in the House of Lords on Monday, Lord Cranbrook stated that he had come to the determination to recommend the issue of a small Royal Commission to inquire as to the necessity for a Teaching University for London, and he hoped that at no great distance of time it would be able to report upon the subject.

IN accordance with the rule which empowers the election of nine persons annually "of distinguished eminence in science, literature, or the arts, or for public services," Prof. A. W. Rücker, F.R.S., has been elected a member of the Athenæum Club.

THE Royal Meteorological Society's ninth annual Exhibition of Instruments will be held at the Institution of Civil Engineers, 25 Great George Street, Westminster, in conjunction with the Society's meeting on Wednesday, the 21st inst., and will be very interesting and instructive. The Exhibition is devoted to apparatus connected with atmospheric electricity. A most valuable collection of some fifty photographs of flashes of lightning from all parts of the world will be shown, as well as some curious effects of damage by lightning, including the clothes of a man torn off his body by lightning, &c. The Exhibition will remain open till Friday, the 23rd inst. Persons not Fellows, wishing to visit the Exhibition, can obtain tickets on application to Mr. W. Marriott, Royal Meteorological Society, 30 Great George Street, S.W.

A PLANT of the common coffee (*Coffea arabica*) is now loaded with ripe fruit in the palm-house at Kew. Seldom, even on tropical plantations, is a tree to be seen with such a crop. Such an object-lesson should not be missed by those who take an interest in economic botany.

THE March Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, contains papers on Forsteronia rubber, patchouli, West African indigo-plants, vanilla, streblus paper, urera fibre, and tea. In the last of these papers valuable information is given as to the growth of tea in Jamaica, Madagascar, and Natal.

AN excellent biographical sketch of the late Asa Gray, by James D. Dana, appears in the *American Journal of Science* for March. The article is also issued separately.

A HEAVY gale was experienced last Sunday in nearly all parts of the British Islands, the storm continuing in many places throughout the entire day. The greatest violence of the gale was felt over the southern districts of England and in the English Channel, where the direction of the wind was from the south-west and west. In Ireland, Scotland, and the North of England, the direction of the wind was easterly, the central area of the disturbance passing completely over the middle of England from west to east. At 8 o'clock on Sunday morning the centre of the storm was close to Pembroke, where the barometer was reading 28·57 inches, and at 6 o'clock in the evening it was over Lincolnshire, the barometer reading 28·8 inches. The storm afterwards crossed the North Sea, and at 8 o'clock on Monday morning the centre had reached Holland, and was still travelling in an easterly direction. At Greenwich the anemometer registered a pressure of 31 pounds on the square foot at 5 p.m. on Sunday, which is equal to an hourly velocity of about 80 miles. The feature of especial scientific interest with respect to this storm is the sudden manner in which it appeared on our coasts: it practically arrived without any warning, and appears to have been formed almost within the area of the British Islands. It would seem to be a secondary or subsidiary disturbance to the storm area which was situated over Scotland on Saturday, and was apparently formed in the south-western segment of the parent cyclone, which is the favourite position for storm development. The passage of such a storm across our islands illustrates very clearly the immense difficulty which underlies any system of forecasting.

IN vol. iii., part 2, of the Indian Meteorological Memoirs, recently published, Mr. Blanford has continued his discussion of the rainfall of India. Part 1, which dealt more particularly with the average conditions of rainfall, was fully noticed in NATURE (vol. xxxvii. p. 164). The part now in question relates to the variations and vicissitudes of rainfall in past years, and their connection with other elements. With the view of ascertaining whether any general laws can be detected, an endeavour is made to determine what peculiarities are associated with the different distribution of rainfall, *e.g.* the variations of prevailing wind currents, distribution of atmospheric pressure, and the frequency and courses of cyclonic storms. The periodical recurrence of droughts and famines since 1769 is recorded, and, from general conclusions drawn, it appears that serious droughts occur in Southern India at intervals of nine to twelve years, and that they generally happen about a year before the sunspot minimum. In Northern India, droughts sometimes occur in years of maximum sun-spots.

AT the meeting of the French Meteorological Society, on February 7, it was announced that M. Janssen had offered five prizes, consisting of silver medals, for the best works relative to the application of photography to meteorology, and M. Teisserenc de Bort offered a similar prize for the best measurements of the height of clouds. M. Moureaux (Secretary) presented a paper on the periodicity of disturbances of declination and horizontal force at Parc-Saint-Maur Observatory for the years 1883–87, showing, by means of curves, that the monthly values of both those elements exhibited two maxima at the equinoxes, and two minima at the solstices; and that, while the monthly variation of the number of disturbances appeared to follow a general law, the diurnal variation seems to be subject to complex laws. M. H. Lasne presented a note on the gyratory movements of the atmosphere, in connection with the experiments of MM. Weyher and Colladon on the motions of fluids. M. Maillot exhibited a kite, arranged to maintain a constant height for some time, and designed for the purpose of facilitating the registration of variations of temperature at certain altitudes.

A TETRASULPHIDE of benzene has been prepared in the pure state by Dr. Otto, of Brunswick (*Journ. für. prakt. Chemie*, 1888, Nos. 3 and 4). When a current of sulphuretted hydrogen gas is led through a warm dilute solution of benzene-sulphinic acid, $C_6H_6SO_2$, in alcohol, the sulphinic acid is reduced to phenyl-disulphide, $(C_6H_5)_2S_2$, a substance already well known. The behaviour, however, is entirely different when a very strong solution is employed: the liquid becomes rapidly yellow, and eventually monoclinic crystals of sulphur and a yellow oil separate. This yellow oil was found to consist of phenyl-tetrasulphide, $(C_6H_5)_2S_4$, the analyses indicating an exceptionally pure product, after careful separation from the free sulphur by dissolving in ether and subsequent evaporation. This tetrasulphide at the ordinary temperature is a very viscid, heavy, highly refracting oil, possessing an unpleasant odour reminding one of mercaptan. It is a comparatively stable compound, remaining unattacked on treatment with sodium sulphite, even when warmed for a long time; but on warming with colourless ammonium sulphide it is reduced to disulphide, polysulphide of ammonium being formed. According to Klason, phenyl-tetrasulphide is also the product of the action of dichloride of sulphur, S_2Cl_2, upon thio-phenol, $C_6H_5 . SH$, the mercaptan of the benzene series, and Otto shows that this is really the case, the reaction going best when the two substances are gradually mixed in carbon bisulphide solution. No extraneous heat is necessary, the operation being itself attended by a considerable evolution of heat. On distilling off the bisulphide of carbon, the resulting oil is found to be identical with the phenyl-tetrasulphide prepared in the above manner.

THE thirty-ninth Bulletin of the U.S. Geological Survey consists of a paper embodying the results of the investigations of Mr. Warren Upham upon the upper beaches and deltas of the extinct Lake Agassiz, which, in Glacial times, occupied the basin of the Red River of the North. Mr. T. C. Chamberlain, geologist in charge of the Glacial Division, in transmitting Mr. Upham's paper to the Director of the U.S. Geological Survey, for publication, wrote:—"This is but an initial contribution, embracing only so much of the data gathered as from their degree of completeness and interest warrant present publication as a record of results. The investigation is still in progress, and the general discussion of data and the eduction of conclusions are reserved until its completion. Meanwhile the great mass of carefully-determined facts here recorded will, besides their inherent independent value, be of important and immediate service to the students of other extinct and shrunken Glacial lakes."

THE U.S. Department of Agriculture has issued an interesting descriptive catalogue of manufactures from American woods, as shown in the exhibit of the Department at the Industrial and Cotton Exposition at New Orleans. The compiler is Mr. C. R. Dodge. He has brought together many interesting facts about the uses of woods in architecture and building, in transportation, in implements of industry, in articles relating to trade, in articles for man's physical comfort or luxury, and in articles for education, culture, or recreation. There is also a paragraph on "miscellaneous uses," under which are such headings as "Gun-stocks," "Artificial Limbs," "Crutches," and "Umbrella-sticks and Canes."

MESSRS. GURNEY AND JACKSON will issue in April the first part of "An Illustrated Manual of British Birds," by Mr. Howard Saunders. The work will be completed in about twenty monthly parts.

WE have received the eighteenth Annual Report of the Wellington College Natural Science Society. It contains a record of much good work done during the past year. The Report includes abstracts of lectures delivered before the Society, observations made of the plants, insects, and birds contained in the Royal Meteorological Society's lists, and a meteorological report for every day of 1887.

IN the twelfth Annual Report of the President of the Johns Hopkins University, Baltimore, Dr. Gilman says that during the last year the number of teachers in connection with the institution was slightly enlarged, and the number of students considerably increased. A new department of instruction—pathology—was initiated; a physical laboratory, the largest and costliest building yet erected for the University, was completed and occupied; a building was set apart for the petrographical laboratory; and an astronomical observatory, for the instruction of students, was equipped. The cost of the physical laboratory, including the land, furniture, gas-fitting, steam-heating, and astronomical dome (but not including large amounts paid previously for instruments and apparatus, and not including the dynamos, nor the telescope), stands, in the books of the treasurer, 174,765·86 dollars. This building will be used by classes studying mathematics, astronomy, and physics.

THE Calendar, for the year 1888, of the Royal University of Ireland has just been issued. The Drapers' Company have offered an exhibition of the average annual value of £35 for three years, to be awarded, on the result of the matriculation examination of this University, to the girl who, complying with certain conditions stated in the Calendar, shall be awarded either first or second class honours in at least two subjects, and who shall obtain the highest aggregate of marks at the examination to be held on July 4 next.

WE have received the Calendar, for 1887-88, of the Imperial University of Japan. An address by President Watanabe, on the occasion of the graduation ceremony, July 9, 1887, is printed as an appendix. If we may judge from the tone of this address, the University is in a prosperous condition, and doing justice, in its courses of instruction, to science no less than to literature and law.

ON February 12, Mr. Jeremiah Curtin read, before the Anthropological Society of Washington, a paper of some interest on the folk-lore of Ireland. Last year Mr. Curtin went to Ireland for the express purpose of finding out how far the old "myths and tales" were still alive in the minds of the people. He visited some secluded parts of the western coast, and "took down personally a large body of myths and stories, some very long, others not so long." "This collection of materials," he says, "is sufficient to fill a couple of 12mo volumes, and will

give some idea of what yet remains in the Celtic mind of Ireland. It is, however, but a small part of the mental treasure still in possession of the people."

In the Proceedings of the American Philosophical Society (July–December 1887) there is a most interesting paper by Dr. D. G. Brinton on ancient footprints in Nicaragua. The discovery of human footprints in volcanic rocks near the shore of Lake Managua, Nicaragua, under circumstances which seemed to assign to them a remote antiquity, was announced several years ago. Dr. Brinton refers especially to a specimen on tufa sent to him from Nicaragua, by Dr. Flint, an accurate representation of which accompanies the paper. It is the impression of a left foot. The total length of the impression is 9½ inches, the breadth at the heel 3 inches, at the toes 4½ inches. The apparent length of the foot itself was 8 inches. The instep was high, and the great toe large, prominent, and exceeding in length the second toe. The greatest depth of the impression is at the ball of the foot, the weight being evidently thrown forward, as in vigorous walking. At this part the maximal depression below the plane of the superficies is 2 inches. Dr. Brinton has no doubt as to the genuineness of the footprints; but their antiquity, he thinks, is uncertain. His own opinion is that there is not sufficient evidence to remove them beyond the present post-Pliocene or Quaternary period.

PROF. DAVID P. TODD, astronomer in charge of the recent American Eclipse Expedition to Japan, has issued a Preliminary Report (unofficial) on the total solar eclipse of 1887. Associated with this document is a Preliminary Report by Dr. W. J. Holland, naturalist of the Expedition.

WE have received an illustrated catalogue of the astronomical instruments and observatories of Sir Howard Grubb, Dublin. During the last few years Sir Howard Grubb has executed important astronomical work for many Governments, Universities, scientific Societies and Academies, and the catalogue affords striking proof of the care he takes to bring his various methods and processes to perfection.

MR. STANFORD has issued an interesting volume, by Mr. A. B. Macdowall, entitled "Facts about Ireland." It is an attempt to show, by means of curves, the recent history of various elements in the social life of the Irish people. Sections are devoted to population, agriculture, education, emigration, evictions and drunkenness, crime, consumption of spirits, bank deposits, &c., and occupations. The mode of representation, which has been made familiar to most people by weather charts, has enabled Mr. Macdowall to bring together in brief compass a great mass of information about some very complicated and difficult subjects.

LAST month Mr. J. Clayton read before the Bradford Naturalists' Society a paper on *Pinus sylvestris*. This fact is worth mentioning, because by using the autocopyist apparatus the author was able to give each member a sheet of drawings, and another of explanations. We have received specimens of these sheets, and it seems to us that the plan might often be adopted with advantage by readers of papers, and by lecturers, on scientific subjects.

INQUIRIES have been made by several correspondents as to the photographic apparatus used by M. Marey in obtaining the results as to the flight of birds set forth in the article in *La Nature* of which we lately printed a translation (p. 369). No complete account of the apparatus has yet appeared, but a summary of the facts relating to it was given in the *Comptes rendus* for July 3, 1882. A note on the subject was printed in the same publication on August 7, 1882. M. Marey proposes to give a full description in a work on the flight of birds and insects, which will be issued in the course of the present year. The object is to obtain an indication, at every instant, of the swiftness of the moving body which is to be photographed, in its passage from point to point. To secure this indication it is necessary to produce, at known intervals, equal to one another, and as short as possible, interruptions in the arrival of light into the interior of the photographic apparatus. These interruptions M. Marey obtains by causing to turn, before the objective, by means of machinery, a wheel which makes ten revolutions in a second. This wheel has ten spokes, each one of which, in its passage, interrupts the light. The "eclipses" thus caused occur, therefore, a hundred times per second; so that in the photograph the space between two consecutive points represents the space crossed by the photographed body in 1/100 of a second. In order to indicate the relative positions of the different parts of the body at the same instant, M. Marey makes one of the spokes of the wheel twice as large as the others. The result, of course, is that there is a longer "eclipse" at the moment when this spoke passes. This arrangement enables the observer to determine without hesitation the relative positions of the different points of the body at every tenth of a second; and it has also the advantage of facilitating the calculation of the times in which the movements are made.

AT Stevens's rooms, on Monday, an egg of the extinct great auk (*Alca impennis*) was sold to Mr. J. Gardner for £220. It belonged to the collection of Mrs. Wise, whose husband bought it of a dealer in Oxford Street in 1851 for £18. It was originally brought to England from Paris, and is now said to have been bought for America.

THE Exhibition of Japanese engravings at the Burlington Fine Arts Club, and that of Japanese pictures in the White Gallery in the British Museum, contain much that is of a specially scientific interest; as, indeed, could scarcely fail to be the case with such exhaustive and well-arranged collections of the pictorial art of a people who, beyond all others, went to Nature herself as the fount of their inspiration. Thus the collection of guide-books and topographical hand-books in cases K, L, and M, at the Burlington Club, give a remarkable picture of the physical features of Japan, and one that, taken in conjunction with such a work as Dr. Rein's, should be of much assistance to geographers. Probably no literature in the world is so plentifully supplied with guide-books as that of Japan; every province, town, and district, has one or more of its own. In many cases they are works of ambitious scope and wide utility. They indicate "all the spots famous for landscape beauties, collect learned records of the historical and legendary lore of the localities described, enumerate the various objects of curiosity and archæological importance preserved in the neighbourhood, contribute scientific notes upon the flora and fauna of the district, and open a fund of practical information as to industries, commerce, and a hundred other matters of interest both to resident and visitor." Botany is remarkably well illustrated in the books shown in case O; while the silhouettes in case H, traced with great accuracy from nature, represent almost every type of the lower middle class Japanese, and should be of some ethnographical value, especially as there is a considerable number of them. The many hundreds of birds and other animals represented in the British Museum collection (it will of course be understood that we are now referring to the whole of the Anderson Collection, consisting of about 4500 examples, not merely to the 273 on exhibition) would form a supplement to the works of Siebold and later writers. For the student of religions the Buddhistic pictures supply many details not to be found in any written records, and the many volumes of popular picture-books show a thousand elements of Oriental folk-lore, customs, and handicrafts that are now on the verge of extinction.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. A. Ballard; a White-fronted Capuchin (*Cebus albifrons* ♂) from South America, presented by Mrs. E. A. Lediard; a Binturong (*Arctictis binturong*) from Malacca, presented by Mr. J. P. Rodger, of Selangor, Malay Peninsula; a Common Quail (*Coturnix communis*), captured at sea, presented by Captain Christian; a Brazilian Tortoise (*Testudo tabulata*) from Brazil, deposited; four Cape Colys (*Colius capensis*) from South Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

ANNALS OF HARVARD COLLEGE OBSERVATORY.—We have received Part 2 of vol. xiii. of the Annals of Harvard College Observatory, containing zone observations with the transit wedge photometer attached to the 15-inch equatorial. These observations were undertaken in order to extend our knowledge of the relative brightness of the fainter stars, and to determine the scales of magnitude employed in the estimates of certain observers, as compared with magnitudes as obtained by means of the meridian photometer. These zone observations were not, however, made with the meridian photometer, but with an adaptation of Prof. Pritchard's wedge photometer, which had been devised by Prof. Pickering. Instead of slipping the wedge along by hand, the telescope and wedge are fixed, and the star is carried from the thin part of the wedge towards the thick by the diurnal motion. An occulting bar is fixed near the thin edge, and the interval between the time of the occultation of a star by the bar, and its extinction by the wedge, is proportional to the magnitude of the star on the assumption of a uniform scale of absorption throughout the wedge. In this way the relative magnitudes, right ascensions, and (by estimating the point on the bar where they are occulted) the declinations of a number of stars were determined with great rapidity, and the results made comparable with magnitudes observed with the meridian photometer by the observation of a sufficient number of standard stars. The observations were made in three zones each 10′ in breadth, and lying immediately to the south of N. Decl. 1°, 50°, and 55°, the first zone being part of those observed more than twenty years ago by Prof. Bond, and the other two being situated on the north and south margins of the zone recently revised with the Harvard College meridian circle. A comparison of the D.M. magnitudes between the 7th and 9th with magnitudes as determined in the preceding manner show that the former closely correspond to the magnitudes derived from the mean of the three zones, the zone at 1° N. giving a value of about two-tenths of a magnitude less than the other two. But for fainter stars the three zones are in close accordance with each other, whilst the D.M. values give in comparison too small a magnitude, the difference increasing rapidly until 9·5 magnitude in the *Durchmusterung* is found to correspond to 10·5 with the wedge photometer. Prof. Bond's scale, on the other hand, corresponds fairly to that of the photometer from 7·0 magnitude up to 11·0, but beyond gives magnitudes which are too large, so that his 13·5 magnitude corresponds to about 12·5 of the wedge.

Prof. Pickering is still continuing the investigation, and proposes to give hereafter a far more complete comparison for D.M. stars brighter than 9·0 magnitude with magnitudes as given by the meridian photometer.

WASHINGTON ASTRONOMICAL OBSERVATIONS, 1883.—The volume of the Observations of the Naval Observatory, Washington, for 1883, has been published, and contains the usual routine observations, the bulk of the volume being devoted to the work with the transit-circle, beside three Appendixes, of which two, by Prof. Hall, on the orbits of the inner satellites of Saturn, and on the observation of certain stars for stellar parallax, have already been noticed. The third Appendix is on the Observatory temperature-room and the competitive trials of chronometers in 1884 and 1886. A number of double stars, the satellites of Saturn, Uranus, and Neptune, and the ring of Saturn, had been observed with the 26-inch equatorial; but no remarkable changes were noticed in the ring. The prime vertical was brought into use on November 14, 1882, and 580 observations of stars with small meridian zenith distances, at the times of the maxima of aberration, were secured. The meridian transit instrument of 5½ inches aperture, by Estel, was also used regularly, and 1408 observations secured with it. The 26-inch equatorial was used for the observation of minor planets, comets, and occultations. The Report of the Superintendent includes a notice of the Transit of Venus Expeditions of 1882, and of the reduction of the zone observations made in Chili in the years 1850-51-52, under Capt. Gilliss. A copy of the letter of the Superintendent, asking for a grant of $586,138 for the purpose of erecting the new Observatory, is also given, together with the recommendation of the architect that the entire amount be appropriated in one sum.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *MARCH* 18–24.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 18

Sun rises, 6h. 7m.; souths, 12h. 8m. 2·0s.; sets, 18h. 9m.: right asc. on meridian, 23h. 54·0m.; decl. 0° 39′ S. Sidereal Time at Sunset, 5h. 56m.

Moon (at First Quarter March 20, 21h.) rises, 8h. 52m.; souths, 16h. 26m.; sets, 0h. 10m.*: right asc. on meridian, 4h. 13·0m.; decl. 16° 30′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′
Mercury..	5 23	10 42	16 1	22 27·5	8 51 S.
Venus.....	5 21	10 18	15 15	22 3·8	12 50 S.
Mars	20 47*	2 7	7 27	13 51·8	8 38 S.
Jupiter....	0 22	4 34	8 46	16 18·6	20 25 S.

THE PUBLIC GARDENS OF BRITISH INDIA, ESPECIALLY THE BOTANIC GARDENS.[1]

THE appearance of the hundredth Annual Report of the Royal Botanic Garden, Calcutta, is an event of no little interest in the botanical world, not alone for what it contains, but also for the evidence it affords of the vitality and vigour of the institution, the primary object of which was to disseminate useful information respecting the vegetable products of the possessions of the "Company," and to introduce exotic plants of economic value.

Dr. George King, F.R.S., the present able Superintendent, gives a concise history of the foundation and progress of the Garden down to the present time; and the appendices show that the establishment was never conducted with greater activity. We might make some interesting extracts from the present Report; but our object now is to give a foreigner's view of the principal horticultural establishments in India.

Mr. Warburg roughly classes the gardens under three heads, according to their degree of scientific and practical utility, as distinguished from purely pleasure-gardens, though no hard and fast line can be drawn, because some of the gardens are maintained partly for pleasure and partly for profit. There are only three real botanic gardens in India—we let Mr. Warburg speak for himself—namely, Calcutta, Madras,[2] and Saharunpore, unless we count the garden at Ganesh Khind, near Poona, which is often erroneously called a botanic garden. Besides these, there is the botanic garden at Peradeniya in Ceylon, which, however, comes under the Colonial Office. Of the officially so-called botanical gardens, two were originally founded as such by far-seeing officials: Calcutta by General Kyd in 1786, and the Ceylon Garden by Sir Joseph Banks in 1810; the latter having been established at Peradeniya ever since 1821. The origin of the Sarahunpore garden in the North-West Provinces I did not ascertain [it was originally a pleasure garden of the native princes, and when Lord Moira conquered the Mahrattas he caused it to be transformed into a botanic garden; and the first Superintendent was Dr. Govan (1816-23), who was succeeded by the better-known Dr. Royle, Dr. Falconer, and Dr. Jameson]; and the gardens of Ootacamund and Singapore have passed through various stages before attaining their present condition. Of agricultural experimental gardens I am acquainted with those of Kandesh (Bombay Presidency), Saidapet (near Madras), Nagpore (Central Provinces), and Hyderabad (in the Deccan).

There is also a horticultural garden in Lucknow, an agri-horticultural garden in Lahore (Punjab), and the beautiful garden at Madras belonging to an Agri-horticultural Society. Similar Societies exist in Calcutta, Rangoon, and probably in other places; the first publishing a special Journal.[3]

In almost every town where there is a considerable European population or garrison there are ornamental gardens or parks, called into existence by the demand, and almost necessity, for some such place for social recreation—riding, driving, and walking—in a tropical country, where many of the pleasures and amusements of our Europeans towns cannot be enjoyed. Then there are numerous extensive and costly gardens belonging to the native princes and nobles.[4]

Respecting the gardens having a practical aim, we may be very concise, as their objects are much the same, subject only to the climatal differences of the various provinces, and consequently the kinds of plants that may be profitably cultivated within their several radiuses of activity. The manner in which these practical ends are attained consists on the one hand of experiments and trials in the acclimatization of useful and ornamental exotic plants; and on the other hand of raising new and improved varieties of native plants; and when successful results follow, propagation on a large scale is practised for free distribution or sale. Thus, for instance, during the year 1884-85 the Calcutta Garden sent out 23,500 living plants to various places in India, and forty-two Wardian cases of plants to foreign countries. Further, some 3000 packets of seeds were distributed; yet the proceeds amounted to only 1075 rupees, because one of the principal functions of the Calcutta Garden is to provide the public gardens and pleasure-grounds with plants.

In the same year the Saharunpore Garden distributed as many as 42,000 plants and 21,300 packets of seeds; whereof 31,400 plants and 14,000 packets to private persons; the amount received being 8500 rupees. But ornamental plants, both as living plants and seeds, occupy the first position, while fruit-trees, timber-trees, and seeds of vegetables take a secondary place.

The Singapore Garden sent out the large number of 163,000 living plants in 1884. These figures, however, are merely extracted as examples of what is done by the different establishments, and afford no idea of their relative importance, inasmuch as the number of plants distributed by each one is subject to the greatest fluctuations; in illustration of which it may be mentioned that the Saharunpore Garden distributed 146,000 plants in 1882-83, against 42,000 in 1883-84; the difference being almost made up by 100,000 plants of agave. Similarly in 1884 the Horticultural Gardens in Madras sold 100,000 plants of the "Mauritius hemp," *Fourcroya gigantea*.

As already observed, the nature of the work of the different gardens varies according to the requirements of each district. In many parts, especially in Ceylon, the Nilghirries, British Sikkim, the interests of European planters have to be considered first; in the rice-growing districts of the Ganges, Malabar, and Ceylon, the things cultivated in the gardens and plantations engage special attention. In Bengal, jute, indigo, and to some extent opium, and in Central and Northern India improvements in the cultivation of cereals, are of primary consideration; while in the Bombay Presidency and some parts of Ceylon cotton is added thereto; often associated with the latter the sugar-yielding palm, *Borassus flabelliformis*. For the dry regions of the Punjab it is a question of finding suitable woody plants for afforestation, as well as for the saline soil of the North-West Provinces, in order to provide fuel for the agricultural districts, and thereby gain the dung of cattle for purposes of manuring. And among other things of vast importance is the conservation and renewal of the rapidly disappearing caoutchouc forests of Malacca.

The Singapore Garden has only been a scientific establishment since 1882, when it was placed under the direction of Mr. Cantley; but much has been done in these few years without destroying the natural beauties of the old garden. A small herbarium has been formed, and the most necessary buildings erected. The new plantations are, as far as possible, systematically grouped. A special charm of this Garden is a remnant of the original forest, traversed only by a few paths, where one can enjoy, in a small way, the delights of tropical vegetation without the fatigue attending excursions in pathless forests. The fern garden and the palmetum promise to be very rich and attractive; but a larger income is necessary to carry out the functions of a botanic garden fully and expeditiously. It is perhaps superfluous to add that the Director has to superintend the gardens and promenades of the town; but in order to understand the whole of the circumstances, it is important to bear in mind that he has also been placed at the head of the newly created Forest Department for the whole of the Straits Settlements—an arrangement which of course causes him no inconsiderable amount of additional labour.

Seeds and plants are continuously being distributed from Kew, where all new things are reported and presented, and where competent authorities are consulted on the merits of the samples sent in. At this centre advice is sought, and there is a constant interchange of ideas and experiences between it and the Indian establishments, the advantages of which are so evident that it is unnecessary to enumerate them.

With the exception of rice, tropical cultivation generally is so uncertain and subject to fluctuation, owing to the conditions of labour, communication, and credit, that improvements are very slow; and the experimental work is not so systematically con-

[1] Chiefly from an article by O. Warburg in vol. xliv. of the *Botanische Zeitung*.

[2] Mr. Warburg refers here doubtless to the Madras Presidency, as the botanic garden is at Ootacamund in the Nilghirries, and not at Madras. It should be understood that we are only extracting passages from a rather long article.

[3] And we may add that there is an experimental garden in the mountains at Mussoorie in connection with Saharunpore; another at Darjeeling, partly pleasure and partly practical; and an important experimental garden at Mongpo (Sikkim), under Mr. J. Gammie: the two last offshoots of Calcutta.

[4] We must pass on to what Mr. Warburg has to say concerning the conditions and functions of the botanical gardens and their adjuncts.

ducted as with us. There are too few officers, and everybody has too much to do; nevertheless many of the reports exhibit an amount of zeal and industry deserving of all the more recognition on account of the difficulties under which much of the work is done.

From this point Mr. Warburg explains and describes in some detail what has been effected by the combined action of Kew and the Indian botanic gardens in the introduction, resulting in the extensive cultivation, of economic plants of the first importance, such as the cinchona, tea, and coffee, the cultivation and manufacture of which have developed into industries of incalculable value. He further alludes to the cultivation of rubber-trees, ipecacuanha, fibre-yielding plants, &c., which is, in many instances, still in a more or less experimental stage. He also enters into particulars and comparisons of the climate of different districts in its relations to cultivation, and altogether his Report is an interesting and instructive one, containing much information new to the English public. He specially mentions the great interest taken in the Madras gardens by Sir Mountstuart Grant-Duff, and the material assistance he extended to Prof. Lawson. And he concludes with a brief review of the literature directly or indirectly connected with the botanic gardens of India, culminating in Sir Joseph Hooker's gigantic undertaking, "The Flora of British India." With regard to the intimate connection between Kew and the Colonial and Indian gardens, Mr. Warburg thinks it is at present most beneficial, though he looks forward to the time when they shall have developed so far as to be less dependent on a central institution.

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iii. fasc. 1 (Paris, 1888).—On the colour of the eyes and hair among the non-nomadic Tunisian tribes, by Dr. R. Collignon, based on the observations of Capt. Rebillet and Lieut. Fannezo. These observations, which were conducted in accordance with the methods employed in France for similar investigations, refer to more than 2000 individuals belonging to the "sedentary" or settled populations of the towns and rural districts. The men observed being all regular soldiers, the tables do not refer to any nomads of Arab race, since all the dwellers in tents are exempt from conscription in Tunis. Expressed in general terms, among these 2030 individuals, dark eyes occurred in 1543 cases, or 7·6 per cent., and light eyes in 69 cases, or 3·5 per cent.; while dark hair occurred in 1887 cases, or 92 per cent., and light hair only in 7 cases, or 0·4 per cent. On considering the data obtained from a comparison of the tables referring to different districts, it is found that the blond type occurs only sporadically, and almost exclusively in the littoral settlements, on which account Dr. Collignon thinks it may be assumed that its presence in the Tunisian population is due to the incidental amalgamation of foreign elements through invasion or immigration by more northern races.—On the colour of the eyes and hair in Denmark, by Herr Soren Hansen (communicated to the Society by Dr. Topinard). From this paper we learn that observations made on 2000 males of the age of twenty, belonging to the southern and eastern districts of Jutland, yielded the following results: light, *i.e.* blue, eyes, 1527; dark eyes, 65; leaving 408 of medium colour. In regard to the colour of the hair it was found necessary to establish four groups, which gave the following figures: dark brown, 306; medium, 1267; light (blond), 333; and red, 94. From this it would appear that the majority of the population have blue eyes, and medium brown, or chestnut, hair. A further analysis of Herr Hansen's tables shows that while the perfect brown type—*i.e.* where both hair and eyes are dark—occurs only in 2·7 per cent.; blond hair and light eyes are met with in 16·2 per cent. Finally the curious circumstance has been deduced that while light eyes are twenty-four times more frequent than dark ones, light hair is only seven times more frequent than dark hair; hence Dr. Topinard is led to ask whether the explanation of this peculiarity may not have to be sought in some general law by which in a mixed race, descended from blond and dark races, the eyes may be more generally transmitted from the former, and the hair from the latter.—On recruiting in the cantons of St.-Omer, by Dr. H. Favier. The enormous difference in the cantons north and south of St.-Omer in the number of persons available for military service has been attracting much notice among French officers of late years. According to M. Costa, who wrote on the subject in 1866, these differences are due to hygienic causes; the district north of St.-Omer, where the rejections are only 227 in 1000, being well adapted to agricultural and other rural pursuits, while in the southern canton, where the rejections amount to 342 in 1000 the lands are almost all marshy, exposing the inhabitants to fevers and other malarian influences by which the race is deteriorated. Dr. Favier does not believe that these causes affect the question in any way, but, even if they did so when M. Costa wrote, statistics prove that of late years, more especially since the stricter law of conscription of 1872 has been put into force, the south canton has shown a gradual diminution in the numbers of rejections; and while he denies the action of malarian causes or the influence of differences of ethnic origin between the people of the two cantons, he believes that to industrial centres, such as d'Arques in the southern canton, may very possibly be ascribed certain conditions antagonistic to the success of recruiting.—On the "*castellets*" of Mont Sainte-Baume in Provence, by Dr. Beranger-Féraud. The presence of numerous little heaps of stones on the higher peaks of Mont Sainte-Baume has repeatedly arrested the attention of strangers, and the fact of their having been deposited by the hand of man is now confirmed by Dr. B. Féraud, who last year made the ascent of the mountain for the purpose of investigating their character and purpose. These so-called "*castellets*" (little castles) are either composed of several stones forming a rude sort of pyramid, or of one large stone inserted in a fissure of the rocky soil. Although widely distributed, they are most frequent in the vicinity of the oratory of Saint-Pilon, where they are found at an elevation of nearly 1000 feet, close to the edge of the vertical wall of rock forming the northern boundary of the range. On inquiry he learnt that these structures were also locally designated *moulouns de joye* (heaps of joy), and that they were not alone intended to testify to the successful ascent of the pilgrims to the summit of St. Pilon, but were frequently designed to propitiate St. Magdalen, to whom prayers are made on the spot for approval of the special maiden whom the worshipper may desire to marry. In the latter case the mound is visited by the builder at the end of a year, and if he finds the stones undisturbed he considers that the saint approves of his choice; if, however, the heap is broken up, this is generally regarded as a decisive barrier against the intended marriage. In this superstition, Dr. B. Féraud sees a survival of the ancient usage of erecting stone monuments as altars, pillars, menhirs, &c., to commemorate some important personal event.—On inequality amongst men, by M. de Lapouge. In this address the view is boldly advocated that a man is what his birth made him, and that education can do no more for him than develop the pre-existing germs derived from his progenitors in accordance with the laws of heredity. This reasoning is extended to classes, nations, and races, who are assumed to be unequal, and incapable of attaining to an equal degree of perfection. The writer divides men into four classes, in the first of which he places those possessed of creative and initiative faculties above their fellows, while it is to the relative numerical preponderance of this class over the others that he refers the undoubted superiority of one race over another. He thus sees in the dolichocepalic blonds the most favoured of all the races of humanity, since, from the dawn of history, all heroes and leaders among men have belonged to this type. In modern times the Anglo-Saxon race has owed its superiority to the preponderance of this dolichocephalic element. He believes that France is suffering from the diminution of this type in its population, together with the rising predominance of the brachycephalic type to which the lower classes of the community belong, while he anticipates as inevitable a great deterioration of the general national character through the amalgamation of the two. Similarly he sees in the present movement for raising the negro races a deep source of danger in the future to the more highly gifted Aryan races, who may in time find themselves beaten down by the brute force of teeming masses of inferior brachycephalic peoples. Such are some of the leading points in M. de Lapouge's treatise, which, notwithstanding its redundancy of diction, and the dogmatism with which certain views are maintained, is a highly interesting, suggestive, and learned contribution to ethical inquiry.

Bulletin de l'Académie Royale de Belgique, December 1887.—On some new derivatives of normal heptylic alcohol compared with their homologues, by C. Winssinger. After describing the mode of formation and special properties of normal heptylic alcohol, of the chlorides of heptyl, heptylic mercaptan, oxy-

sulphide, sulphone, and some other new bodies, the author develops some general considerations on the homologous series to which belong the heptylic sulphureted derived substances. These considerations throw fresh light on the evolution of the physical and chemical properties of compound bodies through the various species of a common genus. Thus it is shown that the chemical character of the heptylic combinations must be considered as the development of properties whose source or origin is already found in the lower terms of the series of which heptyl is a member.—A contribution to the study of the development of the epiphysis and of the third eye in reptiles, by M. Francotte. This third eye, of the invertebrate type, already described by Graaf and Spencer, is here exhaustively studied in a large number of reptilian embryos from the province of Namur, in all of which it is very distinctly traced from the epiphysis at the roof of the thalamencephalon to the complete development of the pineal organ. In one species of lizard this eye passes through a series of successive phases each realized in a permanent way in one or other of the adult reptiles. But in all of them the optic nerve has disappeared, which connected the organ with the nerve-centres for a short time in the embryonic state.—This number of the *Bulletin* contains an exhaustive memoir on the fresh-water fishes of Belgium, by Baron Edm. de Selys Longchamps.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 16.—"A new Method of determining the Number of Micro-organisms in Air." By Prof. Carnelley, D.Sc., and Thos. Wilson, University College, Dundee. Communicated by Sir Henry Roscoe, F.R.S.

This is a modification of Hesse's well-known process. It consists essentially in the substitution of a flat-bottomed conical flask for a Hesse's tube. Its chief advantages are: (1) much smaller cost of flask and fittings as compared with Hesse's tubes; (2) very much fewer breakages during sterilization; (3) great economy in jelly; (4) freedom from leakage during sterilization; (5) results not vitiated by aërial currents.

"Notes on the Number of Micro-organisms in Moorland Air." By the same Authors.

A number of determinations made last August "on the heather" in the north of Forfarshire show that the pure air from the hills and moors far removed from towns was free from Bacteria, but contained on the average 3·5 moulds per 10 litres of air. In winter the number would be still less.

Linnean Society, March 1.—Mr. Carruthers, F.R.S., President, in the chair.—An interesting collection of ferns from the Yosemite Valley was exhibited by Mr. W. Ransom, who also showed some admirable photographs of rare plants, many of them of the natural size.—Mr. J. E. Harting exhibited a coloured drawing, life-size, of a South American game bird (the Rufous Tinamu) which has been successfully introduced into this country at Brightlingsea, Essex, by Mr. J. Bateman, and made some remarks on its affinities, peculiarities of structure, and habits. In a discussion which followed Prof. Mivart, Mr. Christy, and Mr. W. H. Hudson took part, the last-named giving some account of the bird from personal observation of its habits in the Argentine Republic.—The first paper of the evening was then read by Mr. E. G. Baker on a new genus of Cytinaceæ from Madagascar. This curious plant, to which the author has given the name of *Botryocytinus*, grows parasitically on the trunks of a tree of the natural order *Hamamelideæ*. Its nearest ally is *Cytinus*, of which the best known species grows on the roots of the *Cistuses* of the Mediterranean basin. The Madagascar plant is without any stem, and the sessile flowers grow in clusters, surrounded by an involucre. Each cluster is unisexual, and the ovary is unicellular, with about a dozen parietal placentæ and innumerable minute ovules. It was discovered during a recent exploration of the Sakalava country, by the Rev. R. Baron, of the London Missionary Sooiety.—The next paper, by Mr. J. F. Cheeseman (communicated by Sir Joseph Hooker, F.R.S.), was entitled "Notes on the Fauna and Flora of the Kermadec Islands," and as regards the flora might be considered as supplementary to a paper on the flora of these islands, published by Sir Joseph Hooker more than twenty years ago (Journ. Linn. Soc., 1856). These islands, situated about 450 miles north-east of New Zealand, between that country and Fiji, were shown to be of volcanic origin, with a fauna and flora resembling to a great extent those of New Zealand. A few land birds were noted as common to New Zealand; and to the list of plants drawn up by Sir Joseph Hooker, from collections made by Macgillivray, several new species were added by Mr Cheeseman, chiefly ferns. A discussion followed, and in illustration of Mr. Cheeseman's remarks, Mr. J. G. Baker exhibited specimens of a new endemic *Duvalia* closely allied to the well-known *D. canariensis* of the Canary Islands and Madeira.

Geological Society, February 17.—Annual General Meeting.—Prof. J. W. Judd, F.R.S., President, in the chair.—The Secretaries read the Reports of the Council and of the Library and Museum Committee for the year 1887. The President presented the Wollaston Gold Medal to Mr. Henry Benedict Medlicott, F.R.S. He also handed to Dr. Archibald Geikie the balance of the proceeds of the Wollaston Donation Fund for transmission to Mr. John Horne, and the Murchison Medal for transmission to Prof. J. S. Newberry. The balance of the proceeds of the Murchison Geological Fund was handed to Dr. Henry Woodward for transmission to Mr. Edward Wilson; and the President presented the Lyell Medal to Prof. H. Alleyne Nicholson, one moiety of the balance of the proceeds of the Lyell Geological Fund to Mr. Arthur Humphreys Foord, and the second moiety of the balance of the proceeds of the Lyell Geological Fund to Mr. Thomas Roberts. The President then read his Anniversary Address, which we have already printed.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: W. T. Blanford, F.R.S. Vice-Presidents: John Evans, F.R.S.; Prof. T. McKenny Hughes; Prof. J. Prestwich, F.R.S.; Henry Woodward, F.R.S. Secretaries: W. H. Hudleston, F.R.S.; J. E. Marr. Foreign Secretary: Sir Warington W. Smyth, F.R.S. Treasurer: Prof. T. Wiltshire. Council: W. T. Blanford, F.R.S.; John Evans, F.R.S.; L. Fletcher; A. Geikie, F.R.S.; Henry Hicks, F.R.S.; Rev. Edwin Hill; W. H. Hudleston, F.R.S.; J. W. Hulke, F.R.S.; Prof. T. McKenny Hughes; Prof. T. Rupert Jones, F.R.S.; Prof. J. W. Judd, F.R.S.; R. Lydekker; Lieut.-Col. C. A. McMahon; J. E. Marr; E. T. Newton; Prof. J. Prestwich, F.R.S.; Prof. H. G. Seeley, F.R.S.; Sir Warington W. Synth, F.R.S.; W. Topley; Rev. G. F. Whidborne; Prof. T. Wiltshire; Rev. H. H. Winwood; Henry Woodward, F.R.S.

February 29.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—An estimate of post-Glacial time, by T. Mellard Reade. The author showed that there exists on the coasts of Lancashire and Cheshire an important series of post-Glacial deposits which he has studied for many years. The whole country to which his notes refer was formerly covered with a mantle of low-level marine boulder-clay and sands, and the valleys of the Dee, Mersey, and Ribble were at one time filled with these Glacial deposits. These Glacial beds have been much denuded, especially in the valleys, where the rivers have cleared them out, in some cases, to the bed rock. Most of this denudation occurred during a period of elevation succeeding the deposition of the low-level boulder-clay. On this eroded surface and in the eroded channels lie a series of post-Glacial beds of a most interesting and extensive nature. They consist of estuarine silt and *Scrobicularia* clay covered by extensive peat-deposits, containing the stools of trees rooted into them. Upon these lie, in some places, recent tidal silts, and on the coast margin blown sand and sand dunes. The series of events represented by the denudation of the low-level boulder-clay and the laying down of these deposits is as follows:—(1) Elevation succeeding the Glacial period, during which time the boulder-clay was deeply denuded in the valleys. (2) Subsidence to about the 25-feet contour, when the estuarine silts and clays were laid down. (3) Re-elevation, representing most probably a continental connection with the British Isles, during which time the climate was milder than at present, and big trees flourished where now they will not grow. (4) Subsidence to the present level, the submersion of the peat and forest-beds, the laying down of tidal silt upon them, and the accumulation of blown sand along the sea-margin extending to a considerable distance in an inland direction. It was estimated, from a variety of considerations, that these events, all posterior to the Glacial period, represent a lapse of time of not less than 57,500 years, allotted as follows: 40,000 years for the elevation succeeding the Glacial period, measured by the denudation of the

boulder-clay in the valleys; 15,000 years for the accumulation of the estuarine silts, clays, peat, and forest beds; and 2500 years for the blown sand. In the discussion which followed the reading of this paper Prof. Prestwich, Mr. De Rance, Dr. Evans, and others took part.—Note on the movement of scree-material, by Charles Davison. Communicated by Prof. T. G. Bonney, F.R.S.—On some additional occurrences of tachylyte, by Grenville A. J. Cole.—Appendix to Mr. A. T. Metcalfe's paper "On Further Discoveries of Vertebrate Remains in the Triassic Strata of the South Coast of Devonshire, between Budleigh Salterton and Sidmouth," by H. J. Carter, F.R.S. Communicated by A. T. Metcalfe.

Mathematical Society, March 8.—Sir J. Cockle, F.R.S., President, in the chair.—The following papers were read:—Supplementary remarks on the theory of distributions, by Capt. P. A. MacMahon, R.A.—Complex multiplication moduli, by Mr. A. G. Greenhill.—Geometrical proof of Feuerbach's nine-point circle theorem, by Prof. Genese.—Isostereans, by Mr. R. Tucker.

Anthropological Institute, February 28.—Francis Galton, F.R.S., President, in the chair.—The election of Mr. Henry C. Collyer was announced.—Dr. Edward B. Tylor read a communication from Mr. Basil Hall Chamberlain, on the Japanese "go-hei," or paper offerings to the Shinto gods. In olden times the offerings were made of cloth, but later on, when Chinese civilization had brought a variety of manufactures in its train, hempen cloth ceased to be regarded as a treasure worthy of divine acceptance, and paper began to be used instead. The "go-heis" used by different sects differ slightly from one another, chiefly in the number of the folds: the Yoshida sect sanctions the use of four folds, while the Shirakawa sect has eight. There is said to be no symbolism attaching to the shape, number of folds in the paper, or the length of the stick; each sect has clung to its traditional practice in these matters. Specimens of "go-heis" were exhibited in illustration of the paper.—Mr. Henry Balfour exhibited a series of decorated arrows from the Solomon Islands, in illustration of his theory of the manner in which the decoration of the shafts was gradually developed.—Dr. Tylor gave a brief account of a paper by Mr. A. W. Howitt, "Further Notes on the Australian Class Systems," and in the course of the discussion the President showed a very simple method of understanding the complicated-looking system of Australian marriages, by supposing a cross-division of the tribes.

EDINBURGH.

Royal Society, February 6.—Sir W. Thomson, President, in the chair.—Prof. Crum Brown showed and described an apparatus for exhibiting the action of the semicircular canals. The apparatus is also capable of application as an instrument for the measurement of the irregularity of angular motion.—Mr. John Murray read a paper on the temperature and currents in the lochs of the west of Scotland, as affected by winds. He showed that when the wind is blowing off shore the warm surface water is blown outwards and cold water takes its place from beneath. When the wind blows on shore the warm surface water is driven inwards. This point is of great importance, as it has an evident bearing on the growth of coral-forming animals.—Mr. Murray also communicated a paper by Mr. W. G. Reid on the solution of carbonate of lime in sea water under pressure. The results of Mr. Reid's experiments show that the solubility is increased by pressure.—Mr. Murray then discussed the distribution of carbonate of lime on the floor and in the waters of the ocean.—Mr. John Aitken read a paper (see NATURE, March 1, p. 428) on the number of dust particles in the atmosphere, giving a full account of the apparatus used and the method of experimenting.

PARIS.

Academy of Sciences, March 5.—M. Janssen in the chair.—Remarks on the first volume of Fourier's works presented to the Academy, by M. G. Darboux. This volume of the complete edition of Fourier's works, now being issued with the aid of the Minister of Public Instruction, contains the full text of the "Théorie analytique de la Chaleur," carefully revised by MM. Darboux and Paul Morin.—On the transformation of the nitrates present in the soil into nitrous organic compounds, by M. Berthelot. The experiments here described have been carried out for the purpose of showing that the nitrates contained in the ground do not occur in an integral state even independently of the formation of the higher plants. On the contrary, they may be changed into nitrous principles of organic nature under the influence of chemical agents properly so-called, or of certain microbes present in the soil. It is suggested that these microbes assimilate the combined nitrogen when presented to them in a convenient form, preferring it to the free nitrogen of the atmosphere, thus reversing the action of the microbes of nitrification. The general inference is that the assimilation of the nitrogen of the nitrates by plants is accompanied, if not preceded, by their transformation into nitrous organic compounds in the earth under the influence of chemical reactions and special microbes. These microbes are perhaps the same as those which fix free atmospheric nitrogen in soil destitute of nitrates. In this way might be formed true azoic compounds derived at once from the oxygenated and hydrogenated compounds of nitrogen.—On perfect numbers, by Prof. Sylvester. A slight omission pointed out by M. Mansion in the author's recent paper on this subject is shown in no way to affect the validity of the demonstration.—On *Saccharomyces ellipsoideus* and its industrial applications to the manufacture of a barley wine, by M. Georges Jacquemin. A process is described by which a tartarized wort of barley is made to yield a true wine of pleasant taste, and more nutritive than grape wine, containing as it does more respiratory aliments, besides an albuminoid substance, and a larger proportion of phosphates calculated to restore the nervous system and the bony tissues. It also differs from white grape wine by being copiously precipitated by tannin, while a portion of the malt may be replaced by crushed grain (wheat or barley) that has not sprouted. This wheat or barley wine is stated to be equal in quality and cheaper than that of pure malt, and the vinous wort in question is an alcoholic fermentation of a totally distinct character from the ordinary yeast of beer.—Immediate solution of equations by means of electricity, by M. Felix Lucas. A method is described by which an algebraic equation of any degree with real numerical coefficients may be directly solved without calculations by means of electricity. The process here explained is much more rapid than the two methods indicated in previous communications. However high the equation, a single operation suffices to obtain all the roots, real or imaginary. "The power of electricity as a calculator is not to be limited."—On the electric conductibility of concentrated nitric acid, by M. E. Bouty. In previous papers it was shown that a very slight addition of alkaline nitrates to the acid increases its conductibility to a considerable extent. Here it is made evident that the addition of water also causes an increase of conductibility nearly proportionate to the quantity of added water. This approximate proportion is maintained even much further than with the nitrates, nearly to $NO_5,4HO$. A table is given showing the degrees of conductibility measured at 0° C., and referred to that of the normal solution of nitric acid at one equivalent per litre, the specific resistance being 4·59 ohms.—On cinchoniline, by MM. E. Jungfleisch and E. Léger. In previous communications the conditions were explained under which cinchoniline is formed and separated in the state of a di-iodhydrate. Here the authors deal with this base and its chief derivatives. That this substance, which has the formula $C_{38}H_{22}N_2O_2$, is isomerous with cinchonine, is made evident not only by the analysis of the base itself, but also of that of a large number of combinations. In ether it forms magnificent rhomboidal prisms, colourless, anhydrous, and often attaining a weight of several grammes. It dissolves readily in ordinary alcohol, but with difficulty in water, its aqueous solution giving a deep blue tint to turnsol (Dutch orchil), and a red to the phthaleine of phenol. Its basic and neutral salts present some remarkable crystallographic properties.—Products of the oxidation of the hydronitrocamphenes, by M. C. Tanret. From the oxidation of these substances the author has obtained several new compounds, which are here described. The new substance, answering to the formula $C_{80}H_{64}N_4O_{16}$, he proposes to call nitrocamphene (*azocamphène*), distinguishing its two modifications as cyanonitrocamphene and leukonitrocamphene. They are isomerous, their analysis yielding the same constituents.—On terpinol, an artificial reproduction of eucalyptol (terpane), by MM. G. Bouchardat and R. Voiry. These researches show that the terpinol of List is formed of a crystallized inactive terpilenol or terpol, $C_{20}H_{18}O_2$, boiling at 218° C.; of terpane, $C_{20}H_{18}O_2$, boiling at 175°, and capable of crystallizing at −1°; lastly of inactive terpilene, $C_{20}H_{16}$. Terpane, which term is here substituted for the older cineol, eucalyptol, cajeputol, spicol, &c., differs also from the active and inactive terpilenols by refusing to

combine either with the acids or the anhydrides to yield ethers. —Deleterious influence of alcohol on offspring, by MM. A. Mairet and Combemale. The results are described of some experiments on dogs, showing that their progeny were injuriously affected for two successive generations by the influence of alcohol administered under various conditions to the parents.

BERLIN.

Physiological Society, February 10.—Prof. du Bois Reymond, President, in the chair.—Dr. Baginski spoke on the origin and course of the auditory nerve. As the result of experiments on young cats, in which the peripheral end of this nerve had been destroyed, and which were then killed at the end of six weeks, he was able to follow the course of the degeneration by means of a series of sections through the root of the nerve to the posterior corpus quadrigeminum. In this way his earlier experiments on rabbits were fully confirmed. The degeneration spread to the olivary body of the same side, and was continued through the trapezium of the pons. After removal of the facial nerve the olivary body was similarly found to be affected. These observations are closely connected with those of von Monakow, who found that destruction of the auditory centre, described by Munk, led to a degeneration which could be traced right into the hinder corpora quadrigemina. At present no observations are in existence as to the course of the anterior root of the auditory nerve.—Dr. Rawitz gave an account of the results of his researches on the eyes of mussels, and explained the same by reference to preparations which he exhibited. Three distinct types may be observed among the eyes, sometimes to the number of one hundred, which occur on the edge of the mantle of Pecten. Each eye consists of an epithelial layer, a lens, and a retina composed of rods, whose ganglionic layer is on the side turned towards the light, while the rods are turned away from the light and abut on the tapetum and layer of pigment cells. The speaker had been able to trace the endings of the nerves through the cells connected with the rods into the rod itself. The mussels are only able to see with the central portions of each eye.—Dr. Virchow presented and explained a plaster cast of the gluteal region. He had had this cast made in order to throw light upon a deep furrow which extends from the gluteus maximus to the tensor muscle, and is not due to the edge of either of these muscles. This furrow may be observed in the sitting posture, and is due to the stretching by the point of the trochanter of a portion of the fascia which envelop the gluteus medius: by this means the gluteus medius is divided into two projecting portions. When this muscle contracts, the furrow disappears.

February 24.—Prof. du Bois-Reymond, President, in the chair. —Prof. Liebreich spoke on the testing of the action of local anæsthetics on animals. There are a number of substances which, when injected subcutaneously, give rise to a localized anæsthesia in the immediate neighbourhood of the place where they are injected. Antipyrin, sal-ammoniac, salts of tannin, resorcin, chloride of iron, and other substances have this action, although there is neither chemical nor physiological similarity between them. They possess, however, this property in common, that they all have a corrosive action on the tissues, when this expression is understood to imply any kind of alteration of molecular structure. The alkaloids, in the cases where they possess a local anæsthetic action, act in the same way, as, for instance, erythrophoein. Cocaine alone is an exception to the rule, inasmuch as it is a local anæsthetic, but does not corrode the tissues. When applied subcutaneously to man, the above substances either produce no localized anæsthesia, or one which is very imperfect. When testing the action of anæsthetics on the eye, it is essential to take into account the difference in sensitiveness of the conjunctiva and cornea, as already pointed out by Claude Bernard.—Dr. Virchow exhibited a plaster cast of the hip-region taken from a female corpse in a hanging position. It brought to light a whole series of most surprising relationships which can never be observed, in preparations made from a corpse in the recumbent position, as at all corresponding to those existing in the erect posture. One of the most striking facts is the considerable stretching of the sciatic nerve, which must be still greater when the leg is advanced, as in walking. —Dr. Virchow further spoke on the striæ medullares acusticæ in man, in connection with the statement made before the Society a fortnight before by Dr. Baginski. His experiments have shown, in correspondence with the results of many other observers, that the striæ can be traced through the raphe to the other side of the medulla. It must still remain an open question whether the fibres which lead to the anterior root of the auditory nerve have a different course in cats and rabbits (examined by Baginski) than they have in man (examined by the speaker), or whether in the above-named animals we have to deal with a frequently-recurring division and rearrangement of the fibres of any one tract.

Physical Society, February 17.—Prof. Helmholtz, President, in the chair.—Prof. Lampe made a report on McGregor's book, "An Elementary Treatise on Kinematics and Dynamics." —Prof. Börnstein exhibited an electricity-meter which enables the intensity of the current to be read off direct.—Dr. Gerstmann gave an account of a preliminary communication by Aubel on the influence of temperature and magnetization on the electrical resistance of bismuth.—Dr. Kötter spoke on a problem in the theory of projectiles—namely, that a bullet shot out of a rifle tends to deviate in a direction away from the side on which the bayonet is attached to the muzzle.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, MARCH 22, 1888.

THE REVENUE METHOD OF ESTIMATING AND CHARGING THE DUTY ON SPIRITS.

THIS subject has attracted some notice since Sir Henry Roscoe put a question to the Chancellor of the Exchequer the other night in the House of Commons, as to whether his attention had been called to the fact that, owing to the present faulty system of charging the duty on spirits, a loss to the Revenue of from £60,000 to £80,000 per annum did not occur, without any corresponding benefit to the trader, and whether he would appoint a Departmental Committee to inquire into an improved system of estimating the percentage of spirit, as proposed by Dr. Derham. To this the Chancellor replied that the above estimated loss was based on an erroneous assumption, and that the introduction of the suggested system would be attended with difficulties comparable with those which would accrue to the substitution of the decimal for the present system of coinage. The grounds of these objections could not of course be given in answer to a question, and therefore the public are not yet in a position to judge how far the Revenue Departments can make them good. The statements of Dr. Derham are, however, perfectly plain, and demand plain answers.

They are (1) That the essential defect of the present system is well known and acknowledged by the Inland Revenue Department.

(2) That this defect depends on the erroneous assumption made by Sikes in constructing his tables that any given quantity of spirit does not alter in bulk or in strength with variations of temperature from the normal of 51° F.

(3) That the only argument which can be advanced in defence of the present system is that deficiencies at temperatures below 51° F. are compensated by over-estimates above 51° F., so that on the whole the Revenue neither gains nor loses.

(4) That on the contrary it is a fact that at least five-sixths of the spirits paying duty are taken out of bond during the nine cooler months of the year when the temperatures in warehouses range from 51° F. downwards, so that in the case of these spirits a constant loss accrues to the Revenue, and also to the trader from under-estimation of his stock, which he must dispose of at that estimate. Whilst in the summer months, owing to the construction of warehouses, evaporation of spirits, &c., the temperature of the spirits does not often exceed 51° F., so that there is but a slight compensating gain to the Revenue from that source.

(5) That the objections to the present plan can be entirely removed by adopting the suggested system, which, without altering the standard of measure—the proof gallon—without introducing any change in the notation of over- and under-proof, or any alteration calculated to confuse the trader, substitutes tables founded on a correct principle instead of an erroneous one, a scientific and exact for an unscientific and inexact instrument, which not only will facilitate the work of the Government officials, but will give correct results at all temperatures.

In consequence of the "*non possumus*" reply of the Chancellor, Sir H. Roscoe gave notice that he should move for a return of the number of proof gallons taken out of duty free warehouses for *consumption* last year. specifying the number of proof gallons at each degree of temperature when the account was taken for payment of duty; all spirits taken out for methylation, exportation, ships' stores, and removal to other warehouses, which do not pay duty, and which may have recently been distilled, being excluded. Such a return would either confirm or disprove Dr. Derham's contention, and there seems no reason why such a return should not readily be obtainable. It appears to us that the comparison of the introduction of the decimal coinage made use of by Mr. Goschen was an unfortunate one. The introduction of the decimal coinage would obviously occasion a great amount of confusion and perplexity, for a time at least, and would in the end only substitute one correct and convenient system for another equally correct though less convenient. The adoption of the improved system of charging duty on spirits would occasion, on the contrary, no material change, none likely to cause confusion or perplexity, but would replace an incorrect and inconvenient system by one at once correct and more convenient. The Chancellor moreover hinted that the vested interests of the trade in the property of the present instruments must be safeguarded. If the new and correct tables became legalized and were adopted, Sikes's hydrometer could equally well continue to be used, or any instrument can be employed which furnishes specific gravities. Mr. Goschen also stated that Dr. Derham's instrument is too delicate for ordinary use. This appears to us to be the weakest part of his argument. The ball in the new instrument, the most vulnerable part of the hydrometer, happens to be of the same size and strength as that in the ordinary Revenue instrument. It is true that a somewhat different method of attaching the poises is adopted, but this is a mere detail, and more a question of taste and opinion than of principle, and it is certain that the form can, if desirable, be made so as to be indistinguishable from Sikes's instrument, for the characteristic feature of the new system is to be found in the bulks and specific gravities of the poises, and not in the shape or size of the stem or bulb.

The Revenue authorities can scarcely, we imagine, fail to admit that certain defects in Sikes's system exist, for these can be demonstrated by reference to Sikes's own tables. Hence we incline to the belief that the erroneous assumption to which the Chancellor referred consists in taking for granted that there is a general correspondence between the temperatures of warehouses and that of the mean shade temperature of the country, for this is the assumption made by Dr. Derham. The returns which have been asked for will decide this point. But meanwhile it may be of interest to see how the large figures of from £60,000 to £80,000 per annum have been obtained. The Customs and Excise deal annually with some forty million gallons of proof spirit or their equivalent, which for the most part lie for a longer or a shorter time in warehouse. If we assume that the average strength of the spirit when removed from warehouse for consumption is 25 overproof, then thirty-two million gallons by measure are equivalent to the forty million gallons upon which the duty is charged, so that, if the rate of removal be

constant, 2,700,000 gallons by measure at 25 overproof are removed each month from bond. Now, taking the mean shade temperatures for the months from November 1886 to April 1887, it appears that, owing to the contraction in these 2,700,000 gallons per month, no less a quantity than 97,268 gallons of 25 overproof or of 121,586 gallons of proof spirit for the six months would accrue in the estimation as now carried on, and the duty on this amounts to £61,000, now lost to the Revenue.

It is true that probably these shade temperatures do not exactly represent the temperatures of the warehouse, which will be more equable, but then the contents of a warehouse if they lose their heat slowly also regain it slowly, and the low temperature contracted during a long and severe winter is perpetuated for a long period throughout the year; so that in all probability the average temperature of the bonded spirit is below 51° not only during six but during nine months of the year, and assuming that the mean temperature did not exceed 47° during these extra three months, the additional loss to the Revenue would amount to £10,000.

The foregoing statements have been published for some time, and have not been confuted except in the usual official Parliamentary style. This, we urge, is insufficient. What the public wants to know, and has a right to learn, is, what, if the Revenue authorities dispute these assertions, are their grounds for so doing? Should this information not be forthcoming, the opinion will gain ground that another Government Department is trying hard "how not to do it."

PRESTWICH'S "GEOLOGY."

Geology: Chemical, Physical, and Stratigraphical. By Joseph Prestwich, M.A., F.R.S., F.G.S., Correspondent of the Institute of France, Professor of Geology in the University of Oxford. In Two Volumes. Vol. II. Stratigraphical and Physical. (Oxford: Clarendon Press, 1888.)

It is just two years ago that we were called upon to notice the first volume of this important treatise; and the author of it has now signalized the completion of his labours at Oxford by giving to the world the second and concluding volume of the work. Its publication has long been eagerly looked forward to, and now that the book is before us, we may safely assert that it more than justifies the high expectations which have been formed concerning it; and we confidently predict that it will add to the already high reputation of the veteran geologist to whom we are indebted for it.

In reading the first chapter of the book, everyone must be struck by the fact that a distinct advance has been made in the mode of treatment of the great problems of stratigraphical geology. Speaking of the "order of succession" and "the breaks in continuity" in the series of stratified rocks, Prof. Prestwich writes:—

"The great time-divisions are of almost universal application; but the smaller 'breaks in continuity,' which are of frequent occurrence in all areas, are subject to constant differences of extent and value; consequently, in filling up the details of the several geographical areas, each one is found to have its own local stamp, and possesses its own special terms, some knowledge of which is as essential to the geologist as is the language of a country to the traveller, if he would pass through it with profit."

The author then proceeds to show how impossible is any universal scheme of geological classification, and to discuss the question, first raised by Edward Forbes and Prof. Huxley, as to how far geological equivalence is to be regarded as being identical with actual synchronism.

He insists that, in distant areas, strata cannot be correlated by identical *species*, but only by the presence of the same characteristic *genera*, and he fully admits the effects of migration of forms of life from one region to another in causing strata of different ages to present very similar faunas or floras. Such considerations as these, the author argues, must always prevent us from regarding the series of formations as being strictly contemporaneous in distant areas, or the breaks between them as being universal ones.

Prof. Prestwich points out some of the difficulties confronting geologists, in the following suggestive passage:—

"In Western North America the great break so conspicuous between the Cretaceous and Tertiary series does not exist, and there are passage beds having characters of the two periods in common. In a similar way the Carboniferous strata in America pass gradually into the Permian, without the unconformity which exists here. In India the Gondwána system forms a consecutive series from the base of the Permian to the top of the Jurassic strata. In New Zealand, again, no marked line can be drawn between the Cretaceous and Tertiary series, the Upper Cretaceous and Lower Eocene forming unbroken and continuous series."

He then proceeds to give not *one* table of classification for the sedimentary rocks, but *six* different ones, adapted respectively to Europe, India, North America, Australia, New Zealand, and South Africa. And having thus at the very outset shown what are the obstacles in the way of the exact correlation of distant deposits, and established a philosophical basis of classification for strata, he takes up the consideration in succession of the several great geological systems; he selects the method of beginning with the oldest, and passing upwards in the scale, candidly admitting, however, that the opposite plan is not without its merits and advantages.

The account given in successive chapters of the several formations, their typical development in this country, the groups of fossils by which they are distinguished, and their chief foreign representatives, is eminently clear and readable. This merit is the more conspicuous from the circumstance that the mass of detailed information to be selected from and arranged in writing a work on stratigraphical geology is so enormous and bewildering, that such works are very apt to suffer in their style, and to become heavy and encyclopædic in character. But Prof. Prestwich has admirably avoided this danger.

The author does not waste any time in discussing barren questions of nomenclature. In the case of the three systems of the older Palæozoic, he follows the common custom of calling the oldest "Cambrian," the second "Lower Silurian," and the third "Upper Silurian"; though pointing out in a footnote the significance of the term "Ordovician."

Very striking features in the book are the chapters in which are summed up the characteristics of the faunas

and floras of the Palæozoic, the Mesozoic, and the Kainozoic divisions respectively. In these reviews of the great geological epochs, the distinctive features of their life-history are ably summarized; and the subject is made clearer by the insertion of sixteen lithographic plates, the fossils represented upon these being very judiciously selected and admirably drawn.

Most readers will look with much interest to the later chapters, in which the author deals with the Tertiary and post-Tertiary deposits, the study of which has been so greatly advanced by the author's own researches. Prof. Prestwich has in several very important points modified some of the conclusions of his classic papers upon these questions. He now accepts, with most modern geologists, the term "Oligocene" as usefully embracing the strata known as the "Fluvio-marine strata" of the Hampshire Basin, and separates them from the Eocene proper. He also points out for the first time the close connection of the so called "Lower Bagshot Sands" with the London Clay, placing them in the Lower Eocene; while the Middle and Upper Bagshots of the London Basin, and the Bracklesham and Barton series of the Hampshire Basin, constitute his Upper Eocene. This view has recently been explained and defended in a paper which the author has read before the Geological Society, and is one which we think will meet with very general acceptance. In his account of the post-Pliocene (or, as he prefers to call them, the Quaternary or Pleistocene) deposits, it will also be seen that Prof. Prestwich has so far departed from his earlier published views as to admit the probability of some of the deposits which contain relics of human handiwork belonging to a period when glacial conditions prevailed in this country.

The work concludes with three chapters of a theoretical character. In the first of these Prof. Prestwich argues against the acceptance of any views, like those of Dr. Croll, which would define the exact date of the Glacial period by reference to astronomical events. Accepting the probability that man may have lived at the period of the greatest glaciation, the author boldly proceeds to challenge the common opinion that this period of glaciation must have been separated by an enormous interval of time from the present day. He even suggests that the Glacial period may not have had a duration of more than from 15,000 to 25,000 years, and the post-Glacial period he thinks may be restricted to 10,000 or 15,000 years!

The facts which seem to have had the greatest weight in leading Prof. Prestwich to these, at first sight, startling conclusions, are those connected with the movements of the great ice-sheets in Greenland. The recent observations of Rink and Helland seem to show that the data afforded by the diminutive Alpine glaciers are utterly inapplicable to the vast masses of ice which must have flowed over extensive areas during the Glacial period. While the Alpine glaciers progress at an average rate of a foot per day, the great Greenland ice-sheet advances 35 feet per day, and the effects produced in a given time by such rapidly moving masses must be proportionately great. There will doubtless be much difference of opinion among geologists upon the important suggestions made by Prof. Prestwich; but in any future discussions of the subject it must be admitted by everyone that the data upon which all our reasoning has to be based has been profoundly modified by the remarkable observations made by the Danish Scientific Commission upon the inland ice of Greenland.

In his penultimate chapter, the author points out the grounds for the view—of which he has long been one of the ablest advocates—that the earth's solid crust is a comparatively thin one; and he indicates the lines of argument by which the objections of mathematicians and physicists to such views can best be met. While demurring to the doctrine of the permanence of continental and oceanic areas, he justly points to the great effects which must result from the flow of ice-cold water over the bottom of the great oceanic depressions.

The last chapter, on "The Primitive State of the Earth," is an attempt to link the geological history on to that arrived at by the studies of the astronomer. Due importance is justly attached to the evidence afforded by meteorites, and an excellent summary is given of Daubrée's admirable researches. But here, as the author freely admits, he is on less secure ground than in the earlier chapters of his book, and the utmost he aims at doing is to supply a working hypothesis.

Both Prof. Prestwich and the Delegates of the Oxford University Press are to be congratulated upon the manner in which the work has been got up. The printing is admirably clear, and the woodcuts, most of which are original, are of exceptional excellence. The plates, which have been very skilfully drawn on stone by Miss Gertrude Woodward, exhibit the characters of the fossils illustrated in a manner superior to what we have ever seen attempted in any geological text-book. The coloured geological map of Europe, which has been prepared under the supervision of Mr. W. Topley, is brought up to date, and is very clear and serviceable.

To the splendid work now so auspiciously completed at the termination of the author's professorial career at Oxford, we heartily wish all the success it so well deserves.

J. W. J.

VACCINATION.

Cow-Pox and Vaccinal Syphilis. By C. Creighton. (London: Cassell, 1887.)

Vaccination Vindicated. By J. C. McVail. (London: Cassell, 1887.)

TWO new books have lately appeared on vaccination; one on the natural history of "Cow-Pox and Vaccinal Syphilis," by Dr. Charles Creighton; the other, "Vaccination Vindicated," by Dr. J. C. McVail.

The first mentioned, that by Dr. Creighton, is a very misleading work. The first four chapters are almost entirely devoted to a wholesale abuse of Jenner, and the fact that Jenner has called the cow-pox the "variolæ vacciniæ," is especially singled out for more than usual criticism; but the very virulence of the abuse will lead to its condemnation, and the memory of the man who deserves so well of his country will not therefore be unjustly thought of by his countrymen.

The whole burden of the rest of the book may be summed up in a passage that occurs on p. 155: "The real affinity of cow-pox is not to the small-pox but to the great-pox." Let it be remembered that these two diseases are placed together by the science of medicine

under the common order of zymotic diseases: is it wonderful that in some things they agree? The thistle and the sunflower both belong to the same natural order in botany, but are they identical? Dr. Creighton entirely suppresses every point in which the dissimilarity of the two diseases appears; but he insists upon nearly all those in which the similarity shows itself. In fact, his whole work is a piece of special pleading which anybody but a lawyer ought to be ashamed of.

It is easy enough to find some sort of resemblance between two inoculable diseases, and arguments of the kind found in Dr. Creighton's book might be multiplied greatly. We present him with another which we should have thought too good for him to have missed, but we will not promise him it will satisfy his readers more than those which he has himself adduced.

When the virus of the great-pox is taken early in the disease it will communicate its own specific characters, and will for a certain time render the individual to whom it is communicated immune from further contamination by the disease; but if the virus is taken in its later stages it will produce in the individual who is inoculated a sore which has often a tendency to ulcerate, to phagedena, &c., and this sore does not convey the constitutional symptoms of syphilis, nor does it render the individual immune from further manifestations of its own peculiarities. This similarity of the two poxes might, in Dr. Creighton's fashion, be shown in the behaviour of vaccinia, for if vaccine lymph is taken early it produces a constitutional disease of short duration which protects the individual from further vaccination for a time at least, and also from small-pox; but if the vaccine is taken late it produces a sore that has a tendency to ulcerate, to phagedena, &c., and which does not convey immunity to the individual against further vaccination or against small-pox. While referring to this point we may observe that all the bad results collected by Dr. Creighton following vaccination were from lymph taken at a too late stage, and the evils produced must be attributable to the ignorance of the vaccinator rather than the innate virulence of the lymph, or more fancifully still to any reversion to type.

Some of the points of dissimilarity he does not mention are these:—

Firstly, vaccination protects from small-pox when its virus is taken at the proper time, but it does not protect us against the great-pox.

Secondly, the microscopical appearances of a true chancre of early date are quite distinct from those of a vaccine vesicle.

Thirdly, the incubatory periods of the two diseases are utterly different.

It is easy to find points of similarity if we only look at the points of likeness. Thus with no great difficulty we might compare a man and a monkey, and it would not be difficult to argue that at a remote period of time they may have had a common ancestor; but now no one in his senses, except perhaps Dr. Creighton himself, would say that they are identical species.

Dr. McVail's book is altogether different. It is one of the most thoughtful works of the kind we have seen. We would commend it to everyone who is anxious to learn the truth about vaccination, especially to Members of Parliament and others who have a voice in the government of this great country, also to all medical men who neither have the time or inclination to dig deep into anti-vaccination literature. They will find complete answers to all the assumed evils of vaccination, as well as the evidences of the value of vaccination as a prophylactic against small-pox. There is also set forth what a fearful disease small-pox used to be, and how it has been robbed of its sting by vaccination.

Dr. Wallace's writing on this subject, whom we are ashamed as scientific men to find in the anti-vaccination ranks, are especially shown up and gibbeted. We may quote two passages in support of this assertion; they occur on pp. 70 and 87. Speaking of the possible errors in registration, Dr. Wallace instances three cases; of one of these Dr. McVail writes:—

"It is pitiful to think of Dr. Wallace as being driven to appeal for one of his three instances of incorrect registration to such ravings as those of Mr. Pickering. But the abuse of vaccination is so largely buttressed by the relation of 'cases,' that the examination of these samples specially selected by so able an author seems not without use as illustrating the character of the whole class."

And on p. 87 Dr. McVail says after careful reading: "I have been further forced to the conclusion that, in this matter, when Dr. Wallace says 'the point in question has been entirely overlooked,' *the statement is a misstatement*, and that when he says 'it is nevertheless a fact,' then *it is not a fact*." The book is throughout so carefully and faithfully written, and deals so well with the tactics of the anti-vaccinators, that it ought to have a wide circulation among those interested in the question. Many are interested in seeing conjuring tricks, and in witnessing optical delusions. So long as the tricks are not understood, there is an inclination in the minds of some to regard these tricks as more difficult of performance than they really are, and some may even attribute them to supernatural agency. The same kind of tricks are played by such men as Dr. Wallace on our literary pursuits. Dr. McVail's book may be taken as exposing the tricks, and showing the mechanism by which they are done.

ROBT. CORY.

OUR BOOK SHELF.

Animal Biology. An Elementary Text-book. By C. Lloyd Morgan. With Illustrations. (London: Rivingtons, 1887.)

THIS volume has been written to meet the requirements of those reading for the London Intermediate and Preliminary Scientific Examinations, as well as for the Oxford and Cambridge Local. In it special attention has been paid to embryology, and there can be little doubt that the information in this volume would enable the attentive student, with some preliminary assistance, to make very considerable progress in the study of both anatomy and physiology.

The author treats of the anatomy and physiology of the vertebrates as exemplified by the frog, the pigeon or fowl, and the rabbit, with occasional references to other types; and of the invertebrate types, the crayfish, cockroach, earthworm, snail, fresh-water mussel, liver-fluke, tapeworm, hydra, vorticella, and amœba, are selected.

The illustrations have been engraved after original outline sketches of the author's, chiefly from dissections or preparations made in the biological laboratory of University College, Bristol. They are all the better for

not being too pictorial; for a student, especially when left to his own resources, is often apt to be misled by over elaborated drawings.

In addition to the anatomical and physiological details given of each of the type forms selected, there is appended to each an excellent general summary of the life-history of the form; so that within the compass of a little over 350 pages we have a really valuable text-book of animal biology, which we would wish to place in the hands of all students. In Ireland, unfortunately, the Commissioners of Intermediate Education have omitted the subject of biology from the schedule for boys, and limited that for girls to the vegetable kingdom.

Practical Guide to Photographic and Photo-Mechanical Printing Processes. By W. K. Burton. (London: Marion and Co., 1887.)

IT is refreshing to find that the text of the second photographic work issued by these publishers is not made subservient to the advertisement of photographic specialties. The work before us is written by a gentleman well known for his practical rather than his theoretical acquaintance with photography. We thus have an account of the practical working of various processes, with a small modicum of theory. The chapters on silver printing and carbon printing are very clear and complete, and if followed out will lead the amateur to successful results. When we come to the photo-mechanical processes, however, there is at first sight presumable evidence of a lack of intimate knowledge of the subject. It may be, however, that there is a greater difficulty in describing these operations than in the ordinary printing processes to which we have alluded. We doubt very much if the descriptions given would enable a tyro to progress at a rapid rate. For the enthusiastic photographer who has time to experiment the directions would suffice to enable him to commence in the right way, and though at first he would inevitably blunder, yet he would after a sufficient number of disasters produce results which he might take a certain amount of pride in showing to his immediate friends, who would be likely to appraise them higher than at their market price.

In another edition we should recommend that the author should either expand the descriptions of his photo-mechanical processes, or omit them altogether. The work itself is nicely got up, the print is good, and the illustrations well executed.

A Treatise on the Diseases of the Dog. By John Henry Steel, M.R.C.V.S. (London: Longmans, Green, and Co., 1888.)

THOUGH the author of this manual does not claim to offer an original book on canine pathology, and though he assumes the modest *rôle* of compilator of canine literature—English and foreign—we venture to say that he is fully entitled to the claim of having produced an extremely useful work; useful in the first place to the veterinary profession, but not less useful to all those who, like sportsmen, dog-breeders, and dog-keepers, wish to possess a ready and authoritative book for study and reference.

All disorders to which the dog is subject are considered minutely, and in addition there are a great many useful data as to the anatomy and physiology of the canine organism well blended together.

The treatment of canine ailments, and the various methods of medical and surgical practice, form an integral part, and while the author's extensive practice enables him to speak with authority, he does not omit to mention the practice of others which he considers most commendable.

The numerous illustrations, copied from standard books, though not of the first order as regards execution and reproduction, nevertheless considerably enhance the text; this is particularly the case with those which illustrate the general appearance of the animal under the various severe internal disorders, as also those on medical and surgical practice.

But it must be regretted that in the illustrations on microscopic objects, of which there are a good many in this book, no statement is made in connection with the figures as to the amount of amplification under which the objects are supposed to be viewed. This is perplexing in itself, but becomes more so when we remember that there are other illustrations of anatomical parts which are represented smaller than natural size. But these minor details, which are easily corrected, cannot detract from the general usefulness of the work. E. KLEIN.

Management of Accumulators. By Sir D. Salomons. Third Edition. (London: Whittaker, 1888.)

THE author has considerably enlarged this edition of his work, and made it in some respects more complete.

The first part deals with accumulators, and principally with those of E.P.S., or Elwell-Parker type. The construction and principle of working of the cells is described, and hints are given as to the best method of setting them up and charging them. The ordinary causes of failure and the methods of guarding against them are discussed.

In the second part the arrangements of an installation for house-lighting are fully described, and hints, founded on the author's experience in lighting his own country-house for some years past, are given as to the management of engines, boilers, dynamos, lamps, switches, &c., as well as descriptions of the methods which he has adopted for so regulating the whole system by automatic appliances, that, as he says, "it is only needful to start and stop the engine, so that a man having no knowledge of electricity may be employed." He gives estimates for the capital expenditure and working expenses of installations of from 25 to 120 sixteen-candle power lamps. From these we learn that one of the latter size can be erected for £6 per lamp without accumulators, which latter add £3 per lamp to the cost, and the automatic regulating appliances bring up the cost to £10 per lamp. For fifty lamps the cost per lamp is about 50 per cent. greater, and for twenty-five lamps about twice as great. The annual cost, including interest and sinking fund, without accumulators, ranges from £2 16*s.* per lamp for 120 lamps to £4 4*s.* per lamp for twenty-five lamps, these figures being increased to £3 9*s.* and £6 respectively when accumulators and automatic regulators are used.

As was the case in the previous edition, there is much useful information in this book, but it is very badly written, so badly that the descriptions and explanations are often unintelligible. As an example we may quote from the chapter on the "Action of Cells with Dynamo" (p. 111). In discussing the relation between E.M.F. and current in machines of different types, he says, "Let us confine ourselves to the shunt dynamo, this has a falling curve, *i.e.* the E.M.F. falls as the current in the circuit is increased, due to two reasons, one is *the armature absorbs more power as the current is increased*" (the italics are ours); "and secondly the lowering of the outside resistance, to obtain an increased current, is in shunt with a fixed high resistance, viz. the shunt winding on the field-magnets, so that when the outside resistance is lowered to zero by short-circuiting the terminals, practically no E.M.F. exists, and no current passes."

Elementary Physiography. By J. Thornton, M.A. (London: Longmans, Green, and Co., 1888.)

THIS is an admirable introduction to the study of Nature by one whose experience in teaching must of necessity have indicated to him the requirements of beginners. The subjects are arranged according to the syllabus of the elementary stage of physiography, which will greatly extend the sphere of usefulness of the book. The treat-

ment is very detailed for an elementary book, but there is nothing beyond the capacity of those for whom it is intended. The author is of opinion—and we quite agree with him—that meagre accounts lead to inaccurate ideas, inasmuch as they are not of sufficiently general application. As far as desirable, and in accordance with the syllabus, simple experiments have been introduced. The main results of the *Challenger* Expedition are also explained, and illustrated by diagrams.

The astronomical portion leaves nothing to be desired. In addition to 150 excellent diagrams, there are ten maps, illustrating the distribution of temperature and pressure, volcanoes and earthquakes, &c. The diagram of the geological formations shows the general physical appearance of the strata, along with the characteristic fossils of each.

The book is beautifully printed, and is sure to win the favour of all who use it, whether as students or teachers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Whewell on the Origin of Species.

IN his essay on the "Reception of the 'Origin of Species,'" Prof. Huxley writes :—

"It is interesting to observe that the possibility of a fifth alternative, in addition to the four he has stated, has not dawned upon Dr. Whewell's mind" ("Life and Letters of Charles Darwin," vol. ii. p. 195).

And again, in the article "Science," supplied to "The Reign of Queen Victoria," he says :—

"Whewell had not the slightest suspicion of Darwin's main theorem, even as a logical possibility" (p. 365).

Now, although it is true that no indication of such a "logical possibility" is to be met with in the "History of the Inductive Sciences," there are several passages in the Bridgewater Treatise which show a glimmering idea of such a possibility. Of these the following are, perhaps, worth quoting. Speaking of the adaptation of the period of flowering to the length of a year, he says :—

"Now, such an adjustment must surely be accepted as a proof of design, exercised in the formation of the world. Why should the solar year be so long and no longer? or, this being such a length, why should the vegetable cycle be exactly of the same length? Can this be chance? . . . And, if not by chance, how otherwise could such a coincidence occur than by an intentional adjustment of these two things to one another; by a selection of such an organization in plants as would fit them to the earth on which they were to grow; by an adaptation of construction to conditions; of the scale of construction to the scale of conditions? It cannot be accepted as an explanation of this fact in the economy of plants, that it is necessary to their existence; that no plants could possibly have subsisted, and come down to us, except those which were thus suited to their place on the earth. This is true; but it does not at all remove the necessity of recurring to design as the origin of the construction by which the existence and continuance of plants is made possible. A watch could not go unless there were the most exact adjustment in the forms and positions of its wheels; yet no one would accept it as an explanation of the origin of such forms and positions, that the watch would not go if these were other than they were. If the objector were to suppose that plants were originally fitted to years of various lengths, and that such only have survived to the present time as had a cycle of a length equal to our present year, or one which could be accommodated to it, we should reply that the assumption is too gratuitous and extravagant to require much consideration."

Again, with regard to "the diurnal period," he adds :—

"Any supposition that the astronomical cycle has occasioned the physiological one, that the structure of plants has been brought to be what it is by the action of external causes, or that such plants as could not accommodate themselves to the existing day have perished, would be not only an arbitrary and baseless assumption, but, moreover, useless for the purposes of explanation which it professes, as we have noticed of a similar supposition with respect to the annual cycle."

Of course, these passages in no way make against Mr. Huxley's allusions to Dr. Whewell's writings in proof that, until the publication of the "Origin of Species," the "main theorem" of this work had not dawned on any other mind, save that of Mr. Wallace. But these passages show, even more emphatically than total silence with regard to the principle of survival could have done, the real distance which at that time separated the minds of thinking men from all that was wrapped up in this principle. For they show that Dr. Whewell, even after he had obtained a glimpse of the principle "as a logical possibility," only saw in it an "arbitrary and baseless assumption." Moreover, the passages show a remarkable juxtaposition of the very terms in which the theory of natural selection was afterwards formulated. Indeed, if we strike out the one word "intentional" (which conveys the preconceived idea of the writer, and thus prevented him from doing justice to any naturalistic view), all the following parts of the above quotations might be supposed to have been written by any Darwinian. "If not by chance, how otherwise could such a coincidence occur, than by an adjustment of these two things to one another; by a selection of such an organization in plants as would fit them to the earth on which they were to grow; by an adaptation of construction to conditions; of the scale of construction to the scale of conditions?" Yet he immediately goes on to say: "If the objector were to suppose that plants were originally *fitted* to years of various lengths, and that such *only* have *survived* to the present time . . . as could be *accommodated* to it (*i.e.* the actual cycle), we should reply that the assumption is too gratuitous and extravagant to require much consideration." Was there ever a more curious exhibition of failure to perceive the importance of a "logical possibility"? and this at the very time when another mind was bestowing twenty years of labour on its "consideration." GEORGE J. ROMANES.

The Fog Bow.

THE complete theory of the rainbow, as developed by Sir George Airy (Camb. Phil. Trans., vi. p. 379, 1836), besides explaining the supernumerary bows, shows that the main bow has a radius somewhat smaller than that calculated on the ordinary geometrical theory. The smaller the drops the greater is the discrepancy. With the tiny drops composing a fog, the discrepancy is so marked that the bow receives a new name—the fog-bow, or "*arc-en-ciel blanc.*" Mr. Mohn's (NATURE, February 23, p. 391) nearly simultaneous measurements of the fog-bow and Ulloa's rings afford a capital opportunity of putting the theory to the test, for from the latter phenomenon we can readily calculate the average size of the particles.

Not having Airy's paper within reach, I have had to be content with the incomplete account given by Verdet ("Leçons d'Optique Physique," tom. i. p. 414). Assuming $\mu = 1{\cdot}333$, I find for the angular discrepancy—

$$\beta = 0{\cdot}467\, m\left(\frac{\lambda}{a}\right)^{\frac{2}{3}},$$

where λ is the wave-length, a the radius of the drop, and m is determined by the condition that the integral—

$$\int_0^\infty \cos \frac{\pi}{2}(w^3 - mw)dw$$

should be a maximum. This integral was calculated by Airy for a series of values of m, but Verdet does not quote the results. Some rough approximations lead me to the conclusion that m lies between $1{\cdot}0$ and $1{\cdot}3$, and very much nearer the latter.

For the radius of the first Ulloa's ring we have

$$\alpha = 0{\cdot}82\lambda/a.$$

Mr. Mohn measured this radius as 1° 31′. Using this value, and taking m as $1{\cdot}25$, I find β is the circular measure of 3° 24′. The geometrical theory gives the radius of the rainbow 42° 2′. So in this particular case the fog bow should have had the radius 38° 38′. Mr. Mohn gives two measurements, taken

shortly before that of the Ulloa's ring, 38° 48′ ± 48′, and 38° 28′ ± 22′ Thus the agreement between theory and observation is singularly perfect. JAMES C. MCCONNEL.

St. Moritz, Switzerland.

"The Teaching of Elementary Chemistry."

IN reply to Prof. M. M. P. Muir's letter, I wish to say that, judging from his answer, Prof. Muir does not seem to consider it necessary in books of which he is senior author to secure that accuracy of which, from his criticisms of the writings of others, one would expect to find him the champion.

The first extract from the books mentioned sounds curiously to chemists. I consider the statement misleading inasmuch as it appears to convey an idea as to the constitution of caustic soda which is not that generally entertained by chemists; that this is not the intention of the authors, however, is manifest from p. 247 of the "Elementary Chemistry," where the usual view is stated.

It is utterly untrue and misleading to state that, "inasmuch as the result of passing chlorine over yellow mercuric oxide dried at about 100° is to evolve oxygen without forming chlorine monoxide, ... it may still be justly said that in making chlorine monoxide 'we carry out a reaction in which oxygen is produced in presence of chlorine.'"

The facts are briefly these:—

(*a*) When chlorine gas is passed at ordinary temperature over yellow mercuric oxide, which has been previously heated to 300°–400°, chlorine monoxide is obtained.

(*b*) When a large quantity of chlorine gas at ordinary temperature comes rapidly into contact with yellow mercuric oxide which has been previously dried at ordinary temperature, a violent reaction, accompanied with evolution of light and heat, ensues, and nearly pure oxygen is the only gaseous product. If both the chlorine and the mercuric oxide be kept cool by means of a freezing mixture, chlorine monoxide is the only gaseous product obtained. With intermediate conditions of temperature, &c., mixtures in varying proportions of oxygen and chlorine monoxide are obtained. (Pelouze, *Annalen der Chem. und Pharm.* Bd. xlvi. 196.)

The formation of oxygen in the second case must therefore be due to the decomposition of already formed chlorine monoxide, or to the occurrence of a reaction the conditions of which render the existence of part of the chlorine monoxide impossible. I think the majority of chemists will agree with me that the appearance of oxygen under conditions which insure the non-existence of (or as itself a product of the decomposition of) chlorine monoxide, can scarcely be admitted as in any measure explaining the *formation* of the latter.

I do not consider it a "verbal quibble" to object to the use of the term "volatilized" as applied to the mechanical removal of particles of a solid substance.

As to the chemical properties of chlorine, bromine, and iodine, I should indeed be open to the gravest charges of non-acquaintance with chemical classification, had I suggested anything so idiotic as that, say, potassium hypobromite and potassium hypoiodite (if the latter exists) could be *identical.*

I called the passages I quoted misleading, because some of them at least were inaccurate. What amount of inaccuracy is required to make a statement misleading may be a matter for difference of opinion. Apparently it is so.

Prof. Muir states that he will decline to take any notice of my anonymous communications. This, at least, is safe ground; but I can wait for the second editions of the two books, and see if the inaccuracies are eliminated. In the second edition of "Elementary Chemistry" I hope Messrs. Muir and Slater will also describe the methods (omitted on p. 19) for removing air from oxygen. Whilst these methods remain unpublished, I prefer to remain Z.

"Kinematics and Dynamics."

MAY I ask a short space in your columns to refer to a few points in Prof. Greenhill's review of my book on "Kinematics and Dynamics," published in your issue of February 16 (p. 361). I shall be as brief as possible.

(1) "In questions involving the size of the earth (pp. 74 and 80), it is the circumference and not the diameter which should be given in metres, the circumference being 40,000,000 metres," the reason being, I suppose, that in illustrative problems round numbers should be employed as data, with the object of facilitating arithmetical calculation. There are doubtless advantages in this course, and in many problems I have adopted it. But should it be made an invariable rule? Problems based on exact data, such as the ones referred to, on pp. 74 and 80, have for many students a greater interest than those based on approximations.

(2) "The expression 'knots an hour' (p. 60) is irritating to a sailor." But the expression "knots" simply would be either misleading or puzzling to a student unacquainted with nautical abbreviations.

(3) "The formula $\frac{1}{2}v^2 = \frac{1}{2}v_0^2 + as$ is to be preferred to that on p. 34, $v^2 = v_0^2 + 2as$; in all cases the factor $\frac{1}{2}$ should go with the v^2 in the equation of energy." The formula quoted is not an equation of energy, but a kinematical equation. Equations of energy (see pp. 253, 256, 328) have in all cases the form approved by Prof. Greenhill.

(4) "In dealing with rotation, the author would do well to study Maxwell's geometrical representation of the direction by means of the screw, right-handed or left-handed." I have done so; but I find that students more readily grasp a specification of the direction of a rotation when it is made by reference to the face of a clock; probably because few of them are so familiar with right-handed and left-handed screws as they are with clock-faces.

(5) "In a linear strain the increment of distance of two points in the line of the strain is properly their *elongation;* while the ratio of the elongation to the original distance is called the *extension*, not the *elongation*, as on p. 167." And yet Thomson and Tait ("Elements of Natural Philosophy," § 139), Clifford ("Elements of Dynamic," p. 158), Minchin ("Uniplanar Kinematics of Solids and Fluids," § 78), and Ibbetson ("Mathematical Theory of Elasticity," § 53), all define elongation exactly as I have done.

(6) "The author, disregarding the vernacular use of the word 'weight,' defines the weight of a body as the force with which it is attracted by the earth" [I don't (see § 290); but let that pass], "but is at variance with his own definition in the statement of the majority of the subsequent examples, relapsing into the language of ordinary life." No references are given to these instances of backsliding. I have looked pretty carefully through the subsequent examples, and can find no case in which I have used the term referred to in any other sense than that given it by definition. I should be glad to have such slips pointed out to me, if there are any.

(7) "A collection of 500 different ways of spelling the name of the town of Birmingham has been made, and a similar collection could be made from the present treatise of different ways of expressing the simple ideas of the pound *weight* and the pound *force.*" It is true that these ideas are expressed by English writers in various ways. And it seems to me desirable that a student should be made acquainted with them. Surely in holding that I should choose one phrase and stick to it, your reviewer is blaming me for not being one of the "mathematical precisionists" at whom he sneers.

(8) "This terminology culminates in the solecisms that on p. 477 we must suppose pressure to be measured in poundals on the square foot in hydrostatical problems; and that if the equation $w = mg$ is supposed to be used with absolute units, the weight of a body is measured in poundals; as if a mathematician asked in a shop for 'half a poundal of tea, or tobacco.'" It is not quite correct to say that, in the hydrostatical equations referred to, pressure must be supposed to be measured in poundals per square foot. In fact it may be supposed to be measured in terms of the unit of pressure of any derived system, as, *e.g.*, the dyne per square centimetre, or even the pound-weight per square foot, provided only the density be measured in terms of the corresponding unit. I am aware that this mode of expressing hydrostatical equations is unusual, but it seems to me to have great advantages, and it was adopted both for this reason and for the sake of making the section on hydrostatics uniform with the rest of the book. With regard to the units in which weight should be measured, the practice of the tobacconist or the tea merchant is surely not our best guide.

(9) "Thus a mathematical precisionist, to express the simple idea of a force of 10 pounds, to be consistent should call it 'a force equal to the weight of the mass of 10 pound weights,' the absurdity of which is evident." The phrase inclosed in quotation marks is not quoted from my book. In my terminology the most precise of mathematicians would express the idea referred to

by the phrase "a force equal to the weight of 10 pounds," which is neither clumsy nor absurd.

(10) "Except for the parts criticized above, on the units of weight, mass, and force, the present treatise shows that the author has read with profit and discrimination the most recent treatises on dynamics." I have been under the impression that in my treatment of these units I had, in the main, followed the most recent treatises on dynamics. May I ask in which of them units are treated in what Prof. Greenhill considers the proper way?

I would like to say also that the elementary proofs of the chief properties of the common catenary, which are given by me, are, with slight modifications, those given in Prof. Goodeve's "Principles of Mechanics." My indebtedness to his book is acknowledged generally in the preface.

I fear my desire to be brief may have made me appear curt. Let me express, therefore, my appreciation of the trouble Prof. Greenhill has taken to form a just estimate of the merits of my book, and of the kindly way in which he has spoken of it.

Dalhousie College, Halifax, N.S., March 1.

Coral Formations.

I am glad to see the theory that the internal lagoons of coral atolls are excavated by the chemical action of sea-water and the removal of carbonate of lime in solution is now being brought to the test of figures.

Mr. J. G. Ross (Nature, March 15, p. 462) calculates from his experiments that in this way a sheet of carbonate of calcium half an inch thick can be removed annually from the surface of a lagoon, but strangely adds, "In other words at the same rate it would require about a century to deepen the lagoon one fathom." According to this method of calculating, 144 years is "about a century."

These figures no doubt suit the theory of the formation of coral lagoons very well, but they appear to me quite destructive of the other and co-relative view that the platforms upon which atolls have been formed have been built up by the accretion of the dead shells of pelagic organisms showered down from the surface of the ocean together with the shells of those organisms which have lived on the bottom. I believe that at no place on the surface of the globe are such dead shells being supplied at a rate that would even balance this supposed rate of chemical destruction.

Yet if these figures be correct we shall have to reckon upon the removal from such platforms of more than half an inch annually in consequence of the quicker action which it is said takes place through greater pressure at greater depths.

If, therefore, we accept the dissolution theory of the origin of coral lagoons, it seems impossible to believe in the building up of platforms of calcium carbonate on volcanic or other peaks from varying and unknown depths to the levels necessary for the growth of reef corals. If, on the other hand, we believe that platforms are so built up, it appears equally destructive of the dissolution theory of the lagoons.

Dr. Darwin indicated this difficulty in his letter to me, published in Nature, November 17, 1887, p. 54, but the figures we are now supplied with enable us to realize it much more vividly.

Park Corner, Blundellsands, March 16.

The Movements of Scree-Material.

I perused with interest the abstract of a paper on the above, read by Mr. Davison at the meeting of the Geological Society on the 29th ult.

The phenomenon seems somewhat akin to the movements in the "Stone Rivers" of the Falkland Islands, though another reason has been suggested by Sir Wyville Thomson as the cause of their progress.

Might it not be possible for motion to be produced in loose materials, and in the molecules of certain coherent substances situated at a high angle of slope, by continual though imperceptible vibrations in the earth's crust?

Apart from the changes wrought by alternating temperature, might not the "downward creep" in the lead on the roof of Bristol Cathedral—as observed by Canon Moseley—be due to a "settling down" of the molecules by the constant vibrations of sounds transmitted through the structure, and having their origin within and without?

Cecil Carus-Wilson.

Bournemouth, March 15.

Were the Elephant and Mastodon contemporary in Europe?

Mr. Howorth asks this question in Nature for March 15 (p. 463). Perhaps this extract from a translation of a note from Prof. d'Ancona, of Florence, will satisfy Mr. Howorth: "The soil of the upper Val d'Arno is ascribed to formations of the Pliocene period." In it have been found "*Mastodon avernensis, Elephas meridionalis.*" Twenty-four other animal remains are identified, all differing from the remains of the bone-caves. In both places respectively these relics belong to contemporary animals.

EXPERIMENTS IN MOUNTAIN BUILDING.[1]

The primary object of these experiments was to explain on what mechanical principles the remarkable rock-structures recently discovered by the Geological Survey in the North-West Highlands might have been produced. In experimenting on the behaviour of strata when subjected to horizontal pressure, it has been usual to regard large rock-masses as practically plastic bodies, and to imitate in the laboratory the great flexures and plications of Nature by compressing layers of clay, cloth, and other plastic or flexible substances. It was, however, evident, as soon as the true structure of the North-West Highland area was unravelled, that the rocks had, to a very large extent, behaved like rigid bodies under the enormous lateral pressure to which they had once been subjected. Instead of following the usual method of using plastic materials, the author therefore set to work to devise strata sufficiently rigid to snap rather than bend and become folded on the application of lateral pressure. It is to this peculiarity in the character of the materials, rather than to any great novelty in the methods, that the interesting results obtained are mainly due.

The experiments were of three distinct kinds. The first series was designed to explain the behaviour of strata when thrust horizontally over an immovable surface, and thus to throw light on the phenomena of "thrust planes," such as are now known to occur abundantly in the North-West Highlands between Loch Eriboll and Skye (see Nature, vol. xxxi. p. 33). To simulate natural strata, layers of damp sand, foundry loam, or in a few cases clay, with laminæ of dry stucco powder between, were employed. In a few minutes the anhydrous powder absorbed enough moisture from the damp beds to enable it to "set" into tolerably rigid sheets. The rock which had thus solidified *in situ*, was next compressed horizontally, by pushing in, by hand, or with the help of a screw, the movable end of the long box in which the strata were formed. One side of the box could be removed at pleasure, and at the end of each experiment it was lifted off, and the section inside revealed, so that it could be photographed or copied if desired.

Fig. 1, which is drawn to a scale of $\frac{1}{12}$ of the original, shows the character of the section produced after the end had been pressed in 20 inches. The central light-coloured band, bounded by stiff stucco laminæ, has undergone no folding, but has become heaped up by means of a series of slightly inclined reversed faults, along which the constant pressure from the right found relief. For this structure the author has proposed the name "wedge structure," as the advancing mass is really raised by being forced over a series of wedges of undisturbed rock.

After pushing the piled-up mass a certain distance

[1] Abstract of a Paper by Henry M. Cadell, B.Sc., F.R.S.E., H.M. Geological Survey of Scotland, read before the Royal Society of Edinburgh, February 20, 1888.

forward, the whole heap always showed a tendency to rise and ride forward *en masse* over the less disturbed beds in front. Fig. 2 shows a typical section produced at this more advanced stage of the movement. This new plane of shear may be called a "major thrust," as distinguished from the "minor thrusts" shown in Fig. ˜, and in the upper part of this figure. The structure of these artificial rock-masses bears a remarkable resemblance to that of the great thrust areas of Sutherland

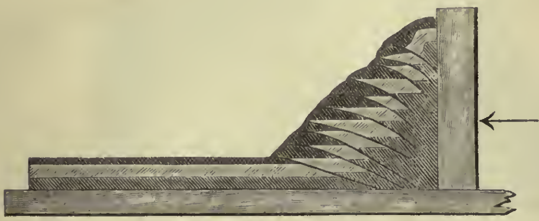

FIG. 1.

and Ross. Everywhere along that great region of earth movement major thrust planes are found truncating sets of minor thrusts, just as has taken place in this experiment. The extraordinary heaping up and local thickening of Silurian strata, and the superposition across their upturned edges of 'tuge slices of Archæan gneiss and Cambrian sandstone, are phenomena which, before the thrust-plane theory had been originated, were quite inexplicable.[1]

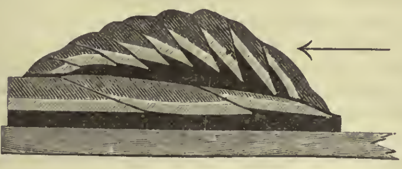

FIG. 2.

The second series of experiments was intended to ascertain how such great thrusts might have originated, and to trace their connection with folds and great terrestrial movements of upheaval and mountain building.

Stratified beds, similar to those employed before, were formed on a band of stout wax-cloth, about 2½ feet long, and 7 inches broad, secured at the ends to vertical blocks of wood. When pressure was applied to the ends, the wax-cloth was thrown into folds, but the folds did not

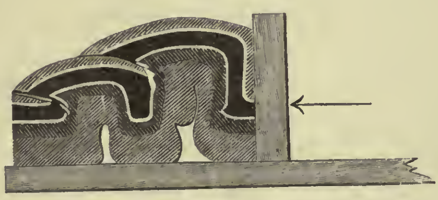

FIG. 3.

in all cases reach the surface, but found relief in thrusts, as shown in Fig. 3.

In this experiment an anticline was first formed at the end of the wax-cloth nearest the pressure. A thrust appeared at the surface, and, on examining the section, this was found to bend down and bury itself in the left monoclinal member of the fold. A second anticline was next started in advance of the first, and, on continuing the push, a second thrust, similarly situated with regard to the underlying fold, was produced. By this means it may be possible to explain how thrusts are connected with movements of deep-seated parts of the earth's crust, and also how, as in the Highlands, they occur over broad areas all inclined in the same general direction. If this section affords the true explanation of their origin, it is clear that thrusting is only a surface phenomenon, and that the complex structures of the North-West Highlands are structures which can only originate at the outer edge of a great mountain-system of elevation.

Fig. 4 represents a section produced with the same apparatus, but here the pressure was applied from both sides. An anticline was started at the centre of the

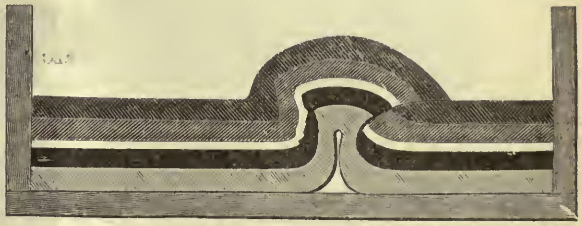

FIG. 4.

wax-cloth, and as the pressure was continued the strata were squeezed into a form closely resembling that known as "fan structure." Two small arches were next formed, one on each side of the original fold, and the pressure was continued. A second fan made its appearance outside the first, and at each side there was a tendency for thrusts to be produced, as shown in Fig. 5. Throughout the experiment the lowest stratum of damp sand next the wax-cloth was compressed and distorted, till, at the last stage of the movement, it became very much "staved together" above the synclinal folds of the wax-cloth on either side, and was completely "nipped out" at the crown of the central fold. During the movement in the mass it was, in fact, made to flow like a viscous body, along a series of approximately vertical planes, which in

FIG. 5.

Nature would be described as planes of foliation. This experiment, then, may help to explain not only the origin of the fan structure of the Alps, &c., but also the common occurrence in the centre of the fan of a core of crystalline rock with vertical foliation.

The experiments of the third series were modifications of those of Prof. A. Favre, of Geneva (see NATURE, vol. xix. p. 103), who covered a band of stretched caoutchouc with beds of adhesive clay, and on allowing the elastic sole to contract, observed the wrinkling up of the surface of the clay into a series of miniature Alpine ridges. The author modified Favre's experiments by separating the upper and lower portions of the clay with sheets of paper, so that the former could be stripped off at the end of the experiment without disturbing the lower part of

[1] The effect of major and minor thrusts is well seen in the section of the Durness and Eriboll district above the map in the second edition of Dr. A. Geikie's "Scenery of Scotland."

the section. After removing the superficial folded layer, the paper covering the lower bed was found to be covered with minute corrugations like those often seen on beds of mica-schist. On stripping off the paper, and again stretching the elastic substratum, the clay adhering to it did not become smoothed down to its original form, but split along a multitude of vertical rents, transverse to the direction of pressure, each of which corresponded to one

Section at head of Loch Eriboll.

of the little ripples on the paper before it was removed. The sides of the cracks were observed to be covered with minute vertical striations like the slickensides of a fault-fissure.

This experiment, the author suggests, may explain the vertical cleavage and foliation found in the deep-seated parts of many old mountain-systems.

SWISS FOREST LAWS.

THE Report of Mr. Conway Thornton to the Foreign Office, on the Swiss Forest Laws, is a careful and interesting piece of work. He divides his subject into two parts: in the first he treats of the history of forestry prior to 1875, the year in which the Act now in force, the Forestry Act of 1875, was proposed; and in the second part he deals with that Act, its provisions and its effects, and the measures taken under the "Règlement d'Exécution," which followed the Act, for the advancement of technical education amongst foresters in Switzerland. It is evident that from a very early date the various cantons endeavoured to preserve the forests. Thus, in 1314 the authorities of Zurich forbade "the felling, floating, or selling" of timber from the Sihlwald; in 1339, Schwyz forbade charcoal-burning near the chief towns of the canton, and a similar decree was promulgated in Fribourg in 1438. Industries using wood were in various cantons restricted in their operations; the laying out of new vineyards was prohibited under heavy penalties for centuries; and finally, during last century, the use of uncloven vine-props was forbidden. The exportation of timber took place only under great difficulties, and even the removal of timber from one place to another in Switzerland was, until 1848, very much restricted. In 1376, Zurich forbade clearings to be laid down in pasture, and Fribourg would not allow sheep-pastures to be established in clearings. Goats were not permitted to be let loose in the woods; and rosin-scrapers were excluded from many of the forests. None of these numerous decrees appear to have had much effect, the very number of them testifying to their powerlessness to check the evil. In many cases the general prohibition against wood-cutting gave way to a partial permission, as, for example, in Zurich, where the number felled was not permitted to exceed a stated total. This instance of Zurich gives us the first scientific treatment of the question, when the felling of the Sihlwald and other woods in the fourteenth century was regulated both as to the amount and the system of cutting.

In 1702, prior to which date attention was paid solely to the maintenance and protection of the timber, the Government appointed a Commission to inquire how the forests might be best preserved, enlarged, and improved; and subsequently issued a decree carrying the recommendations of the Commission into effect. In 1725, Berne followed the example of Zurich, and published forestry orders, which, like those of the latter, contained directions for the cultivation of timber and for permanent improvements. Similarly, in other cantons, improved systems were introduced; thus, in Fribourg, the compulsory planting of marshy meadow-land was decreed; in Lucerne a season was set apart for felling, the growth of oaks was recommended, and the formation of clearings was forbidden. In 1755 an excellent forestry code was drawn up by Joseph Wilhelm, Prince-Bishop of Bâle. About 1760, two scientific Societies—the Physical Society of Zurich and the Economical Society of Berne—made great efforts to introduce improved knowledge of woodcraft into Switzerland, and with this object they made strong representations to their respective Governments, and the Forestry Decrees of 1773 and 1786 were the results of their interference. The substance of these decrees may be stated to be the surveying of forests, the appointment of officials who would supervise planting, experiment on exotics, and help in teaching a more scientific system of wood-cutting. By means of these measures some real progress was made, which, however, was stopped by the general confusion during the beginning of this century; but, immediately peace was restored, the Helvetic Government turned their attention again to the forests, which by this time had suffered severely. Soleure was the first to start a system under which technical instruction, chiefly in forestry and geometrical surveying, was given to two citizens from each woodland district, the better qualified being chosen foresters. From this time until 1830, forest laws were drawn up universally, prescribing the modes in which timber was to be felled. Zug, in 1821, tried to give an increased value to her forests by endeavouring to extend scientific teaching among the people. In consequence of the disastrous floods in Switzerland in 1830, from this time we find that forest laws were more generally enacted and more rigidly enforced than they had ever been before. The number of officials was increased, and great attention was paid to their training. In fact, the spread of the science of forestry in Switzerland dates from this period. At first the people thwarted the officials in every way, but, becoming gradually enlightened as to the utility of the Government measures, they ceased from actual opposition. Even the most backward of the cantons began

to realize that their true interests lay in the preservation of the forests, both as a commercial speculation, having regard to the advancing price of timber, and as a support for precipitous ground, and on account of its domestic and national uses. With regard to the latter, it is worthy of note that the respective cantons, from the earliest times, supervised the numerous public woods; and that the frontier forests were always better looked after than any others, on account of their importance as a defence in time of war, and at the commencement of the eighteenth century woods were protected, as being safeguards against avalanches and landslips.

Hitherto the students trained in forestry had been sent to the schools in Germany, but in 1855 the Confederation took the matter up and established a Forestry School, in which henceforth Swiss students were educated in the art of wood-cutting and the kindred sciences. In 1858 a long and searching inquiry was made into the supposed connection of the forests and the course of the mountain torrents, and, as a consequence, the State aided the School of Forestry in their efforts to plant anew the ground where springs abounded, and officials were appointed for this purpose. With regard to these officials, mention of whom occurs in all the forest laws of Switzerland, we first hear of them in 1314, when, as in subsequent centuries, they were supposed to be aided by the inhabitants, every one of whom in a woodland district was sworn to disclose any breach of the decrees which came to his knowledge. For centuries these officials were mere guardians, commonly called *Bannwärte;* but the punishment of offenders rested with councils of magistrates, &c. The ordinary forest-keeper was generally nothing more than an intelligent wood-cutter; but when it was seen that some technical teaching was necessary, the skilled man, and, later still, the man with a knowledge of natural science and mathematics, was always preferred. In 1868 the disastrous floods gave a fresh impetus to the spirit of inquiry into the action of the forests on the rainfall and the course of the torrents; and we find in the revised Federal Constitution of 1874 an article inserted, giving the Federation control over the forests and waterways, and authority to interfere in any way they might think fit. Under this article two officials were appointed—the Federal Inspector of Forests, and also a Sub-Inspector. The Forestry Societies unanimously adopted a programme which, being presented to the Federal Council, was embodied in the Forest Law proposed by the Council in 1875. This proposed enactment led to much discussion in the Assembly, but was finally passed by both Houses on March 24, 1876. The district to be subject to the law included not only the high mountain ranges, but also the hills bordering on the plains, as sharing in the protection afforded against floods and avalanches by the works which were intended to be undertaken in the former. The district was bounded by a line starting from the east of Lake Leman along the south of the plain between the Alps and Mount Jura, thence to the north of Lake Constance—that is, a tract of country in all about 60 per cent. of the whole of Switzerland, or 6,750,000 acres, about 15·8 per cent. of which was forest land. It was decided that the rights of private owners should not be infringed except in case of necessity—that is to say, where the woods of private owners were "protecting" woods; in other words, where, on account of their position, they might have an influence on the climate, avalanches, landslips, &c. Each canton was required to maintain an efficient staff of officials; and to each individual who had received technical training an area of about 17,500 acres was assigned if in the plains, and 25,000 acres on the mountains. All the woods under official supervision, including, of course, private woods which came under the class "protecting" woods, were to be demarcated, all clearings were to be immediately planted afresh, and where necessary new forests were to be created, the Federal treasury bearing from 30 to 70 per cent. of the cost, or, in the case of replanting protecting woods, from 20 to 50 per cent., according to the difficulty and the importance of the works, which were always required to receive the approval of the Inspector-General before the Federal subvention was granted. All servitudes or easements in "protecting" woods were to be redeemed within ten years, and no new ones were permitted to be created. Anything which might endanger the utility of the forests was strictly forbidden; cattle were not allowed to graze, nor could leaves be collected except in fixed spots. To this enactment was added a "Règlement d'Exécution," which provides, among other things, for the course of education to be given to each student of forestry by the canton to entitle it to the Federal subsidy. The time of the course is not to be less than two months, which may be divided into two half-courses of a month each, but the whole course must be taken within a year. Instruction must be given in the following subjects:—(1) Forest-surveying and measurement in detail; calculations of the dimensions and value of single trees, and of outlying tracts of wood; road-making; safeguards against avalanches, &c. (2) Study of the different kinds of timber and of noxious plants. (3) Elementary knowledge of soils, and of their component parts. (4) Fundamental notions of the laws of climate and meteorology. (5) Cultivation and care of forests. (6) Book-keeping and other general branches of instruction valuable for under-foresters. A preliminary and a final examination are prescribed, and no license is granted except on good answering in the latter. The Federal Government pay the teachers, who are appointed by the canton subject to the approval of the Federal Government.

At the outset there were great difficulties in carrying out this law. Some of the cantons had not their codes of regulations drawn up till 1881, and, with the exception of the cantons of Zurich, Fribourg, and Vaud, the survey was not quickly completed. In 1886, however, the Army Staff finished the triangular survey intrusted to them. In 1886 the redemption of servitudes prescribed by the Act was not ended, and up to that time £9150 had been thus expended. There is not in the cantons an uniform organization for carrying out the Forest Law, and Dr. Fankhauser, one of the highest officials of the Forest Department, does not think that such an organization is possible, having regard to the differences in position and ideas of the various cantons. At the present time each canton possesses in a measure its own scheme of forestry organization. There are, however, two main systems in existence in the Federal district, the first of which prevails in the central, eastern, and southern parts of Switzerland. Each canton is divided into districts of from 17,500 to 35,000 acres each, and over each district the canton places an officer who has received scientific training; under him are the keepers and deputy-foresters, chosen by the owners from among the students of the local forestry school, and paid by them. Each deputy has about 3000 acres to take care of, and has but to carry out the orders of his superior as to felling, clearing, and replanting. In the next, however, a different system obtains. Here the country is far less mountainous, and the inhabitants industrial rather than agricultural in their pursuits. In these cantons the district forester has from 7500 to 17,500 acres under him, and in this district he marks out all the fellings to be performed, and in fact does everything but the manual labour, which he leaves to his inferiors. This district includes, among other cantons, Zurich, Berne, Lucerne, and Neufchâtel, where timber being very high in price, and the opportunities of sale being numerous, the country is frequently reafforested by private individuals, while in the other cantons the State is forced to do nearly everything. The cantons not within the control of the

Federal law differ from those here spoken of in their organization. In Bâle Campagne with its 37,000 acres of forest, 75 per cent. of this being public, has no officials whatever. Laws have been passed, but the people set them at naught; and similarly in Thurgovie there is the greatest opposition to any interference with what the people consider to be their ancient rights; and here also there are no officials, except one who has the care of 300 acres of State forest.

The salaries of the forest officials vary very much in the different cantons, but even in the best-paid districts the remuneration is very modest. Under-foresters receive sometimes a fixed salary, sometimes only daily wages when employed. If the former, the sum varies from £24 to £48; occasionally it reaches £60. If the rate of pay is per day, which is unusual, it is generally fixed at 4*s*. District foresters usually receive from £88 to £112 a year. In Uri, however, £120 is given, and in Glarus and a few other places as high as £160 per annum. Cantonal forest inspectors receive from £120 to £180 a year, besides allowances, which are always given to the higher officials when travelling on duty, ranging from 5*s*. to 8*s*., with the cost of the journey.

NOTES.

We regret to announce the death of Signor Giacomo di Brazza, brother of the Governor of the French Congo Settlements, also an African traveller well known by his investigation of the Ogowé River. He died at Rome, aged thirty.

Herr Andor Semsey has presented the sum of 8000 florins (£800) to the Natural Science Society of Budapest, for the printing of a work by Herr Otto Hermann on Hungarian birds.

The International Congress of Americanists, which met in 1886 at Turin, proposes holding its seventh session at Berlin early in the month of October. The Organizing Committee already includes such well-known names as Virchow, Reiss, and others.

Mr. A. W. Pickard-Cambridge has taken first place in Classics among the senior students at the last Cambridge Local Examination, and has been offered, in consequence, an Exhibition at St. John's College, Cambridge. He has won this honour at an almost unprecedentedly early age, being only fourteen years old. He has been a pupil of Weymouth College for the past four years, and is the son of the Rev. O. Pickard-Cambridge, F.R.S., the well-known naturalist.

A report of the Cambridge Local Examinations and Lectures Syndicate laying down a scheme for the examinations for commercial certificates has been confirmed by grace of the Senate. The examination is to be wholly separate from the local examinations, there being no papers of questions common to the two, and no common classification of successful students. The standard set by the Syndicate is that suitable for well-prepared students of seventeen. Amongst the compulsory subjects are arithmetic, and physical and commercial geography, whilst the optional subjects include algebra and one of the following five subjects in elementary science: (1) inorganic chemistry, theoretical and practical; (2) organic chemistry, theoretical and practical; (3) mechanics, including hydrostatics and pneumatics; (4) sound, light, and heat; (5) electricity and magnetism.

According to the *Oldham Evening Express* of March 16, what is described as a full-grown summer butterfly took refuge from a blinding snowstorm in a dwelling-house at Lusley Brook, near that town. The wings are said to be beautifully variegated; and on obtaining shelter in a warm room the butterfly thoroughly revived.

At the last meeting of the Calcutta Microscopical Society a paper was read by Mr. Simmons on the mango weevil, a pest which is spreading rapidly in India. He has devoted much attention to the weevil, and in this paper he gives much useful information as to its geographical distribution, the extent of the damage done by it, with the observations of English and American entomologists on its ravages among fruit. This lecture is believed to be the first attempt made in India to systematically study the habits of the weevil.

The Fund which has been established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to $25,000. As accumulated income is again available, the Trustees desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but it is the intention of the Trustees to give the preference to those investigations *which cannot otherwise be provided for*, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from this Fund, in order to receive consideration, must be accompanied by full information, especially in regard to the following points:—(1) Precise amount required. Applicants are reminded that one dollar is approximately equivalent to four English shillings, four German marks, five French francs, or five Italian lire. (2) Exact nature of the investigation proposed. (3) Conditions under which the research is to be prosecuted. (4) Manner in which the appropriation asked for is to be expended. All applications should be forwarded to the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. It is intended to make new grants at the end of 1888. The Trustees are disinclined, for the present, to make any grant exceeding $500.

The following is a list of the grants already made from the "Elizabeth Thompson Science Fund":—(1) $200 to the New England Meteorological Society, for the investigation of cyclonic movements in New England. (2) $150 to Mr. Samuel Rideal, of University College, London, England, for investigations on the absorption of heat by odorous gases. (3) $75 to Mr. H. M. Howe, of Boston, Mass., for the investigation of fusible slags of copper and lead smelting. (4) $500 to Prof. J. Rosenthal, of Erlangen, Germany, for investigations on animal heat in health and disease. (5) $50 to Mr. Joseph Jastrow, of the Johns Hopkins University, Baltimore, Md., for investigations on the laws of psycho-physics. (6) $200 to the Natural History Society of Montreal, for the investigation of underground temperatures. (7) $210 to Messrs. T. Elster and H. Geitel, of Wolfenbüttel, Germany, for researches on the electrization of gases by glowing bodies. (8) $500 to Prof. E. D. Cope, of Philadelphia, Penn., to assist in the preparation of his monograph on American fossil vertebrates. (9) $250 to Mr. W. H. Perkin, Jun., for experiments on the synthesis of uric acid. (10) $125 to Mr. Edw. E. Prince, of St. Andrews, Scotland, for researches on the development and morphology of the limbs of Teleosts. (11) $250 to Mr. Herbert Tomlinson, of University College, London, England, for researches on the effects of stress and strain on the physical properties of matter. (12) $200 to Prof. Luigi Palmieri, of Naples, Italy, for the construction of an apparatus to be used in researches on atmospheric electricity. (13) $200 to Mr. Wm. H. Edwards, of Coalburg, W. Va., to assist the publication of his work on the butterflies of North America.

The latest reports received by the Hydrographic Office of the United States about the logs of the great raft abandoned south of Nantucket about three months ago, prove that,

though they are now widely separated, their general drift has been in an east-south-east direction, the logs being found a little to the southward of this line. That they were not carried more to the northward and eastward by the Gulf Stream, as would be expected, was probably due to the strong north-west winds which prevailed during the latter part of December and the first part of January. Fortunately, no vessel has been disabled by collision with them, although the German ba k *Bremen*, which was in company with the logs for five days, in latitude 39° north, longitude 62° west, had her sheathing torn and rudder injured.

We have received from Mr. R. T. Rohde, of the New Oriental Bank, a well-known authority on questions connected with currency and banking, a pamphlet entitled "A Practicable Decimal System for Great Britain and her Colonies." In criticizing the Report on Decimal Coinage of the Parliamentary Committee of 1853, he proposes, amongst other things, to preserve the sovereign as the standard unit of the country, but to call it five dollars British sterling, each dollar being divisible into 100 cents, a cent thus being nearly one halfpenny in value; the sovereign and half-sovereign to remain, as before, the only gold coins in the country, the latter to be legal tender for an amount not exceeding £5, and the former for any amount. In the silver and copper coinage he would not make any alteration. He also advises the allowing of the use of the cental of 100 avoirdupois pounds, divisible into any decimal subdivision of such pound avoirdupois; the using of the foot as the standard measure, such foot being divisible into 100 equal parts, ten of which make one decimal inch. As a measure of capacity, he would suggest a vessel equal to one-tenth of an Imperial gallon, such ves el to contain one pound avoirdupois of distilled water at a temperature of 60° F.

An interesting experiment in the planting of waste saline tracts in India has been carried out by Mr. Maries, superintendent of the gardens of the Maharajah of Durbhunga. The results have been communicated to the Agricultural Department, Bengal, and are contained in the last report of the Director. Mr. Maries says that six years ago, when he went to Durbhunga, he did not know what to do with patches of saline soil, on some of which not even weeds would grow. He dug the soil to the depth of two feet, and planted it thickly at the commencement of the rainy season with trees which had been grown in pots till they were about three feet high. In three years the ground was filled with roots, and to all appearances the salt had gone. When the trees were thinned out last year, leaving only the best, the ground was found to be in good condition. Similar experiments have been carried out in other places, and now Mr. Maries has splendid plantains growing on soil which a few years ago would not even grow a weed. He employed various kinds of trees in his reclaiming operations, but he says that the best were the *Inga Saman*, or rain trees, and the *Albizzia Procera*. The former is valuable as producing an enormous quantity of surface-feeding roots, and these decaying yearly leave a rich vegetable deposit on the soil. The trees soon completely change the character of the soil. The timber is excellent for fuel, and the trees bear lopping well. It is such an enormous water absorber that it would most probably be very useful in swampy places as a fever preventive, like the willow which is planted in China around the villages in the rice districts.

M. Léotard, Secretary to the Scientific Society of Marseilles, describes, in a recent issue of *La Na'ure*, the appearance of certain peaks of the Pyrenees as seen from Marseilles and its neighbourhood. Every year, about February 18 and October 31, Mount Carrigou, situated in the Eastern Pyrenees, and 2765 metres above the level of the sea, may be distinguished from Notre-Dame de la Garde in Marseilles, projected on the disk of the sun as the latter is about to set. From the top of Marseille-Veyre, 8 kilometres south of the town, the same observations may be made about February 13 and October 28. A straight line drawn from Notre-Dame de la Garde to the summit of Carrigou is 253 kilometres. Both Carrigou and the peak of Treize-Vents have been seen frequently since 1808, and this year M. Léotard and some of his colleagues made observations on the subject, and secured illustrations.

Referring to a journey of exploration in Australia which M. Ernest Favenc proposes to take, the *Colonies and India* says that no group of colonies in the world have taken more interest in exploration than those in Australia. In Melbourne especially, scientific Societies have given attention to this subject. It appears that the design in respect to a trip which M. Ernest Favenc proposed to take has now assumed a definite shape, and that he will pursue his object if only the Victoria and New South Wales branches of the Royal Geographical Society of Australasia will subscribe the necessary funds to send a surveyor with him. His intention is to start for Western Australia, there to inspect a large area of unstocked country, and subsequently to undertake a trip into the unexplored region between the tracks of Forrest and Warburton. If he finds the season favourable, then he proposes to make south, cutting the tracks of the other explorers at right angles. It should be mentioned that the explorer makes it a condition that the surveyor shall also be a fair mineralogist and know something of botany. Horses, saddlery, and rations will be found by the leader, but the passage, instruments, and salary of the surveyor selected are to be provided by the Societies named. When the matter came before the Victorian branch, at a meeting of the Council, a sub-committee was appointed to deal with the applications for the post of surveyor, which, it is believed, will be numerous.

The storm which was experienced on the Atlantic coast of the United States on the 11th and 12th inst. was apparently due to a disturbance which was situated over Georgia on the 10th, and which subsequently moved rapidly up the American coast. The storm apparently commenced with a warm southerly wind and heavy rain, which changed very suddenly to a north-westerly gale and violent snowstorm. The character of the storm was that common to the blizzard of the United States, and the intense cold of the north-westerly wind was evidently due to the rear of the disturbance stretching for a long distance over the cold continent of America. The loss occasioned by the storm, both to life and property, is immense.

The Italian Meteorological Office has issued a report on the climate of Massowah, based upon the observations made with standard instruments by the officers of the Italian expedition, between May 1885 and September 1887. The discussion is divided into two periods (1) May 1885 to May 1886; and (2) June 1886 to September 1887. The results show that the mean monthly temperature is above 86° in the months May to October. The maximum occurs in August: 108° in 1886, and 101°·8 in 1887. The minimum occurs in February; in two ten-day periods the thermometer fell to 66°, but there is little difference between January and February. Rainfall is very scarce and erratic, the fall of a few days may exceed that of the rest of the year. In the first twelve months 4·1 inches fell on thirty-four days; in the second, 4·3 inches on twenty-six days. The prevalent winds are northerly and southerly. The latter predominated from June 1885 until the end of the year; from January 1886 until September 1887, northerly winds prevailed. The above temperatures, while showing that Massowah is very hot, are lower than those sometimes quoted, apparently owing to more careful exposure in the present investigation.

The New York Academy of Sciences (says *Science*) was organized in 1817 as the Lyceum of Natural History. It is fourth in point of age among American scientific Societies. The name and constitution were changed in 1876. The Annals, begun in 1824, have been distributed in all lands, and have given world-wide reputation to the Society. The Transactions, begun in 1881, give a record of the meetings, papers, and discussions, are published in monthly or bi-monthly numbers, and make an octavo volume each year. The library now numbers over eight thousand titles, and is especially rich in sets of the publications of foreign Societies. It is now on deposit in the Library Building of Columbia College, and is accessible to the public from 8 a.m. to 10 p.m. every day of the year except Sundays. The cabinet was destroyed by fire in 1866. Previous to that date it was the principal collection in the city, and did a noble work. The Academy has long looked forward to the time when it could secure a building of its own, such as the corresponding Societies in Boston and Philadelphia have long enjoyed. It is not to the credit of New York that its oldest scientific organization, after nearly three-quarters of a century of steady and persevering activity, should be still unprovided with a building, while many other cities can show noble monuments of scientific interest and public spirit. Why should not the recent meeting of the American Association in this city be permanently commemorated by the erection of a fire-proof building for the accommodation of the Academy, or perhaps of several other Societies under the same roof—a building which should be at once a benefit and an honour to the metropolis of America? The interest of the community has been aroused and quickened in the direction of science by the meeting of the Association, and the Academy of Sciences would now invite the citizens of New York to take a greater interest in its work.

Pure trichloride of nitrogen has at last been prepared and successfully analyzed by Dr. Gattermann, of Göttingen. The first result of these researches upon this terribly explosive substance brought to light the fact that the chloride of nitrogen prepared as usual by the action of chlorine gas upon ammonium chloride is by no means a homogeneous substance, that it really consists of a varying mixture of several chlorides. Moreover, it was found that the longer the time during which the chlorine was allowed to act, the more nearly the composition of the product approached NCl_3; but pure NCl_3 can never be obtained in this way, owing to the excess of ammonium chloride always present. Dr. Gattermann, however, prepared a quantity of this crude product, as richly chlorinated as possible, washed it well with water until all the sal-ammoniac was removed, drained it as free as might be from the water, and then led over it a rapid stream of chlorine. The resulting oil was again washed, carefully dried, happily without accident, and finally analyzed. The percentage of chlorine found was almost identical (89·17) with that required for NCl_3 (89·10). The success of these dangerous operations is all owing, it appears, to the fact that they were performed upon dull wintry days, when the sun's actinism was very low; indeed, Dr. Gattermann was almost led to believe that the disasters which have imparted to the history of this compound so tragical a character must have been owing to some fault of the experimenters. But at last—it was about the thirtieth preparation—the oil quietly reposing in the chlorinating apparatus suddenly exploded with its usual detonation. At the same moment Dr. Gattermann noticed that the sun had broken through the clouds, and was shining upon his apparatus. Here then was the cause of these apparently spontaneous explosions: chloride of nitrogen is violently dissociated by the wave-motion of light. Following this up, it was found that the burning of a piece of magnesium ribbon in proximity to the oil was quite as effective in producing an explosion. Finally, Dr. Gattermann has determined the temperature of dissociation of the compound. About half a gramme was heated in a thin-walled tube placed in a beaker of liquid vaseline, the thermometer being read off by means of a telescope placed at a safe distance. As high as 90° C. the oil remained unchanged, but at 95° it exploded with such violence that the whole apparatus was destroyed. One feels much regret on reading Dr. Gattermann's concluding observations, in which he states that his eyes and nerves have been so much affected that he is obliged temporarily to give up all further work upon this interesting substance.

Messrs. Crosby Lockwood and Son are about to publish the following books:—"Waterworks: being Notes on the Storage of Water in Reservoirs, &c.," by Charles Slagg; "Practical Surveying: a Text-book for Students preparing for Examinations or the Colonies," by George W. Usill; "Granites and our Granite Industries," with numerous illustrations, by G. F. Harris; a treatise on "Asbestos, and the Asbestos Mines of Canada," by Robert H. Jones; "The Mechanic's Workshop Handy-book," by P. N. Hasluck; and the fourth edition of "A Treatise on Metalliferous Minerals and Mining," by D. C. Davies.

In a recently-published Report on the Fisheries of New South Wales, Mr. Griffin, the American Consul at Sydney, refers to the great wealth of the colony in this respect, which is totally neglected. Up to the present, no attempt has been made to develop an export trade in fish. In fact, there are only eleven hands employed in the whole colony in fish-curing, with a capital of no more than £250, and the output does not annually exceed £200 in value. Yet the amount of tinned fish imported by the colony last year exceeded 2000 tons, of which about one-half was from the United States, and almost all the remainder from Great Britain. With regard to the species of fish suitable for preserving which are to be found in the waters of the colony, the mullet (*Mugil grandis*) is there in abundance, and when well cured is superior to anything of the kind in the world. Generally, it may be said that the fish fauna of Australia differs very little from similar species in Europe and America. The most remarkable fish in Australia is the *Phyllopteryx*, described as "the ghost of a sea-horse with its winding sheet all in ribbons about it; and even as a ghost it seems to be in the last stage of emaciation, literally all skin and grief."

The resistance of pollen to various external influences is the subject of a recent inaugural dissertation by Herr Rittinghaus in Bonn (*Naturf.*, 1, 1888). As to temperature, he found most pollen able to bear 90° C. half an hour, without losing the power of germination. A temperature-maximum was reached at 104°·5 for ten minutes. In conditions favouring germination, pollen does not bear such high temperatures as in the air-dry state. A moderately raised temperature (32°) accelerates growth of the pollen tubes. Low temperatures (*e.g.* under 9°) prevent germination, though a cooling to 20° for forty minutes can be borne without injury. As to *liquid* chemical reagents, the plasma of pollen proved very sensitive to antiseptics (more so, as a rule, than micro-organisms), but the resisting power is pretty different in different sorts of pollen. Chloroform *vapour* acting for twenty minutes was fatal, bromine vapour in five minutes, ammoniacal vapour in ten to twenty minutes. Rotation, several hours, of a spherical vessel holding pollen with nutritive solution, did not prevent free germination. The retention of the power varies widely in different plants. Thus, *Cyclamen* lost it soonest, in seventeen days; while *Clivia*, a narcissus, still had it on the sixty-sixth day (*Pæonia* fifty-eight, *Camellia* fifty-one, *Azalea* forty-two). The average is thirty to forty days.

A recent number of the *Indian Agriculturist* contains a notice of a little book written in Bengalee, by a Hindoo gentleman, Nidhiram Mookerjee, and published at the Bangabasi Press, Calcutta. The work is on pisciculture, and gives us the results of the labours of an ardent student of fish and their

habits. He established a fish-farm on his own estate, and watched over it for many years. He divides his subject into five parts. In the first place, he discusses the fish supply of Bengal, and in doing so shows that the supply is frequently not equal to the demand—a fact due chiefly to the absence of skilled fishermen. And so it happens that at various seasons breeding and unmatured fish are brought to market to meet the demand. The second chapter treats of the best food for fish; the third of hatching and breeding, and the proper precautions to be taken at those times. The fourth part deals with the question from a commercial and speculative point of view. A little capital, the author says, if wisely invested in pisciculture and in fisheries produces a greater return than in any other industry; for while, as Prof. Huxley says, an acre of land will produce in the year a ton of grain or two or three hundredweight of meat, the same extent of water in a good fishing-ground will yield a greater weight of fish in a week. The author begs of his countrymen to pay attention to this much neglected subject; he puts his practical experience before them, and thinks, that in a country like Bengal, where fish forms a large portion of the dietary of the people, it is a pity that more is not known of this subject. One of the most valuable portions of this little work is the fifth, in which he gives a scientific description and classification of almost all the known fish in the waters of Bengal, with their Bengalee equivalents.

THE additions to the Zoological Society's Gardens during the past week include two Stock-Doves (*Columba œnas*), British, presented by Lieut.-Colonel W. G. Dawkins; a Gayal (*Bibos frontalis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

DISTRIBUTION OF THE SUNSPOTS OF 1886 AND 1887.—Prof. Spoerer points out in a short note in the *Astronomische Nachrichten*, No. 2828, that the predominance of the southern hemisphere over the northern as to the numbers and areas of sunspots which they have displayed has continued throughout the two years just past. It would seem, indeed, as if the maximum for the southern hemisphere had fallen later than for the northern, for after the last return of the great group of November 12–25, 1882, the latter hemisphere became comparatively quiescent for a considerable time, and from that date the predominance of the southern hemisphere has been almost uninterrupted, the displays it exhibited during the latter part of 1883 and the earlier months of 1884 being so considerable and so numerous as to make the date of maximum the same for the sun as a whole as for the southern zone. So in the decline since the maximum, not only has the mean spotted area of the northern hemisphere been scarcely more than half that of the southern, but the running down in latitude has been more marked in the former than the latter. Thus in 1884, the northern zones above lat. 25° were already free from spots, whilst in the south the zone 25° to 30° was still occupied. In 1886 spots had ceased to be seen in the zones north of N. lat. 20°, but were still seen in the corresponding southern belt; whilst in 1887 they had almost vanished from the zone N. lat. 15° to 20°, though still fairly numerous at a like distance from the equator on the other side. The actual distribution of the spots is shown by Prof. Spoerer in the following table:—

Year.	+20°		+15°		+10°		+5°		0°		−5°		−10°		−15°		−20°		−25°	Totals. N.	S.
1886		17		30		40		14		50		45		68		47		5		101	215
1887		2		22		15		14		19		56		27		14				53	116

THE TOTAL ECLIPSE OF THE MOON, JANUARY 28.—By the kindness of Dr. E. Lindemann we are enabled to give the following further list of occultations observed during the total eclipse of the moon on January 28:—Amherst, U.S., 7; Clinton, U.S., 3; Copenhagen, 25; Harvard College, U.S., 23; Madrid, 20; Montreal, 6; Moscow, 15; Nice, 24; Princeton, U.S., 8; Toulouse, 13; Utrecht, 15; Washington, 11; West Point, U.S., 2. The weather was also favourable at the Birkdale Observatory, Southport, and at Berlin and Dun Echt; but at the last two Observatories, and also at Lord Rosse's, the occultations were not observed. The sky was cloudy at Herény, O'Gyalla, Quebec, Rio Janeiro, Stockholm, and Vienna.

SPECTROSCOPIC DETERMINATION OF THE ROTATION PERIOD OF THE SUN.—Mr. Henry Crew, Assistant in Physics at the Johns Hopkins University, has recently published (*American Journal of Science*, February 1888) a series of observations made with a fine Rowland grating of 14,436 lines to the inch, of the relative displacement of certain lines in the solar spectrum, as given by the opposite limbs, with a view to determine the rotation period of the sun. The result which he obtained from 455 settings in the course of observations ranging over four months and a half, gives, for the mean equatorial velocity, $v' - v'' = 2{\cdot}437 \pm {\cdot}024$ miles per second, corresponding to a true period of 25·88 days. But an unexpected and remarkable circumstance was brought out by the investigation, in that the observations seemed to show a gradual *increase* of daily angular motion with higher heliographical latitude, whilst, as is well known, Carrington found a *decrease* of such motion for the spots. Mr. Crew gives for the equation of this change—

$$v = 1{\cdot}158 \cos \chi^\circ (1 + 0{\cdot}00335\ \chi^\circ),$$

whence we have for the daily angular motion of any point in the reversing layer—

$$\theta = 794' (1 + 0{\cdot}00335\ \chi^\circ),$$

whilst Carrington obtained for the sunspots—

$$\theta = 865' (1 - 0{\cdot}191 \sin \tfrac{7}{4}\chi^\circ).$$

The greatest irregularities in the value of $v' - v''$ occurred between the latitudes 15° and 25°, *i.e.* in the chief spot zone.

It should be added that different lines gave different values of $v' - v''$, with nearly as large a range as the different latitudes did, but there appeared to be no connection between the order of the velocities and the order in which the elements causing the lines observed are generally supposed to be distributed in the solar atmosphere. The double line, 1474 K, of which one component is due to iron, and the other is the line of the corona, gave no evidence of variation in width on one limb, as compared with the other, so if the two lines be produced by absorption from different layers, those layers cannot be drifting with respect to each other at a higher rate than one-third of a mile per second.

The spectrum of the fourth order was used throughout. Attempts were made to measure the relative displacement of the D_3 line, as given by opposite limbs, but with this dispersion the definition was not sufficiently good to permit satisfactory measures of the line to be made.

NEW MINOR PLANET.—A new minor planet, No. 273, was discovered on March 8, by Herr Palisa at Vienna. This is Herr Palisa's sixty-first discovery.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *MARCH* 25–31.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 25

Sun rises, 5h. 51m.; souths, 12h. 5m. 54·3s.; sets, 18h. 20m.: right asc. on meridian, 0h. 19·4m.; decl. 2° 6′ N. Sidereal Time at Sunset, 6h. 34m.

Moon (Full, March 27, 22h.) rises, 15h. 12m.; souths, 22h. 28m.; sets, 5h. 29m.*: right asc. on meridian, 10h. 43·4m.; decl. 10° 51′ N.

GEOGRAPHICAL NOTES.

In a previous number we referred to the return of M. Edouard Dupont, Director of the Brussels Natural History Museum, from his visit to the Congo for the purpose of scientific exploration. Some of the results of his visit he described the other day to the Belgian Society of Engineers. M. Dupont pointed out that the African interior is drained mainly by four great rivers—the Nile, the Niger, the Zambezi, and the Congo—each of which has to break through the low range that bounds the interior somewhat saucer-shaped table land. The Congo, before making its great final effort, is to some extent dammed back into the reservoir known as Stanley Pool. M. Dupont's journey extended from the mouth of the river to the *embouchure* of the Kassai. The subsoil of the Lower Congo he found to be a soft and impure limestone covered with sand and clay. The mountainous region begins before arriving at Boma, and may be divided into three sections, according to the composition and aspect of the rocks. There is in the first place granite, gneiss, mica-schist, quartzite, and amphibolic rocks, in strongly inclined beds, and extending from Fetish Rock, below Boma, to the neighbourhood of Isanghila. The river from Vivi rushes in a series of cataracts through a gorge 55 miles long. Then follow schists and sandstones; and a little beyond Isanghila, at the great bend of the Congo, appear masses of limestone, very similar to those of the Meuse, and which alternate with the schists for about 35 miles. Then follow schists and red sandstones to beyond Manyanga. At Isanghila the banks rise into walls, some 700 feet high, of rough-grained, almost horizontal sandstone. This ends at Stanley Pool, where begins the Upper Congo. There is an immediate change in the strata. Some coherent sandstones show themselves at the base of the new deposits, and are topped by a great mass of soft sandstone, of the whiteness of chalk. M. Dupont traced these new rocks to the mouth of the Kassai, where there was nothing to indicate that they soon came to an end. He believes, on the contrary, that they constitute the subsoil of the greater part of the Upper Congo. M. Dupont is convinced, from his observations on the Congo, that the waters in the interior of Central Africa were at one time accumulated in a great lake, of which Stanley Pool is the last remnant. Gradually rising to the height of the mountains that bordered the plateau, they at last overtopped them, and, rushing down towards the Atlantic, gradually scooped out the channel now occupied by the Lower Congo. Stanley Pool, he considers, is the final stage of this supposed great internal lake.

A Brussels telegram announces that Lieut. Van Gele has at last succeeded in tracing the connection between the Mobangi and the Wellé, proving that the latter flows into the Congo, and is not the upper course of the Shari, thus solving one of the few remaining hydrographical problems in Africa.

In Ergänzungsheft No. 89 of *Petermann's Mitteilungen*, Prof. R. Credner concludes his very valuable monograph on "Reliktenseen,"—lakes which have remained behind after the departure of the sea from a particular area, as contrasted with continental lakes, which have from their origin been altogether independent of the sea. In the present instalment Prof. Credner deals in detail with the geological evidence, and with the various classes of "Reliktenseen" and the mode of their formation. He divides such lakes into three great classes: (1) such as have been formed through the damming up and isolation of parts of the sea through the elevation of the land above sea-level, as in the case of Lake Pontchartrain and the Kurische Haff; (2) such as are due to the isolation of basin-formed depths of the ocean-bed as a result of "negative changes in level"—emersion lakes, as Loch Lomond and Lakes Wetter and Wenner; (3) those caused by the retirement or shrinking of mediterranean seas, as the Caspian and Lake Aral.

At the last meeting of the Royal Geographical Society, Mr. Douglas W. Freshfield read a paper giving the results of his visit to the Caucasus last summer in company with M. de Dechy. Mr. Freshfield dealt at great length with the orography, the glaciation, geology, and ethnology of the Caucasus, and it is impossible to give an adequate idea of his important paper in a note. We can only refer to one or two important corrections which he made in the prevalent statements about the Caucasus. Some existing misconceptions are due to the fact that the Russian staff map embraces only the lower features, the higher ranges being unmapped. Mr. Freshfield dealt mainly with the part of the chain between Elbruz and Kazbek—the Central Caucasus. The geological structure of the chain has been represented with general accuracy by M. Ernest Favre, a son of the well-known Genevese geologist, who visited it in 1868. The backbone, composed of two or more ridges closely parallel, with many short spurs, is in great part gneiss or granite mixed up with crystalline slates. By what seems a strange freak of Nature, it is, east of Adai Choch, rent over and over again to its base by gorges, the watershed being transferred to a parallel chain of clay slates ("Palæozoic schists"), which has followed it from the Black Sea. There are clay-slate formations north as well as south of the granite backbone; but on the north they take the form of rolling downs—of any peaks they ever had they have long been denuded. What the mountain climber looking out from any northern outlier of the granite chain sees is a limestone crest, turning its precipitous face towards the snows, sinking gradually to the low foot-hills which fringe the steppe. It is pierced by deep romantic defiles through which the glacier torrents make their escape. South of the Caucasus, parallel to, but much further from the main chain, runs a line of limestone heights, the most conspicuous summits of which are the Quamli, close to the Rion, and the Nakerale range, the limit of the Radsha. At the foot of the latter lie the coal-mines of Khebouli, recently connected with Kutais by a railway. Over the summit plateau spreads one of the noblest beech forests in the world, varied by an undergrowth of azaleas, laurels, and box, such as we try vainly to imitate in our English parks. Parallel chains and longitudinal valleys characterize this portion of the chain. In the most reputable treatises it is stated that there are not 50 square miles of glaciers in the Caucasus altogether. Mr. Freshfield shows that such a statement is ludicrously absurd. The glaciers of the main chain are many, and some of them are enormous. Among those that have the largest basins Mr. Freshfield mentions, between the Djiper Pass and the Mamisson on the south side, the Betsho, the Ushba, the Gvalda, the Thuber, the Zanner, Tetnuld, and Adish, the Sopchetura at the western and at the eastern source of the Rion. On the north side there is a great glacier in every glen; the Karagam and the Bezingi are the largest; next come the Dychsu, the Zea, the Adyrsu, and Adylsu, and a host of others lying not only on the main chain, but on its spurs, which are glaciated to an extent of

which the Ordnance map gives no hint. On the "Palæozoic schist" range, south of Suanetia, there are glaciers not very inferior to those of the Grand Paradis group, near Aosta. Dismiss for ever, Mr. Freshfield says, that preposterous fiction about the 120 square kilometres of ice in the Caucasus. It is too soon to say how many square kilometres there really are. One estimate, Von Thielmann's, would make the extent covered by ice close upon 2000 square kilometres, or equal to that in Switzerland—political Switzerland, not the Alps. Mr. Freshfield dwelt on many other points in connection with this interesting range, his notes on the inhabitants of the Caucasus being specially valuable, correcting as they do many prevalent errors.

OUR ELECTRICAL COLUMN.

CONSIDERABLE attention has been drawn to the peculiarities of manganese steel by a paper read before the Institution of Civil Engineers, by Mr. Hadfield. Not only is such steel entirely non-magnetic, but its electric resistance is extremely high. Prof. Fleming (*Electrician*, March 9) gives the following figures:—

German silver	20·9	·044
Platinoid	32·8	·021
Manganese steel	68	·122

The first column gives the resistance in microhms per cubic centimetre at 0° C., and the second column the average percentage variation of resistance per 1° C. between 0° and 100° C. These figures agree very well with those given by Prof. Barrett at the British Association meeting at Manchester.

HEIM has been investigating the electro-positive character of magnesium, with the view of replacing zinc in primary batteries. He finds that in a Daniell cell its E.M.F. is 2 volts, in a Grove cell it gives 2·9 volts, and in a Leclanché cell 2·2 volts. In a bichromate cell it gives as much as 3 volts.

MAGNESIUM can now be produced for about 8*s.* per lb., but local action is considerable, and its constancy uncertain. Hence, except for exceptional circumstances, its practical use is still questionable.

PROF. OLIVER LODGE has been giving some admirable lectures on lightning-protectors at the Society of Arts, and has pronounced the use of copper for such purposes as doomed. He argued that the supposed area of protection was mythical, and that the true way to protect a building was Maxwell's cage. He advocated iron, and showed copper to possess "inertia" to such an extent as to render its use dangerous. He also found that under certain circumstances, such as sudden violent discharges, untempered by time, points were of no use, but he suggested the use of barbed wire along the ridges and eaves of roofs.

THAT careful and accurate worker, Prof. Roberts-Austen submitted a paper to the Royal Society on the 15th inst., in which he narrated his recent inquiries into the mechanical properties of certain alloys that will have an important bearing on the metallic conductors employed in electrical enterprises. He has found that the tenacity of pure gold is very much diminished by the smallest admixture of impurities, and that this follows the order of the atomic volumes of the elements. Those elements the atomic volumes of which are higher than gold greatly diminish its tenacity. Doubtless the same principle is applicable to copper and other metals. The abnormal price of copper has raised a great demand for some better conductor than iron, or some improvement of iron in this respect.

DERHAM'S HYDROMETER.

THE Revenue system of estimating the duty on spirits consists of hydrometer, and tables of strengths for each degree of temperature from 30° to 80° F. When constructing the present Revenue tables of strengths, Sikes ignored the expansion and contraction of spirits due to variations of temperature from the standard temperature of 51° F., and assumed that the strength of any given sample of spirits remained the same at all degrees of temperature. From this false assumption it follows in practice, for example, that 100 gallons 40 overproof at 51° are estimated at 98·9 gallons at 30°, and 101·6 gallons at 80°, of the same strength as at 51°; reducing these quantities to the standard of proof strength, we have—

At 30°	...	98·9 × 1·40 = 138·5 gallons of proof,
51°	...	100·0 × 1·40 = 140·0 ,, ,,
80°	...	101·6 × 1·40 = 142·2 ,, ,,

showing a discrepancy of over 3½ gallons, although the same actual quantity of spirit is present in each case.

In its original construction, Sikes's hydrometer was not intended to furnish specific gravities, but simply so many indications, respectively corresponding to the strengths in his tables. But it has since been found necessary to supply a table of specific gravities corresponding to the indications of the instrument. It is well known that scientific precision cannot be attained in experiments with the hydrometer, consequently the specific gravities in this table are far from accurate: for example, the specific gravity at the proof point, to the accurate definition of which the Inland Revenue attaches so much importance, is given as ·9233, instead of ·9236. The whole specific gravity table is in fact incorrect, the error sometimes amounting to two subdivisions of the stem. The errors, however, arising from this source are trifling compared with those inherent in the tables of strengths. For the purpose of constructing correct tables of strengths, the best data and those susceptible of the most accurate determination are the specific gravities of the spirits and the percentage by weight of alcohol they contain. The specific gravity of proof spirit, as defined by the Spirit Act is ·9236; therefore the weight of one gallon is 9·236 pounds. Proof spirit contains 49·3 per cent. by weight of alcohol, of specific gravity ·79385 at 60°; therefore one gallon of proof spirit contains—

$$\frac{9 \cdot 236 \times 49 \cdot 3}{100} = 4 \cdot 553 \text{ pounds of alcohol.}$$

To determine the true ratio of any spirit to proof spirit nothing more is required than to ascertain the weight of alcohol in one gallon of the spirit, and to divide that weight by the pounds of alcohol in a gallon of proof spirit; for example, spirit having a specific gravity of ·825 at 60° weighs 8·25 pounds per gallon; its percentage by weight of alcohol is 89·13; therefore one gallon contains—

$$\frac{8 \cdot 25 \times 89 \cdot 13}{100} = 7 \cdot 353 \text{ pounds of alcohol,}$$

equivalent to

$$\frac{7 \cdot 353}{4 \cdot 553} = 1 \cdot 615 \text{ gallons of proof spirit.}$$

Or 100 gallons are equivalent to 161·5 gallons of proof spirit, and the spirit is said to be 61·5 overproof. It is obvious that although the bulk and specific gravity of a spirit vary with the temperature, the percentage by weight of alcohol it contains does not vary from that cause. The specific gravity of the spirit in the preceding example is ·839 at 30°; the weight of one gallon therefore is 8·39 pounds; its percentage by weight of alcohol is 89·13 as before; therefore one gallon contains—

$$\frac{8 \cdot 39 \times 89 \cdot 13}{100} = 7 \cdot 478 \text{ pounds of alcohol,}$$

equivalent to

$$\frac{7 \cdot 478}{4 \cdot 553} = 1 \cdot 642 \text{ gallons of proof spirit.}$$

The strength of the spirit, therefore, at 30° is 64·2 overproof.

It should be here pointed out that the diminished bulk of the spirit at 30°, as compared with its bulk at 60°, is exactly compensated, in estimating the equivalent value in proof gallons, by the increased strength at the former temperature; for 100 gallons of spirit 61·5 overproof at 60° contract to 98·33 gallons at 30°; and, reducing to proof strength—

100 × 1·615 = 161·5 gallons of proof spirit,		
98·33 × 1·642 = 161·5	do.	do.

whence it is evident that, by the employment of correct tables of strengths, the estimate of the equivalent value of a given quantity of spirit in gallons of proof spirit would be identical at all degrees of temperature. The spirit tables published by Dr. Derham, to which Sir Henry Roscoe lately called the attention of the Chancellor of the Exchequer, are calculated on this principle.

Dr. Derham also supplies what has long been wanted, a scientific hydrometer having a succession of poises to continue the series the indications of which are also specific gravities. It is well known that, in order to effect this, the increment to the total bulk of the instrument with each successive poise should be the bulk of the graduated stem. Bates's saccharometer is a more or less successful mechanical adaptation of this requirement. But it had escaped previous inventors that, in order to perfectly satisfy the conditions of the problem, the specific gravities of the successive poises should bear an exactly defined relation to the specific gravities to be indicated by the instrument. The principle upon which the calculation of the hydrometer is based is that—

$$\frac{\text{weight}}{\text{bulk}} = \text{specific gravity.}$$

Let W = weight of hydrometer; B = bulk of hydrometer; G = initial specific gravity of the instrument; g = specific gravity of any poise; a = the number of degrees of gravity indicated in the length of the stem; and unity = bulk of graduated stem; then, since the bulks of the poises must be multiples of the bulk of the graduated stem, according to their position in the series,

$$n = \text{bulk of } n\text{th poise.}$$
$$ng = \text{weight of} \quad ,,$$

By the definition of specific gravity,

$$\frac{W}{B} = G\text{; and } \frac{W}{B-1} = G + a,$$

whence

$$W = BG\text{, and } \frac{BG}{B-1} = G + a,$$

and

$$Ba = G + a.$$

Again, generally, with nth poise attached,

$$\frac{BG + ng}{B + n} = G + na,$$

whence

$$g = 2G + (n+1)a.$$

And if the hydrometer were intended to indicate gravities from ·780 to 1·000, the value of the stem being ·020, and the initial specific gravity accordingly of each range ·800, ·820, ·840, &c., the successive specific gravities of the poises would be 1·60, 1·62, 1·64, &c.

THE CŒLOM AND THE VASCULAR SYSTEM OF MOLLUSCA AND ARTHROPODA.[1]

THE object of the author was to establish the fact that the system of blood-containing spaces pervading the body in Mollusca and in Arthropoda was not, as sometimes (and indeed usually) supposed, equivalent to the cœlom or perivisceral space of such animals as the Chætopoda and the Vertebrata, but was in reality a distended and irregularly swollen vascular system—the equivalent of the blood-vascular system of Chætopoda and Vertebrata. Hence he proposed to call the body-spaces of Mollusca and Arthropoda "hæmocœl," in contradistinction to "cœlom." It had been held by previous investigators that in Mollusca and Arthropoda the cœlom and the vascular system were united into one set of spaces—whether by a process of gradual fusion, or owing to the fact that the two systems had never been differentiated from a common original space representing them both in the ancestors of these two great phyla. the author stated that he had been led to the view which he now formulated by his discovery of distinct spaces in both Mollusca and Arthropoda, which appear to be the true cœlom, and are separate from the swollen vascular system.

In Mollusca the pericardial space is the chief representative of cœlom. It is usually taught that the pericardium of Mollusks contains blood, and is in free communication with veins; but the author had succeeded in showing by observations on the red-blooded *Solen legumen* (already published, *Zoolog. Anzeiger*, No. 170, 1884), and by more recent careful investigation of *Anodonta cygnea*, *Patella vulgata*, and *Helix aspersa*, that the pericardium has no communication with the vascular system, and does not contain blood. The perigonadial spaces (so-called generative glands) and the pericardial space (which has arborescent tubular outgrowths in some Lamellibranchs forming Keber's organ) are, then, the cœlom of the Mollusca. It is quite distinct from the hæmocœl. In Cephalopods, and in the archaic Gastropod Neomenia, the pericardial and perigonadial cœlomic remnants are continuous, and form one cavity. There is strong reason to believe that in ancestral Mollusks the hæmocœl was more completely tubular and truly vasiform than it is in living Mollusks. In the later Mollusks the walls of the vessels have swollen out in many regions (especially the veins), and have *obliterated* the cœlom, which has shrunk to the small dimensions of pericardium and perigonadium. There are, however, many Mollusks with complete capillaries, arteries, and veins, in certain regions of the body. These had been recently studied by the author by means of injections, and by silver impregnation, and drawings illustrative of them were exhibited to the Section.

With regard to the Arthropoda, Prof. Lankester formulated the same view, viz. that the ancestral blood-vessels have swollen and enlarged, especially the veins, so as to form large irregular spaces, which have blocked up and so obliterated the previously existing cœlom. Nevertheless the cœlom still persists in some parts of the Arthropod body quite separate from the swollen blood-vascular system. It persists as the tubular generative glands (perigonadium), and also as a system of small spaces (lymph-system) in the connective-tissue of Astacus and of Limulus, and as the internal terminal vesicle of the green glands and other nephridia present in various Arthropoda. Prof. Lankester stated that he had been led to this view with regard to the vascular system and cœlom of the Arthropoda by the results of his histological investigations on the vascular system and connective-tissues of Astacus and Limulus, and by the results obtained in his laboratory by Mr. Gulland in studying the development of the nephridial "coxal gland" of Limulus (already published, with note by Prof. Lankester, in the *Quart. Journ. Micr. Sci.*, 1885, vol. xxv. p. 515). He had also been led to this view by the attempt to explain theoretically the origin of the peculiar structure of the Arthropod's heart and blood-holding pericardium.

The Arthropod's heart and pericardium are absolutely peculiar to the group, and characteristic of all its members—even of Peripatus. The author had asked himself how the existence of a tubular heart with paired valvular apertures in each segment of the body—lying within a blood-holding sac—could be explained. He conceived that it might best be explained by that tendency of the veins to dilate and to form irregular large blood-sinuses, which on other grounds we have reason to consider as a structural tendency of Arthropods. Each pair of valvular apertures in the Arthropod's heart represents a pair of distinct tubular veins which in the ancestors of the Arthropoda brought blood to the heart from the gills. These veins have dilated, and their adjacent walls have been absorbed, so that we now have, instead of a series of veins, a great continuous blood-sinus on each side of the heart or dorsal vessel.

Capillaries of the finest dimensions were shown by Prof. Lankester to exist in certain parts of Astacus and of Limulus. In studying these he had come across the remnants of cœlom. Between the capillaries and unconnected with them—in the connective-tissue of both Astacus and Limulus—is a system of spaces containing a coagulable fluid. (These spaces were described and figured in Limulus in 1884 by Prof. Lankester in the *Quart. Journ. Micr. Sci.*) It is into this system of spaces that the tubular nephridium which becomes the coxal gland of Limulus opens. Hence these spaces are remnants of the cœlom, elsewhere blocked up and obliterated by the swollen veins which form the hæmocœl. The tubular generative glands of Arthropods are to be explained as perigonadial cœlom communicating with the exterior through modified nephridia. Beddard's discovery of such a condition of the ovary and oviduct in the earthworm Eudrilus is confirmatory of this explanation.

The views which had been thus arrived at by Prof. Lankester and very briefly indicated in the note in the *Quart. Journ. Micr. Sci.*, 1885, p. 515, have received a startling and demonstrative confirmation in Sedgwick's brilliant results as to the development of cœlom and hæmocœl in Peripatus, published in the *Quart. Journ. Micr. Sci.*, February 1888, and announced early in 1887 to the Cambridge Philosophical Society.

[1] Abstract of a Paper read in Section D, at the Manchester meeting of the British Association, by Prof. Ray Lankester, F.R.S.

THE TEETH OF THE MYXINOID FISHES.

IN the course of my work upon the morphology of the Vertebrata, it has occurred to me to ascertain how far the generally accepted account of the structure of the teeth in Cyclostomata exhausts the facts at our disposal. The inquiry is one of extreme interest in relation to the disputed affinities of this group with the other fishes. It is well known that Balfour regarded the Myxinoids as the survivors of a very primitive group which had never possessed true jaws. Dohrn, on the other hand, while holding that these fishes retain very many primitive characters, has always asserted their degenerate nature as a canon of his doctrine of the ancestry of Vertebrates. He has endeavoured to produce evidence of this in several of his "Studien," but so far as I am aware, the secondary character of the sucking mouth of the group has never yet been fully proved.

In Balfour's "Comparative Embryology" (vol. ii. p. 264), we read, "I am acquainted with no evidence, embryological or otherwise, that they (the Myxinoid fishes) are degraded gnathostomatous forms."

As the nature of the mouth in this group was one of Balfour's arguments against Dohrn's gill-cleft origin of the mouth of all Vertebrates,[1] and as my own views of the nature of the hypophysis cerebri are also affected by Balfour's reasoning, I may perhaps be allowed to state why I attach great importance to the structure of the teeth in the Myxinoids. With the exception of these animals and Amphioxus, all Vertebrates are known to possess true teeth and true jaws; but it appears to me that if it can be shown that the Myxinoids present traces of true teeth, it must be assumed that they once had true biting jaws. For true teeth are necessary appendages of biting jaws, while they are never found except when true jaws are present. It is important to note that Huxley long ago insisted upon the presence, in the lamprey, of a true mandibular jaw-apparatus, homologous with that of the gnathostomata.

All previous investigators of the group, from Johannes Müller to Parker, have described only the horny nature of the teeth, and that simply because no one has till now made microscopical sections of them. It must here suffice to point out that the current view is correct only so far as the Petromyzontidæ are concerned. They alone possess only horny teeth. In *Petromyzon marinus*, these are curiously complicated, in that they are represented by three horny cusps or thimble-like bodies lying one upon the other, and each arising in a special groove at the base of the tooth. (Prof. Howes writes me that he has long known of this fact.)

Myxine and Bdellostoma, which retain many more primitive characters than the Petromyzontidæ, possess true teeth in the sense of those of other Vertebrates. These are hidden by the aforenamed horny cones, which are formed above them, and, in fact, each horny tooth in these two genera has a true odontoblastic pulp underlying it. The following is a brief description of the appearance of such a tooth in longitudinal section, as exemplified in Bdellostoma. Outside all is the bright yellow horny layer, formed from a "horn groove" at the base of the tooth. Within this is a stratified epithelium, which extends inwards as far as the true tooth; I am unable, however, to find any modified layer of epidermic cells which might represent the so-called enamel organ of other developing teeth. The true tooth is mainly composed of a very hard conical cellular mass, which is probably calcified (I have not yet tested it chemically). It possesses a true pulp-cavity with blood-vessels, &c., while it is made up of cellular elements, which are arranged in a somewhat radiate fashion. The cells are hard, possessed each of a large nucleus longitudinally striated, especially at the apex of the tooth and near the surface.

The apex of the cone is surmounted by a small cap of bright transparent structureless matter, which is either dentine or enamel; from its appearance, and from the fact that the pulp is very hard and obviously calcified, I am inclined to regard it as an enamel structure. While as yet it is not possible to follow the development of this cap, it appears to me to be a secretion of the pulp-cells; and, should it turn out to be enamel, we shall have striking confirmation of the enderonic origin of that layer, advanced by Huxley more than thirty years ago. I, for one, do not believe his view to be so improbable as is generally supposed.

The teeth of Myxine present essentially the same structure as those of Bdellostoma; they are, however, smaller, weaker, and more degenerate, for the cap of enamel (or dentine) is, in them, reduced almost to nothing—indeed, it can only be found after very careful search, and I think that from some of the teeth it is entirely absent.

With this discovery, true teeth come to be characteristic of all the lowest Vertebrates except the outcast Amphioxus, and thus the gulf separating the latter from the former becomes widened. Some zoologists explain the absence of spinal ganglia in Amphioxus by assuming that they are still within the spinal cord: might one hint that they can now also suppose that the teeth of Amphioxus are still within the gums?

In view of the facts here stated it becomes an interesting question for the palæontologist as to how far the "Conodonts" really are the remains of Myxinoid teeth. Zittel's view that they are really Annelidan teeth seems to me the more probable one (*Handbuch der Palæontologie*, Bd. iii. p. 38).

J. BEARD.

Anatomisches Institut, Freiburg i/B.

[1] Amphioxus is here left entirely out of account. Personally, I do not intend to commit myself in seeking to compare any organs of Amphioxus with those of the higher Vertebrates. I would rather leave Amphioxus alone, but I may at least remark the possibility that the mouth in Amphioxus may turn out to be the homologue of the hypophysis—gut passage in Myxine and Bdellostoma. The fact that no hypophysis has yet been discovered in this animal is only in accordance with other negative comparisons between it and other fishes.

MODELS ILLUSTRATING THE MODIFICATION OF THE ARTERIAL ARCHES IN VERTEBRATES.

HAVING recently, with the help of my assistant, made some simple and inexpensive models illustrating the modifications of the arterial arches in Vertebrates, which I find very useful for purposes of demonstration, I send a short description of them to NATURE. Students, as a rule, find it difficult to understand figures of these structures, and a model, in three dimensions, gives a much more accurate idea of their general relations than any drawing can do.

My models are founded mainly on the figures given by Boas, in his paper "Ueber die Arterienbogen der Wirbelthiere" (*Morphol. Jahrbuch*, Band xiii. Heft 1).

The various vessels are represented by stout brass wires (about $\frac{1}{8}$-inch in diameter), bent to the proper form and soldered together; and each model is made, in the first place, to represent six arches. In the case of the fish, the ventral aorta and lower half of each arch (representing the afferent branchial trunk) is painted blue, to indicate that the blood contained therein is venous; the upper half of each arch (representing the efferent trunk), together with the epibranchials and dorsal aorta, are coloured red, to show that they contain arterial blood. The heart is modelled out of modellers' clay, and fixed on to the ventral aorta before being dried; it shows the typical parts of the fish-heart, and is painted blue.

At present I have only made two other models, representing these structures in air-breathing Vertebrates, the types taken being the frog and the mammal. In these, similar colouring is used, but those parts which disappear in the adult are painted *white*. The various parts of the heart are also coloured red or blue, according to the nature of the blood contained in them.

Thus, in the frog the left auricle is red, the right auricle and sinus venosus blue, and the ventricle purple, to show the mixed character of the blood. The first, second, and fifth arches, the portion of the epibranchial between the third and fourth arches, and the ductus Botalli of the sixth arch, are white; the third arch (carotid and lingual artery), red; the fourth (aortic) arch and dorsal aorta, purple; and the lower part of the sixth (pulmonary), blue. In the mammal, the left side of the heart, the left aortic arch, dorsal aorta, and carotids, are red; the right side of the heart, and the pulmonary artery, blue; and the remaining parts, which disappear in the adult, white.

The paint I have used is Aspinall's oxidized enamel.

As this method of illustrating blood-vessels is also particularly useful for lecture-purposes, I intend, later on, to model whole vascular systems in the same way.

W. N. PARKER.

University College, Cardiff.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A small revolution has been effected in the teaching of geometry by the adoption of a regulation allowing any proofs of the propositions in Euclid to be given in the "Little-Go" or previous examination. No proof, however, of any proposition occurring in Euclid will be admitted in which use is made of any proposition which in Euclid's order occurs subsequently.

The estimates for the new plant-house (£2760) and research laboratory (£250) at the Botanical Gardens are accepted, Messrs. Boyd, of Paisley, being engaged for the former, Mr. Sindall for the latter. Sir Joseph Hooker, Mr. Thiselton Dyer, and several skilled horticulturists have inspected the plans, and they meet with general approval. The proposed fern-house, stove, and orchid-house, have a combined area of 2660 square feet, as compared with 2290 square feet, the area of the corresponding present houses.

The apparent boycotting of the Cambridge mechanical workshops by the Museums and Lecture-Rooms Syndicate, and other Cambridge authorities has led to a considerable diminution of work, and consequently to a serious reduction of profit in the workshops, which have also suffered to some extent by the unfortunate rejection of the Engineering Tripos scheme. In a recent discussion Prof. Cayley expressed the opinion that it ought to be as much a matter of course to send University mechanical work to the University workshops as to send University printing work to the Pitt Press. He considered the work done by the workshops compared very favourably with similar work done by contractors. Mr. Lyon, superintendent of the workshops, claimed that, while much of the work done outside for the museums had to be frequently repaired, none of the mechanical workshops' work had required this. They had done the work for the Morphological Laboratory for £1000 less than was estimated. A good deal of testimony was given to the excellence of their work, against which it was stated that the Syndicate thought they could get their work done cheaper and better by a professional builder.

A scheme has been prepared for the future fitting up of the old Botanic Gardens site with University buildings in extension of the museums and lecture-rooms. The most salient points are that the site between the new Chemical Laboratory and the Museum of Human Anatomy is declared sufficient for the new Museum of Geology, and that the next buildings to be taken in hand should be those for Human Anatomy and Physiology. It is also proposed to accommodate the Department of Pathology in the old Chemical Laboratory.

Mr. Wilberforce will deliver a course of lectures on Dynamo-Electric Machines at the Cavendish Laboratory during the Easter term.

Among the Fellows elected at King's College last week were Mr. A. P. Laurie, who obtained a first class in the Natural Sciences Tripos, Part II., June 1884, and Mr. H. W. Richmond, Third Wrangler 1885, and placed in Division I. in the third part of the same Tripos, 1886.

Mr. R. Pendlebury, Fellow of St. John's, has been appointed a University Lecturer in Mathematics for five years.

Open Scholarship examinations in which natural science Scholarships may be awarded will be held at Downing College on May 29, and at Peterhouse in October. The Clothworkers' Exhibition in physical science will be competed for in connection with the Oxford and Cambridge schools examination in July.

SCIENTIFIC SERIALS.

IN the *Journal of Botany* for February, Mr. G. S. Boulger calls attention to the exceedingly loose way in which the term "endosperm" is applied by botanical writers to structures in Angiosperms, in Gymnosperms, and in Vascular Cryptogams which have no real homology with one another.—A very interesting new fern from New Guinea (*Polypodium Annabellæ*) is described and figured by Mr. H. O. Forbes, belonging to the small group in which the fertile portion of the frond is only an extension of the lower barren portion.—In this, and in the number for March, Mr. J. G. Baker continues his synopsis of *Tillandsieæ*, and the editor commences an exceedingly useful alphabetical biographical index of British and Irish botanists no longer living.

American Journal of Science, March.—Asa Gray, by J. D. Dana. The attention of the readers of NATURE has already been directed to this memoir, written by the friend and associate probably most competent to appreciate the life-work of the eminent American botanist.—Calibration of an electrometer, by D. W. Shea. In the various forms of the quadrant electrometer, and in the different methods of setting up the same instrument, the curves of calibration obtained are well known to correspond in a very irregular manner with the curves given by Maxwell's mathematical theory. In this paper are given some observations with an electrometer of the Mascart form, which show variations apparently due to change in the sensibility with variation in the temperature. The accompanying tables exhibit the changes in the form of the curves for various charges of the needle through the range of temperature attainable, at the time, in the room where the electrometer was set up.—On the so-called Northford (Maine) meteorite, by F. C. Robinson. One of the numerous specimens of this "meteorite" contained in various cabinets in Maine, and perhaps elsewhere, has recently been analyzed by Mr. Charles Fish in Mr. Robinson's laboratory. That it is not of meteoric origin seems settled by this analysis, which corresponds closely with some recorded analyses of copper-slag.—History of the changes in the Mount Loa craters; Part 1, Kilauea (continued and concluded), by James D. Dana. The subjects discussed in this paper are: the size of the Kilauea conduit; the ordinary work performed by this crater; the kinds and sources of the vapours concerned; the effect of the expansive force of vapours in their escape from the liquid lavas (projectile action), and within the lavas (vesiculation and its mechanical effect); lastly, work of vapours generated outside of the conduit—fractures, displacements, and other results.—The Taconic system of Emmons, and the use of the name Taconic in geological nomenclature, by Charles D. Walcott. In this first paper on the North American Taconic system, the author deals (1) with the Taconic area in general and the geological work within it; (2) with the geology of the Taconic area as known at the present time. The Taconic area, as here studied, is stated to comprise the Taconic range running north and south nearly along the border-line between the States of New York, Vermont, Massachusetts, and Connecticut, with the country immediately adjacent to the range on the east and west. The strata included within the whole area are grouped under six terranes, identified as Middle Cambrian (1 and 5), Upper Cambrian (2), Calciferous, Chazy, and Trenton limestones (3), and Hudson shales, sandstones, &c. (4 and 6).—On the crystalline form of polianite, by E. S. Dana and S. L. Penfield. The true crystalline form of the anhydrous manganese dioxide, MnO_2, from Platten, Bohemia, to which Breithaupt has given the name of polianite, has been the subject of much discussion. Köchlin's recent contribution to its elucidation has induced the authors to continue their own studies, which establish beyond all doubt the independent position of polianite as a tetragonal crystal isomorphous with cassiterite and the allied species of the RO_2 group.

NEARLY the whole of the number of the *Nuovo Giornale Botanico Italiano* for January is occupied by a monograph by Sig. A. N. Berlese of the genus of Fungi *Pleospora*, of which 104 undoubted species are described, several of them new to science, besides a considerable number of doubtful species. The eight plates, in which the essential characters of nearly all the species are illustrated, as well as monographs of the allied genera *Clathrospora* and *Pyrenophora*, are postponed to the next number.—Prof. A. Beccari also describes three new species of palm from New Guinea.

Rendiconti del Reale Istituto Lombardo, February 9.—On colour-hearing, by Tito Vignoli. A somewhat detailed account is given of this obscure psychological phenomenon, cases being described in which not only sound produced the sensation of colour and colour of sound, but also cases in which sensations of smell and taste were stimulated by sound and colour. Rejecting the explanations hitherto advanced, the author refers the phenomenon to the primæval condition of the brain itself before the various senses became differentiated and localized in this organ. These senses must be regarded as so many forms of the primitive and essential condition of the nerve-tissue in which they became gradually specialized. But although the protoplasmic substance of the brain was thus made the seat of distinct sensations by virtue of incident forces and slow selection, still it has never

ceased to possess the aptitude as a whole for receiving all kinds of impressions from without, and in fact it is this general aptitude that has rendered possible the evolution of the special senses in special centres. Thus the common origin of all the senses would seem to offer the readiest explanation of their occasional confusion even in the human brain itself, the highest development of all. Colour-hearing might in this way be regarded somewhat as a case of reversion or atavism.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 23.—"On Remnants or Vestiges of Amphibian and Reptilian Structures found in the Skulls of Birds." By W. K. Parker, F.R.S.

(1) *Jacobson's Organ.*—This remarkable structure, which must be looked upon as an accessory olfactory organ, is present in certain of the higher Vertebrata, or *Amniota.* It consists of a paired cavity, which early becomes separated off from the proper nasal chamber, and which opens into the mouth by the anterior incisive foramen. It is innervated by branches from the olfactory and trigeminal.

Jacobson's organs are largest in Snakes, Lizards, and Monotremes, and next in order come the Marsupials, Edentates, Insectivores, and the Mammalia generally. Their presence in Man is doubtful, and what has been described as a rudiment of them has probably quite another explanation.[1] They are not known to exist in Chelonians, Crocodiles, and Birds.

In the Snake and Lizard, these structures lie each in a little dish, formed by the vomer of that side, covered in by another vomerine bone—the septomaxillary. They are also protected at the opening of the capsule by a pedate tract of cartilage, derived from the alinasal fold, which, in the Snake, frequently becomes detached from its root. In low Mammalia there are several vomers, and in most of the lower Mammals a pair of small anterior vomers lie on the inside of Jacobson's organ, but the capsule itself is formed by a peculiar fold of cartilage—the recurrent cartilage,—which closes in upon itself, and unites its edges round the organ. As a rule, these "recurrent cartilages" retain their union with the alinasal folds, as in the Lizard; in the Rabbit (Howes) they are distinct, as in the Serpent.

Now in Birds these cartilages not unfrequently appear, but no Jacobson's organ has been found with them. The Birds whose vomerine region comes nearest to that of a low Mammal are the Turnicidæ, or Hemipods, and the great group of the Passerine birds (Coracomorphæ, or Ægithognathæ of Huxley). It is not uncommon for the "ox-faced" vomer of these birds to be formed of two pairs of bony centres, and these become not only fused together, but actually grafted upon the floor of the cartilaginous nasal capsule, in the same manner as is common in the lower kinds of Mammalia.

Remnants of the cartilaginous capsule of Jacobson's organs are found not only in the Hemipods and in the lower Neotropical Passerines (*Homorus, Synallaxis, Anæretes*), but also in some of the highest of the singing-birds—namely, the Wren (*Anorthura troglodytes*)—and also in some of the Woodpeckers (Picidæ), outside the Passerine Order.

In a paper on the "Skull in the Ostrich Tribe" (Phil. Trans., 1886, pl. 10, Fig. 14, *a.i.t.*), the present author figured and described, but did not then fully understand, a peculiar cartilage perched right and left upon the large vomer of the *Rhea.* He, however, has for a long time been satisfied that this is one of the vomerine or Jacobson's cartilages, and this view is strongly corroborated by the recent description of the palate of *Apteryx*, given by T. Jeffery Parker (Proc. Roy. Soc., February 23, 1888). Now if the figure of the transversely-vertical section through these cartilages and the crura of the vomer in the *Apteryx*, be compared with various figures in the present author's "Memoirs on the Mammalian Skull" (Parts I., II., and III., "Phil. Trans."), it will be seen that it so nearly corresponds with sections of the skull of the Pig, the Edentates, and the Insectivores, especially those taken just behind Jacobson's organ, that without explanation it would be impossible to tell which figure belonged to the Bird, and which to the Mammal.

(2) *Parasphenoid.*—This bone forms a large superficial basicranial beam in Ganoidei, Teleostei, Dipnoi, and Amphibia. It corresponds to the subcutaneous part of a dermal scute formed inside the skin of the mouth, developed for support to badly ossified endocranium.

The parasphenoid of the Frog is dagger-shaped, and reaches from near the foramen magnum behind, to the nasal capsule in front, the "guard" of the dagger supporting the auditory capsules. Now in Serpents only the *blade* is present; in Lizards only a very fine thread of bone representing the blade; in some, *e.g.* *Trachydosaurus rugosus* (Cyclodontidæ), even this is wanting. It is not present in those very amphibian forms, the Chelonians; and only a small remnant of the "guard" right and left can be found in Crocodiles, consisting of two "basitemporal" plates, soon covered over by the huge pterygoid.

In all Birds basitemporals are large, as large as in Frogs and Toads; this is equally true of the *Dinornis* and of the smallest Humming-bird. There is a tendency for them to break up into lesser bony parts; thus for a day or two in the chick there are two "basitemporal" and one "rostral" centre; but in several species of the Ranidæ, *e.g.* the Bull-frog, the point of the dagger-shaped bone is separately ossified, and remains distinct.

In the Paradoxical Frog (*Pseudis paradoxa*) there is no "handle" to the dagger; the same form of parasphenoid is common among the water-birds, *e.g. Alca, Uria.* This is an ossification which is the earliest to appear in skulls that take on any kind of ossification; it is also the first bone to appear in an embryo bird, as in the larval Frog.

(3) *Prenasal Rostrum.*—Scarcely any Urodeles, and only a few of the Anura, show any special elongation of the "intertrabecula" or prenasal rostral cartilage; this must have been very long in the Ichthyosauria, as in the Selachii, and as in the embryos of all Birds.

(4) *Palato-pterygoid arch or arcade.*—In the Frog, after metamorphosis, during which the hinge of the jaw becomes shifted far backwards, three regions may be distinguished in the forepart of this arch; thus the suspensorial part or pedicle is the ethmo-palatine, the anterior free spike the pre-palatine, and the hinder part which runs into the pterygoid is the post-palatine.

The anterior part of the pterygo-palatine arcade is distinct from the pterygoid in Urodeles, and the pterygoid in them is an outgrowth of the quadrate which grows forwards towards the palatine, but does not coalesce with it, except in *Ranodon sibiricus.*[1] The "post-palatine" tract of cartilage is developed as a distinct nucleus in the Axolotl (*Siredon*).[2]

The only Reptiles in which the author has discovered any distinct trace of the *endoskeletal* palatine is in the Green Turtle, in which it is very small (see *Challenger* Reports, vol. i. part 5, plate 12, Figs. 9, 9*a*, 9*b*: *e.p.a.*).

This endoskeletal cartilaginous palatine, with its peduncle and fore and hind ray or *crus*, appears in several kinds of birds, in addition to their normal *parosteal* palatine—a mere membrane bone, as in Reptiles and Mammals. This vestige or remnant remains in the adult; it is of no apparent use, and occurs in the Families in the oddest way; sometimes, however, it is present in all the members of some particular Family-group, as for instance in the Musophagidæ or plantain-eaters (*Musophaga, Schizorhis*, and *Corythaix*).[3] It is also found in the Oil Bird (*Steatornis caripensis*) and in the Green Tody (*Todus viridis*), and it is also well developed in *Scythrops* (see Linn. Soc. Trans., ser. 2 (Zool.), vol. i. plate 23, Figs. 3 and 4, *o.u.*).

In that nearly extinct Neotropical type, *Steatornis*, this curious partly ossified remnant has the three crura, all well marked, and their morphological meaning is evident; albeit the whole piece is so small and feeble that it can serve no purpose in the solid palate of that remarkable bird.

To show how unexpectedly this remnant exists, a list of the Birds in which it has been found in a segmented state as a distinct bony element of the face is added below; it often shows itself as a mere process of the ecto-ethmoid, but these cases are not included in the list.

[1] See Gegenbaur, "Ueber das Rudiment einer septalen Nasendrüse beim Menschen," *Morphol. Jahrbuch*, Bd. xi., 1885. At the time when the present paper was read, the author was not aware of Gegenbaur's conclusions with regard to the supposed rudiment of Jacobson's organ in Man.

[2] See W. K. Parker, "On the Skull of the Urodeles" (Phil. Trans., 1877, Plate 24, Figs. 1–3).

[3] See Reinhardt, "Om en hidtil ukjendt Knogle i Hovedskallen hos Turakoerne (*Musophagides*, Sundev)," Copenhagen, 1871, Plate 7.

Motacilla yarrelli, *Budytes rayi*. Motacillidæ.
Todus viridis. Todidæ.
Steatornis caripensis. Steatornidæ.
Schizorhis, *Musophaga*, *Corythaix*. Musophagidæ.
Dicholophus. Dicholophidæ.
Procellaria, *Prion*, *Thalassidroma*, *Diomedea*, &c. Procellaridæ.
Larus, var. spec. Laridæ.
Tachypetes. Tachypetidæ.

Another more partial remnant is seen in the Coracomorphæ or Passerine birds generally, which together make up nearly half the number of known birds.

A distinct nucleus representing the post-palatine region of the Frog's skull reappears in the Crow and the Sparrow, and in all the Passerines, as far as they have been worked out. It lies outside the hinder part of the normal parosteal palatine bone, becomes a solid ear-shaped tract of hyaline cartilage, acquires its own osseous (endosteal) centre, and this, when ossified, coalesces with the normal palatine bone.

These facts, and many others that could be mentioned, make it evident that, in seeking for a clue to the uprise of the Feathered Fowl, we may leave out of immediate consideration all the existing types of Reptilia: ancient Amphibians, or Reptiles just rising out of Amphibian lowliness, are the forms that alone will help us in this search. We do get some light upon the Reptilian relationship of Birds, but it is at best a scattered light; the head of a Bird is like that of the *Ichthyosaurus* in its great facial elongation, the neck- and limb-regions of a Bird are those of a *Plesiosaurus*, whilst the hips and legs are like those of the Ornithoscelida.

But these are not all, or nearly all, the vestigial structures that may be seen in the Bird's skull, to say nothing of the skeleton generally;[1] they are sufficient, however, to justify the assumption that Birds arose, by secular transformation, either from the lowest and most ancient of the true Reptiles, or equally with Reptiles from archaic Amphibia, low in structure, but full of potential excellence, and ready, *pro re nata*, to become Reptile, Bird, or even Mammal, as the case might be.

[1] As regards the skeleton of the manus and pes, the indications of at least five carpals (two of these in some types undergoing further subdivision), three small additional rudiments of digital rays in the manus, five tarsals, and a rudiment of the fifth metatarsal, are all important facts bearing upon this subject.

Physical Society, March 10.—Prof. Reinold, President, in the chair.—Mr. G. L. Addenbrooke exhibited and described a compact form of reflecting galvanometer, lamp, and scale, which he has designed as a portable commercial instrument, and also a modified Post Office Wheatstone's bridge.—Mr. E. C. Rimington read a paper on the measurement of the power supplied to the primary coil of a transformer. The first part of the paper contains a proof of a formula given by Prof. Ayrton at a recent meeting of the Society of Telegraph-Engineers for measuring the power given to a transformer by using a Siemens's wattmeter, and the disadvantages of the method are enumerated. A method is then described in which a high-resistance dynamometer is used. One coil of the dynamometer is placed as a shunt to the primary coil, and the other as a shunt to a known inductionless resistance, R, placed in series with the primary. The time constants of the dynamometer coils are made equal by adding an inductionless resistance to the one having the greatest time constant. Thus arranged the difference of phase between the currents in the dynanometer coils is the same as that between the P.D. and current in the primary of the transformer. The mean power, p_m, is shown to be

$$p_m = \frac{K}{R} \delta (1 + \tan^2\phi_1),$$

where $\frac{K}{R}$ is the constant of the dynamometer for watts, δ the reading of the torsion head, and ϕ_1 the lag angle of the currents in the coils of the dynamometer which can be determined from their time constant and periodic time. The best method of arranging the dynamometer in order that R may be as small as possible is discussed. Prof. Ayrton pointed out that the formula first referred to by the author was given to show *why a watt-meter should not be used*, and that the method suggested by Mr. Rimington was a modification of the well-known electrometer method, but with an additional serious objection, that the periodic time must be known. He also described a direct-reading method of using an electrometer, on ordinary transformer circuits, suggested to him by Mr. Sayers. Mr. Blakesley thought the above formula, given by Mr. Rimington, would only be true where there is no iron in the circuit. He described a method of determining the power by observations on two low-resistance dynamometers, one of which is placed in the primary circuit. Of the other dynamometer, one coil is placed in the primary and the other in the secondary circuit. The power is given by

$$p_m = A\alpha_1 r_1 + r_2 \frac{m}{n}, C\alpha_3$$

where r_1, r_2, m, n are the resistances and numbers of convolutions of the primary and secondary coils, A and C the constants of the dynamometers, and α_1, α_3 their reading. A geometrical construction from which the formula is deduced was given. Mr. Sumpner said all the formulæ at present obtained were founded on the assumptions that the induction coefficients of a transformer under working conditions are constant, but, in a paper to be brought before the Society shortly, he hoped to show these assumptions to be erroneous. In replying, Mr. Rimington said, if the periodic time was not known beforehand, it could easily be determined from the note given out by a telephone placed near the transformer.—On the magnetic circuit in dynamo machines, by Prof. W. E. Ayrton and Prof. J. Perry. An abstract was read by Prof. Perry. The authors have worked out a number of formulæ for dynamo machines, involving the thickness, t, of the armature winding, and α the highest permanent current density per square centimetre of cross section of that winding. One of them is

$$W = \frac{2vNt\alpha}{10^8},$$

where W = highest permanent output in watts, v = circumferential velocity, and N = total induction through the armature. As the winding is thin, $t\alpha^2 = q^2$, a constant. For the best modern machines, which do not get too hot, q has a value of about 288. It is shown that the best permanent output is a maximum when the magnetic resistance of the space occupied by the armature winding is equal to all the other magnetic resistance in the circuit, and the best machines are found to satisfy this condition. From this important result the characteristic of such a dynamo can be drawn with considerable accuracy. For small inductions the air resistance only need be considered, and a line drawn on squared paper connecting N and S′A′, satisfying

$$N = \frac{4\pi S'A'}{10} \div \frac{2(d + t)}{a_2},$$

gives the first part of the characteristic, where S′A′ = ampere-turns, d = clearance, and a_2 = the area of the pole pieces exposed to the armature (increased by a fringe of 0·8 $(d + t)$ all round). From the maximum value of N (viz. $a_1\beta_1$) where a_1 = area of diametral section of iron in armature, and β_1 = maximum induction (17,000 to 18,000), find the value of S′A′ from the formula

$$N = \frac{4\pi S'A'}{10} \div \frac{4t}{a_2},$$

and plot the values of N and S′A′ as the co-ordinates of a point. A curve drawn through this point to touch the line first drawn, at a point corresponding with $N = \frac{1}{2}a_1\beta_1$ will not differ materially from the characteristic of the constructed machine.—A note on the employment of an electro-dynamometer for determining the difference of phase of two harmonic currents of electricity, by Mr. T. H. Blakesley, was taken as read. This is a claim of priority for a method published by the author in the *Electrician* of October 2, 1885, which has recently been described and claimed as the invention of Prof. Ferraris, in a paper communicated to the Royal Academy of Science of Turin. In a book on "Alternating Currents," published at the end of 1885, Mr. Blakesley shows how the method can be used for determining induction coefficients and capacities.

Chemical Society, March 1.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—The origin of colour and the constitution of colouring matters, by Prof. H. E. Armstrong, F.R.S. The majority of compounds, especially those of carbon, are colourless; and in the case of elements

whose compounds are invariably coloured, the greatest diversity of colouring is often noticeable among the several compounds of one and the same element—as in those of chromium or manganese, for example: it is therefore clear that colour is in a high degree conditioned by special forms of intramolecular structure, and consequently that any attempt to determine the "origin of colour" must be based on a knowledge of the structure of coloured matters. For this reason it has become possible only within recent years to discuss the relation between colour and constitution, and, so far, the discussion has been limited to two papers by Graebe and Liebermann (*Ber. deut. chem. Gesellsch.*, 1868, 106) and by Witt (*ibid.*, 1876, 522) respectively. To illustrate the idea on which the argument in the paper is based, the author compares the unsaturated hydrocarbons with the paraffins. In the paraffins, which are singularly inert compounds, and all but colourless even in the infra-red and ultra-violet regions of the spectrum, the carbon atoms are united only by single affinities, and the remaining affinities are engaged by *monad* atoms; the unsaturated hydrocarbons, however, are not only more reactive than the paraffins, but the beginnings of colour are manifest in them in regions above and below the visible spectrum, whilst they are conventionally represented by formulæ in which the carbon atoms appear as united by two or three affinities of each, typified by straight lines or dots. Within recent years, however, the idea has found favour that "affinity has direction," and the author would apply this hypothesis to polyad atoms generally; and in formulating compounds in which such atoms are united by more than single affinites, would represent the polyad atoms as united by curved lines in order to suggest that the affinities are under strain in consequence of their being free to act only in certain directions. In the paper, the author cites a number of cases among inorganic compounds which he thinks afford evidence that the production of colour is dependent on special modes of atomic arrangement, and particularly on such modes of arrangement as involve the existence of a condition of strain in the resulting system, due probably to peculiarities in the affinity relationships of the constituent elements of the system which prevent complete mutual neutralization of the affinities. The occurrence of colour therefore is more frequently than not concomitant with a high degree of reactivity, the coloured compound being usually one of "high potential" or slight stability. Among carbon compounds there is no instance of a hydrocarbon being coloured, giving the term its conventional meaning; and omitting nitro-compounds, there are very few exceptions to the rule that derivatives of hydrocarbons containing only monad radicles are colourless; the exceptions, moreover, are of a very noteworthy character, being either *central* derivatives of anthracene, *i.e.* compounds formed by displacement of the hydrogen atoms of the central nucleus of anthracene—which although not coloured is significantly fluorescent; or the monad radicle contains at its origin a radicle such as CO. Attention is then drawn to the quinones and their derivatives, Fittig's ketone formula being throughout adopted for these compounds. The constitution of the better-known dye-stuffs is then discussed, and the author is led to conclusions which in some cases are different from those hitherto accepted; for example, the azo-dyes are formulated $O\smile C_6H_4\smile N.NHR'$ and $HN\smile C_6H_4\smile N.NHR'$; and rosaniline with its congeners, certain of the phthaleïns, and methylene-blue are also formulated on the quinone type. In the discussion on the paper, in which Profs. Debus, Rücker, and Dewar, Dr. Morley and others took part, Prof. G. C. Foster said that it appeared to him that the real question raised by Dr. Armstrong was whether a definite relation could be traced between chemical composition or chemical structure and the existence and position of absorption-bands in the spectrum of the transmitted radiation. The presence or absence of coloration, as it could be judged of directly by the eye, gave no conclusive answer to the question, for a substance might be as colourless as water, and still exert strong absorption in the ultra-red, or it might have strongly-marked absorption in the ultra-violet. But, more than this, a body might exert selective absorption within the visible spectrum, but if it happened to absorb two complementary colours it would be judged of by the eye as though it were destitute of selective absorption altogether. The subject, therefore, seemed to him to involve a systematic study of absorption-spectra.—Researches on chromorganic salts, Part II., by Mr. E. A. Werner.—Note on benzyldithiourethane, by Dr. A. E. Dixon.

Zoological Society, March 6.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of February 1888, and called special attention to some examples of a Finch from New Caledonia (*Erythrura psittacea*), and to five specimens of a Pheasant (*Phasianus principalis*) from Afghan Turkistan. The pheasants had been brought home and presented by Major Peacock, R.E., of the Afghan Frontier Commission, at the request of Sir Peter Lumsden, G.C.B., C.S.I.—The Secretary exhibited (on behalf of Lieut.-Colonel H. M. Drummond Hay) a specimen of the Desert Wheatear (*Saxicola deserti*), lately killed in Scotland.—A paper by Prof. G. B. Howes and Mr. W. Ridewood, on the carpus and tarsus of the Anura, was read. The authors recorded observations made upon thirty-seven genera and sixty species, in all stages of development, representatives of all but three or four less important families. The authors were at variance with previous writers in points which had necessitated a reconsideration of the morphological value of the leading elements of both carpus and tarsus. They had failed to discover, at any stage, a trace of a third proximal element in either fore or hind foot, while they showed that Born was in error in regarding the *naviculare* as the prehallux tarsal. In the hind foot they recorded the discovery of a fourth tarsal, and in the fore foot that of a fifth carpal, which latter in *Xenophrys* was bony. Consequent upon this they regarded the element hitherto held to be the fifth carpal as a postaxial *centrale*; whence it followed that the Anura are, as a group, unique in the possession throughout of a double *centrale carpi*. The authors discussed the various changes undergone by the pollux and prehallux, and the several views concerning the morphological value of the latter. A second part was added, in which the peculiarities of the several families of the Anura were given in order, and the bearings of the structures in question upon classification briefly discussed. The Discoglossidæ were shown to combine most completely the least modified conditions of both fore and hind feet.—Mr. R. Bowdler Sharpe read descriptions of new species of birds, of which specimens had lately been received from the Island of Guadalcanar, Solomon Group, collected by Mr. C. M. Woodford. These were named *Astur holomelas*, *Astur woodfordi*, *Astur shebæ*, *Baza guadalcanarensis*, *Ninox granti*, *Graucalus hololius*, *Edoliisoma erythropygium*, and *Pomarea erythrosticta*.—Mr. W. R. Ogilvie Grant contributed a complete list of the birds obtained by Mr. Woodford on the Islands of Guadalcanar and Rubiana. These were altogether sixty-six in number, the new ones being *Nasiterna aolæ*, *Myzolema sharpii*, *Phlegœnas solomonensis*, *Ardeiralla woodfordi*, and *Nycticorax mandibularis*.

Entomological Society, March 7.—Dr. D. Sharp, President, in the chair.—Mr. J. H. Leech exhibited, and made remarks on, a number of butterflies forming part of the collection made for him last summer by Mr. Pratt, at Kiukiang, Central China. The specimens exhibited included *Papilio Macilentus*, hitherto only recorded from Japan, varieties of *P. Sarpedon*, and a supposed new species of *Papilio*; a series of *Sericinus telamon*; *Charaxes narcæus*, and var. *mandarinus*; *Palæonympha opalina*; new species of *Lethe*, *Apatura*, and *Neptis*; and a series of *Argynnis paphia*, with the var. *valezina* of the female. Mr. Leech stated that all the females of *A. paphia* taken at Kiukiang belonged to the var. *valezina*, the typical form of the female being unknown there. Mr. Poulton expressed his interest in Mr. Leech's statement that *valezina* was the only form of the female of *Argynnis paphia* known at Kiukiang, and said he considered this fact would probably throw a new light on the question of the dimorphism of the species. Mr. Jenner-Weir said he had in the course of some years obtained a series of forms intermediate between the typical female and the variety *valezina*. Mr. H. Goss, Dr. Sharp, and Mr. McLachlan, F.R.S., continued the discussion.—Mr. Champion exhibited, for Mr. J. J. Walker, R.N., about 950 species of Coleoptera, recently collected by the latter near Gibraltar. Mr. McLachlan called attention to the large number of water-beetles included in Mr. Walker's collection.—Mr. Verrall exhibited living specimens of *Aspidomorpha sanctæ-crucis*, from the caves of Elephanta.—Mr. Slater exhibited specimens of a species of weevil which had been doing much damage to maize sent to the Colonial Exhibition.—Mr. W. White read a paper entitled "Experiments upon the colour-relation between the pupæ of *Pieris rapæ*, and their immediate surroundings," which comprised a detailed account of a series of observations carried on at the author's instigation by Mr. G. C. Griffiths. The various experiments were intended to act as a test of the conclusions arrived at by Mr.

Poulton in his paper on the subject in the Transactions of the Royal Society; and to effect this object different and additional influences had been brought to bear on these pupæ, so that an analogy might be drawn between the two sets of results. Mr. Poulton, Lord Walsingham, F.R.S., Mr. Jacoby, Dr. Sharp, and Mr. White took part in the discussion which ensued.

PARIS.

Academy of Sciences, March 12.—M. Janssen in the chair.—Remarks accompanying the presentation of the second edition of his "Traité de Physique Mathématique," by M. H. Resal. To this edition have been added sections on mathematical optics and thermodynamics, enlarging the work from one to two volumes.—On the combination of measures of the same magnitude, by M. J. Bertrand. An attempt is here made to estimate the consequences of rejecting measures assumed to be less accurate as departing furthest from the mean in the doctrine of probabilities.—New theory of M. Lœwy's equatorial *coudé* and equatorials in general, by MM. M. Lœwy and P. Puiseux. An improved method is described for more accurately determining the constants both of bent and straight equatorials, with the most rapid processes for mounting and rectifying these instruments.—On phosphorus and phosphoric acid in vegetation, by MM. Berthelot and G. André. As a general result of their experiments, made especially on *Amaranthus caudatus*, the authors find that, after the normal flowering, the employment of phosphorous, and even to some extent of nitrous, manures seems almost, if not altogether, useless, whereas potassic manures may still be advantageously continued as long as vegetation lasts.—Classification of the Gasteropods, based on the various dispositions of the nervous system, by M. H. de Lacaze-Duthiers. This is a purely synthetic treatise, summing up the long and numerous analytical studies on the nervous system of various mollusks, such as Gadinia, Aplysia, Tethys, and many others described in the *Comptes rendus* and elsewhere. The object is to ascertain what data may be supplied by these different types of nervous systems for a physiological classification of the secondary groups of Gasteropods. Two sub-classes with five orders are proposed for the whole class.—On a general theorem of convergence, by M. J. L. Jensen. The studies undertaken by the author with a view to a generalization of the theory of convergence of a series with positive terms have led to an unexpected simplification of the present theory. It is shown that the criteria of Cauchy, of Duhamel and Raabe, of Bertrand, and others, may henceforth be treated summarily as simple corollaries of one general theorem.—On the measurement of magnetic fields by diamagnetic bodies, by M. P. Joubin. The author's renewed attempts to utilize the magnetization of diamagnetic bodies for measuring the intensity of a magnetic field seem to demonstrate the existence of several states of magnetic equilibrium in diamagnetic bodies. This unexpected result is in accordance with theory according to Duhem's calculations, as well as with the general considerations recently set forth by M. Brillouin.—On the magnetization of diamagnetic bodies, by M. P. Duhem. The grounds are explained which render highly probable the existence of several states of magnetic equilibrium for diamagnetic bodies placed in a given position and subjected to the action of given magnets.—A new eolipyle, by M. Paquelin. The apparatus here described has the advantage of working in any position without the risk of explosion, and consumes not more than 90 grammes of fuel in the hour.—Determination in wave-lengths of the two red rays of potassium, by M. H. Deslandres. This determination, made at the request of M. Lecoq de Boisbaudran, yields for the stronger ray 766·30, for the weaker 769·63, giving a mean 767·965, compared with 588·89 of the D_2 sodium ray, which served for the calculation of the constant.—On the decreasing solubility of the sulphates, by M. A. Etard. The sulphates of iron, cadmium, magnesium, lithium, rubidium, and potassium, as well as anhydrous selenious acid, all present the same phenomenon of decreasing solubility. But that of iron, like the previously described sulphate of copper, changes direction twice, first increasing and remaining constant, then decreasing; the complete series of transformations being accomplished between $-2°$ and $+156°$ C.—Action of roasting on several oxides and salts of manganese, by M. Alex. Gorgeu. The anhydrous protoxides heated briskly leave a red oxide; slowly roasted, so as to avoid incandescence, and then kept at a dull red until the weight of the residuum ceases to change, they yield a sesquioxide; lastly, when heated from 200° to 430° C., the oxidation of the MnO obtained at a high temperature is very slow, and appears not to go beyond the manganite $MnO_2 4MnO$, even after forty or fifty hours. Several other details are given of these interesting experiments.—On the collection of star-fish brought to Europe by the French Scientific Mission to Cape Horn, by M. Edmond Perrier. This collection comprises no less than 553 specimens, referred to 38 distinct species, of which 23 are new. This gives to the southern waters of the American continent a total of 57 species of these organisms.—M. J. Kunstler describes a new Foraminifer from the Arcachon basin.

ELEMENTARY INSTRUCTION IN PRACTICAL BIOLOGY.

A Course of Elementary Instruction in Practical Biology. By T. H. Huxley, LL.D., F.R.S., assisted by H. N. Martin, M.A., M.D., D.Sc., F.R.S. Revised Edition. Extended and Edited by G. B. Howes, Assistant Professor of Zoology, Normal School of Science and Royal School of Mines; and D. H. Scott, M.A., Ph.D., Assistant Professor of Botany, Normal School of Science and Royal School of Mines. With a Preface by Prof. Huxley, F.R.S. (London: Macmillan and Co., 1888.)

THE appearance of the first edition of "A Course of Elementary Instruction in Practical Biology" in 1875 marked an epoch in biological education. The great effects which the doctrine of evolution had been gradually producing in the general system of biological education were then set forth, and widely extended, by means of a clearly written volume containing an account of thirteen types of the organic kingdom. On the appearance of a greatly extended edition of the work, it may not be out of place to say a few words upon the "type-system" of biological education for which the book in its earlier form has done so much. The immense educational success of the work may perhaps be best judged by the fact that, since its publication, an ever-increasing demand has rendered necessary the production of quite a number of new books following the "type-system," and constructed on an identical plan, but dealing with other forms of life.

The important changes in teaching which have followed these publications are seen in the far smaller amount of systematic and classificatory work which is now imposed upon beginners, and its replacement by the acquisition of a thorough knowledge of well-selected types. Remembering that classifications are no more than a condensed abstract of the opinion of the day upon the relative affinities of organic forms, it is clear that no one of the suggested schemes of arrangement can be regarded as final, except as perhaps expressing in the best way the results of a limited state of knowledge. We know that opinion on the subject of affinity has greatly changed in the past, and as long as new facts are revealed by biological research, so long will opinion continue to change in the future. From its necessarily shifting character, and from the fact that the teacher cannot fairly insist upon the accuracy of its conclusions, classificatory biology is eminently unsuited to the needs of a beginner. And there is also another reason, in that classification, if properly taught, is far too advanced a subject to be made an element in early education. If classification is the concise expression of biological opinion, it should nevertheless represent an opinion arrived at after the consideration of *all* the facts and arguments which bear upon the question. The true and only vindication for any suggested modification of existing schemes of affinity must lie in the decided proofs of a better accordance with existing facts. Whoever suggests a modification is under a great responsibility, for, if the alteration is not an improvement, it will certainly be pernicious in adding to our present state of confusion. It is to be hoped that the whole subject will be treated in a more serious spirit in the future than has been accorded to it in the past.

If, then, classification must be dethroned from the high educational position it has held for so long, and which it still maintains to a considerable extent in botanical teaching, what is to be put in its place? Under the type-system a beginner is set to acquire a thorough knowledge of certain central forms of life, each of which is an example of, and a key to, the understanding of an important organic group. At first the types only represent the very largest groups, such as the sub-kingdoms, so that the amount of implied classification is extremely small. As the student progresses, the number of types increases, and the less important organic groups are represented, so that at the end of his course the advanced student finds himself a master of the solid framework of classification, and then the filling in of the details can be carried on in an intelligent and satisfactory manner. It is at this advanced stage of education that advantage can be gained by means of the celebrated "Hunterian system." The comparative study of long series of homologous structures, considered out of relation to the organisms in which they occur, can only confuse the beginner who is not well acquainted with the organisms themselves. But just as the type system prepares the way for, and in fact culminates in, all that is educationally important in classification, so, when a large number of types has been thoroughly learnt, and the varied relations of organ to organ, and of isolated structure to the whole organism, have been grasped in very many instances, then, and not till then, can great advantage be gained by the Hunterian method. And the *extensive* use of this system will be wisely postponed to a very late period; in fact, until the student is beginning to make use of the training which he has received in the wide fields of biological research. The Hunterian system must always form the backbone of a large part of biological research, although it would be most unwise to make it a fundamental part of biological education. It must, however, be conceded that there are certain systems of structures (such as the osteological and dental systems) which especially lend themselves to this mode of teaching, but on account of this very facility such subjects are liable to assume too great a relative importance in biological training.

One incidental, but by no means necessary or even natural, result of the prevalence of the type-system is to be greatly deplored. This result, which is especially found among students of botany, follows from the habit of rejecting the good as well as the bad points in a disused system. Just as the introduction of section-cutting has led to a too great neglect of dissection and the examination of solid structures, so the prevalence of the type-system seems to threaten the existence of the field naturalist and botanist. Those who follow the old, and, upon the whole, the very foolish system of botanical education which a few years ago was the only system taught, have at least one great advantage: they have a keen and intelligent interest in any country walk, while if they possess a little originality and perseverance, they can contribute something towards the solution of some of the most difficult biological problems. But it is not at all uncommon for the successful student of the newer

system to speak of field botany with utter contempt, as a subject unworthy of notice. This is a very unfortunate thing, for there are many most interesting questions which can only be settled by field-observation; and field-observation is in itself a most important, and at the same time a most enjoyable, side of biological training. The same contrast also holds, although to a less extent, on the zoological side. It is much to be hoped that we may be able to correct this great error which has unfortunately attended a healthy, and, upon the whole, highly beneficial educational reaction. It is to be observed that the excellent general descriptions of the types which form so important a feature of the work are in every way calculated to avert this error.

The most striking thing in the revised form of "Practical Biology" is the reversal of the old arrangement, so that the student is now led to begin with a Vertebrate type, and from this to work his way down to the lowest forms of life, and from these, again, upwards to a type of the flowering-plants. There is little doubt that such a change will be met by conflicting criticisms. I believe, however, that the majority of those who have had the widest experience of biological teaching, and especially those who have instructed students in the first use of the microscope, will heartily agree with Prof. Huxley's defence of the alteration, in the preface to the revised edition. The process by which a student first learns to see with the microscope is almost like the education of a new sense-organ suddenly conferred upon a mature organism. We know that under such circumstances it would be a very long time before the impressions conveyed by the new organ could be harmonized with the well-known experiences resulting from the stimulation of other organs. Accustomed to judge of the shapes of objects by their appearance in three dimensions, the student is suddenly provided with a field of vision in which shapes have to be nearly always inferred from the appearance of solid three-dimensional objects when seen under conditions which prevent them from being examined in more than two dimensions at any one time. For it is a long time before the student can accustom himself, by focussing at successive depths, and by making the most of the limited third dimension of depth which the high powers of the microscope provide, to judge accurately of the forms of objects. And the novel conditions under which a student sees with the microscope effectually prevent him from making the best of the impressions he receives. Thus, if the section of a solid object presented the appearance of a circle 1 inch in diameter, and if two other sections at right angles to each other and to the first section presented the appearance of a rectangular figure 3 feet by 1 inch, nearly everyone would readily infer that the shape was that of a cylinder 3 feet long by 1 inch in diameter. But precisely similar data, when presented in the field of the microscope, do not readily lead the student to any definite conclusions as to the forms of objects, and in reality a long course of discipline is necessary in order to make him form any clear conception of the actual shape of the object at which he is looking. I therefore think that it is expedient to begin the course of biological teaching with organisms which only require the use of a microscope for the investigation of part of their structure, and thus to gradually work downwards to the minutest organisms, in which the whole investigation depends upon high microscopic powers. Thus the gradual training in the use of the microscope will proceed parallel with its gradually increasing necessity.

The addition of the earthworm, the snail, and of Spirogyra is a great improvement upon the former edition of the work. If a choice were necessary, the snail is in many respects a more suitable type than the Anodon. In spite of the greater structural simplicity of the latter form, the anatomical details are more difficult to demonstrate by dissection and more difficult to see when dissected than those of the snail. This objection to the Anodon of course only applies to its selection in preference to the snail in the earlier edition; it is in every way desirable that the Lamellibranchs, as well as the Gastropods, should be represented by a well-known type. These newly added types and the additions to the descriptions of those in the previous edition, and to the practical directions, so increase the size of the volume that it contains almost exactly twice the number of pages present in the earlier form of the work. The practical directions given in the appendix appear to be excellent, and to contain in a very small compass an immense amount of information upon the most recent and approved methods. There are a few slips and indefinite statements which should be modified in succeeding editions, which will doubtless be called for at no distant date.

Thus, on p. 383 we are told that *one or two per cent.* of the sugar is unaccounted for in fermentation; but for the rest it is only loosely stated that the *greater part* is resolved into carbonic anhydride and alcohol and *a small part* into glycerine and succinic acid. On pp. 384 and 386 it would be well to represent the numerical proportions of the formulæ by the same method. On p. 462 it is wrongly stated that the cotyledons become green in the type selected. They are in reality hypogeal. On p. 467 no phosphorus is mentioned in the culture solution in which it is stated that the bean-plant will grow. It should read: "potassium phosphate, iron sulphate," instead of "potassium and iron sulphate." In the note on p. 475, "discolour" is used for "decolorize." On p. 483 the student is advised to procure 2 ounces of microscopic slides and half a gross of cover-slips!

Such slight errors can easily be put right, and they would in most cases be detected by the student in reading the book for the first time. They cannot be considered as seriously detracting from so excellent a book, and one which, in the extreme clearness of its style, is so admirably adapted to the needs of the beginner.

E. B. P.

A TEXT-BOOK OF EMBRYOLOGY.

Lehrbuch der Entwickelungs-geschichte des Menschen und der Wirbelthiere. Von Dr. Oscar Hertwig, o.ö. Professor der Anatomie und vergleichenden Anatomie der Universität, Jena. (Jena: Gustav Fischer, 1886.)

THE brothers Hertwig are highly esteemed as original investigators in the field of embryology wherever that science is cultivated. The completion of a systematic work by one of them on the conventional lines of human embryology is therefore a matter of some moment. An

embryologist who bends himself to the requirements of the stereotyped curriculum of human anatomy as demanded alike by German and English directors of medical education, necessarily abandons more or less the consistent scientific treatment of a branch of human knowledge. There is a conventional embryology of the medical school just as there is a conventional anatomy, histology, and physiology, and as there would be a "medical" chemistry, physics, and biology, and a "medical" alphabet, if some professional men in London were to have their own way. Prof. Hertwig has suffered somewhat by submission to these demands. The second half of his work consists chiefly of a description of the development of the various organs, and would more appropriately find its place in that dullest, but most necessary, of treatises—a text-book of human anatomy. The first part, however, is not open to this objection, and even in dealing in the usual way with the development of the organs of the human body in the second half of his work, Prof. Hertwig has managed to bring in a good deal of that scientific interest which is briefly indicated by Goethe's word "morphology." Nevertheless the detachment of the consideration of the mode of origin of the organs of the human body from that of their adult structure and of the structure and development of the same organs in other animals is, in our opinion, an antiquated and mistaken usage, which we are sorry to find so able an author as Prof. Hertwig constrained to follow.

In his first part Prof. Hertwig adopts a more general and truly scientific treatment, and does not distinctly aim at supplementing the work of the topographical anthropotomist. His first chapter is a description of the sexual products, and his consideration is by no means limited to the ovum and spermatozoon of the human species. A comprehensive, though brief, account of the subject with reference to various recent writers is given, and the classification of animal eggs proposed by Balfour is adopted, viz. alecithal, telolecithal, and centrolecithal.

The maturation of the egg and its fertilization are treated in the second chapter, with special reference to the Echinoderma and other Invertebrata, where it has been possible to study this subject with advantage. A third chapter treats of the process of egg-cleavage—the formation by division of the first embryonic cells; a fourth, of the general principles of development—the latter decidedly brief and undeveloped to a degree which is disappointing. Then we come to a chapter on the development of the two primary germ-layers—or on the gastræa theory, as Prof. Hertwig puts it—in which the apparent differences of development of these two layers in various Vertebrata are considered and reconciled, numerous illustrations being introduced into the text, of which a larger number are taken (with ample acknowledgment both in the text and in the special titles of the cuts) from the "Comparative Embryology" of the late Prof. Balfour than from any other source.

The development of the two (parietal and splanchnic) middle germ-layers (cœlom theory) is the next subject of consideration, and is elucidated by a consideration and figures of the process in Sagitta, Amphioxus, Triton, the Mole, &c. The seventh chapter, on the history of the germ-layer theory, is an able and fair statement of the history of embryological doctrine such as every student should be familiar with, and it brings us to the special Hertwigian doctrine of pseudocœl and mesenchyme. The latter is further placed before the reader in the chapter on the development of connective substance and blood. In dealing with the special subject of this book Prof. Hertwig has no occasion to enter upon the question of the pseudocœl—a theoretical conception which, in our opinion, is unnecessary, and not supported by even plausible evidence. The use of the term "mesenchyme" for those cell-elements of the mesoblast layer which lie below the layers immediately bounding the cœlom, and which give rise to connective-tissue and to blood, is, in our opinion, inadvisable. The distinctness which is implied in the use of this term is not, it seems to us, in accordance with the facts of embryology, and we think that embryological appearances may be more correctly stated without introducing the conception of a distinct "mesenchyme," and without postulating a "pseudocœl" in certain Invertebrata, and by adhering to what we may call the "uniformitarian" system, which seeks to explain "pseu docœl" and "mesenchyme" as a special modification of the normal "cœlom" and "mesoblast" respectively—these modifications arising independently under given mechanical conditions in various developmental histories. At the same time, it must be admitted that the attempt to assign a special importance and genetic persistence to "mesenchyme" on the part of the brothers Hertwig has led them to bring many important embryological facts into clear view. The speculations of His as to parablast and archiblast are finally rejected, and a comparatively harmless, though, it would seem, superfluous, theory replaces it.

In the chapter on the primitive segmentation of the body, we come to closer quarters with the ultimate aim of the treatise, viz. the human embryo; and this is followed by chapters on the "Formation of the External Form," and on the "Egg-membranes of Birds and Reptiles," and on the "Egg-membranes of Mammals." These are well illustrated by some of the best amongst already familiar woodcuts (from Balfour, Kölliker, and Turner), and by a coloured plate. At length, in the last chapter of the first portion of his work, Prof. Hertwig brings us to the human interest which has been the motive of all the previous exposition. Here are discussed the "Human Egg-membranes." The medical student is at last rewarded for his patience in wading through the chapters of a scientific treatise, and has the embryo of Allen Thomson, of Coste, and of Krause made clear to him. An excellent account of the structure of the human placenta, accompanied by many woodcuts and by a coloured plate, is given.

Then follows the second "Abtheilung," with its necessarily uninteresting and disjointed account of the development of organs. Whilst recognizing the value, and, in many features, the originality, of this part of the work, we must insist that even so accomplished a writer as Prof. Oscar Hertwig could only do justice to this subject by treating it as part of a comprehensive work on the morphology of Vertebrata, and this the space at his command has not allowed him to attempt. The student will, however, find clear expositions and the latest information on the development of the organs of Vertebrata, with a special reference to the higher Mammalia or man. As an example of the thoroughness with which

Prof. Hertwig has availed himself of the latest inquiries, we may call attention to two figures of the pineal eye of Chameleon and Hatteria, copied from Prof. Baldwin Spencer's memoir in the *Quart. Journ. Micr. Sci.* of last year. Full justice is done by Prof. Hertwig to Mr. Spencer's researches and their significance. We can cordially recommend this text-book of embryology as presenting a decided advance in scope upon the current German treatises on human embryology, one of its merits being that it embodies, among other good things, the teachings and many of the drawings of our "unvergesslicher" Balfour.

E. R. L.

A TREATISE ON ALGEBRA.

A Treatise on Algebra. By C. Smith. (London: Macmillan, 1888.)

THIS, the latest text-book on elementary algebra, is intended for the higher classes of schools and for the junior students in the Universities. The title of the book "A Treatise on Algebra," together with the fact that in the preface the book is affirmed to be complete in itself, is likely to convey the impression that the work is more extensive and ambitious in its scope and design than is really the case. In regard to the matter treated of, it covers much the same ground as Todhunter's "Algebra," which it greatly resembles; it differs from it chiefly in a different arrangement of the parts of the subject, and in the introduction of elementary notions of "elimination" and "determinants."

As regards rearrangement of the subject-matter, there is one very gratifying novelty: before making any use of infinite series, the author introduces a chapter in which he discusses some of the tests of the convergency of such series. There is no doubt of the soundness of this course, and for this single reason many teachers would be inclined to prefer this book to others of the same nature.

The principal feature of modern elementary algebraical text-books seems to be that they are written without any reference to the light shed upon the relative importance of different parts of the subject by the progress of algebraical research. A comprehensive survey of the existing knowledge of the science should induce an author to lead the schoolmaster, and not to follow him. It is not too much to expect that a book like the one under notice should bear some traces of what is taking place in the development of the science to which it seeks to introduce a student. It is perfectly true that certain fundamental notions must necessarily be presented in much the same detail relatively in every book, independently of the date of production; but beyond this an author may easily be too conservative in his ideas to be able to compile a work which shall be of the greatest advantage to a student who intends subsequently to continue his reading at a University or elsewhere. Even from the narrow point of view of an examination it would be advisable to give some small indications of the directions in which explorations have been recently taking place, for it is well known that problem papers at the Universities and elsewhere frequently contain matter taken from researches quite recently published. The absence of modern ideas in a book gives a teacher but little opportunity of pointing out to promising pupils the roads to the frontiers of the science. This is the more to be deplored just now, when a premium is placed at Cambridge upon originality of thought in connection with examinations for Fellowships.

As an instance of what is meant, it may be observed that the subject of "reversion of series" is omitted altogether, although it has of recent years come into great prominence. As a fact, for the last three years one of the chief points of interest in pure mathematics has been Sylvester's theory of reciprocants, which are simply reversion invariants; that is to say, those functions of the coefficients of a convergent series which remain unaltered after the process of reversion has been carried out. One has a right to expect, for this reason, that a "Treatise on Algebra" published at the present time should make some allusion to the existence of such a process; in the older text-books, such as Young's "Course of Mathematics," and the "Algebra" published in Chambers' series, the subject received a special heading, whilst in more recent works it appears merely as an example. The present time is not happily chosen for its complete banishment.

"Scales of notation" give place here to "systems of numeration"; this is in accordance with the German "Zahlensysteme," and seems to be a more suitable nomenclature.

The definitions throughout the book are very carefully given. One or two are open to criticism, as in the case of "cyclical order"; this is defined in reference to a "cyclical change of letters." In modern mathematics this process is termed a "cyclical substitution of the letters," and is one of the fundamental ideas of the extensive "theory of substitutions." There seems to be no good ground for shirking the word "substitution," which fulfils requirements of simplicity and suggestiveness, and is the word with which the student will afterwards become familiar. It seems a pity that in the chapter on permutations the opportunity is not taken to introduce a few of the leading ideas of this theory.

In defining "symmetrical expressions" the author states that an expression which remains unaltered by the "cyclical change" is *also* considered symmetrical; the modern definition of a symmetrical function is that it is such that it remains unaltered when any substitution is impressed upon the letters. The expression $(b-c)(c-a)(a-b)$, instanced by the author as being also called symmetrical, is in reality a two-valued (sometimes called an alternating) function, falls under a different (the alternating) "group of substitutions," and is not properly called symmetrical.

In the chapter on theory of numbers—a particularly clear one—the idea of congruences is happily introduced with Gauss's notation. One would have liked to see also some of the notions of Sylvester's "constructive theory of the partition of numbers," as the ideas are very simple and useful, and moreover algebraically expressible most elegantly. The partition of numbers is rapidly becoming a most important part of the "theory of numbers," a fact which must soon be recognized by authors of books of the same scope as this one.

Other portions of the book which are well presented are "factors" (including many of the first notions of the "theory of equations"), "imaginary and complex quantities," and "binomial theorem."

One would like to see "piles of shot" relegated to the examples, as in these days of rifled guns and elongated projectiles it seems an anachronism. The book is logical, well printed, and illustrated by the best set of examples that can be found in any book of the same kind.

P. A. MACMAHON.

OUR BOOK SHELF.

My Telescope. By a Quekett Club Man. (London: Roper and Drowley, 1888.)

THIS volume is described by its author as a simple introduction to the glories of the heavens. It is not designed as a guide to the use of a telescope, but simply to give such an account of its teachings as may interest non-astronomical readers. The main features of the various celestial bodies are described, but, for some reason or other, comets are not considered at all. Most of the descriptions are very meagre; thus, nebulæ and star-clusters are disposed of in a page, and that not closely printed; even the sun—"the ruler of our system"—is described in a little over three pages. The scantiness of the information given is the greatest fault of the book.

In the little that the book does contain, many mistakes occur. Thus, the moon is stated to present a marbled or mottled appearance because her surface is unequally refractive (p. 62), and the velocity of light is twice put down as 184,000 miles per second (pp. 46 and 72.)

The illustrations are moderate, and the book has a generally neat appearance. The place it is to occupy in astronomical literature, however, is not very clear, as there are already many cheaper books in existence which contain the same information, and much in addition.

Hand-book of Perspective. By Henry A. James, B.A. Cantab. (London: Chapman and Hall, 1888.)

THIS small book contains the principles of perspective explained in a plain and concise way. The author seems to have taken great trouble to make his meaning as clear as possible, and has spared no pains in getting together a good collection of examples, which are all worked out and accompanied in each case by a diagram.

The examples themselves would form a useful and practical course on the subject, since they are arranged in a progressive order, starting with the projection of a single point, and taking up in turn lines, surfaces, and solids.

Beginners will find this volume very serviceable to them, pictures as well as diagrams being given to illustrate the various positions of planes, lines, &c.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Coral Formations.

IN the last paragraph of my letter which appeared in your issue of the 15th inst. (p. 462), I remarked:—"It is quite reasonable to suppose that the dead coral so dissolved in the formation of lagoons is carried out as material for fresh coral growths."

Mr. T. Mellard Reade, in a letter on the same subject, dated 22nd inst. (p. 488), in criticizing the results published by Mr. Ross's letter of the 15th (p. 462), remarks:—"I believe that at no place on the surface of the globe are such dead shells being supplied at a rate that would even balance this supposed rate of chemical destruction."

Can Mr. Reade give any observations or figures in support of his view of the rate of accumulation of oceanic calcareous deposits?

Laying aside all question as to arithmetical error, and without committing myself to the accuracy of Mr. Ross's figures (or even insisting on my own), as to the amount of dead carbonate of lime dissolved in any given time by sea-water in lagoon formation, but taking it as a fact that it is soluble in a marked degree (as is proved by the experiments made by Mr. Ross and myself), and that coral reefs can only exist in regions under the influence of the great warm tropical ocean currents, then we may expect the waters of coral-bearing regions to contain a greater proportion of lime than is found elsewhere, thus forming the calcareous food for continuous extension of the coral formations.

Of course, a distinction must be drawn between the so-called *dead* and living coral, in thus far that the latter is protected from the solvent action of the sea-water by its vitality, while the former, as referred to in my last letter, is peculiarly susceptible to this influence.

ROBERT IRVINE.

Royston, Edinburgh, March 26.

Professor Rosenbusch's Work on Petrology.

READERS of NATURE interested in the study of petrology will be grateful to Dr. Hatch for his lucid review of Rosenbusch's great work, and those who are not able to profit directly by the German original will be glad of the *résumé* given of the latest classification of the massive rocks according to the views of the greatest living authority on the subject.

A translation of Rosenbusch's book into English is much to be desired. Rich as we are in fragmentary literature on the subject, a leading text-book is still wanting. Dr. Hatch would deserve well of his fellow petrologists if he would give them a translation of the work he reviews so well. There might be room for some cutting down in dimensions, especially in the treatment of the "neo-volcanic" rocks. Rosenbusch himself is conscious that this part of the work is, perhaps, a little overloaded with detail, as he says that with a new structure "the scaffolding is not removed before the house is finished," and possibly a competent translator might consider that a little less scaffolding would still be sufficient.

There will no doubt be more or less difference of opinion among authorities as to the correctness of the views which have governed Rosenbusch in his system of rock-classification, especially on one or two points. But none will deny that this classification, with the immense research and study accompanying and supporting it, fully given to the student in this latest work, are a splendid achievement.

Dr. Hatch does well, especially in the interest of younger workers in petrology, to insist on the purely arbitrary nature of *any* system of classification, so far as the separate "rock-types" are concerned; such types passing more or less gradually into others, on either side of them, in all cases. Rosenbusch himself points this out, but a further emphasis of the warning was well in place.

In working with a large text-book like the one in question, with its minute treatment of small details, the student is apt to neglect this consideration of the passage of one rock into another, or at any rate to devote too little attention to it. Nothing, however, could be a greater safeguard to him in this respect than to make for himself a tabular arrangement of Rosenbusch's system, so that the eye can follow in a moment the relationships of the different rock-types to each other. I think it is a pity that such a map, as it were, does not accompany the book. The attentive study of it would not only much assist the worker in his detailed use of the book, but would also greatly aid the beginner to "keep his head level" and steer clear of the sad pitfall of going in too much for "pigeon-holes."

Perhaps an outline table of this sort, which I inclose, may be of a little use to some of your readers, if only to give a compact view of Rosenbusch's classification and of how he connects the main rock-types in series through the four divisions of plutonic rocks, dyke-rocks, palæo-volcanic rocks, and neo-volcanic rock.

An amplified table on the same model, with the various

leading sub-types under each main type, is what I have tried to indicate. Such a table makes clear at once not only the passage of, say, syenites into trachytes, diorites into andesites, but also that of trachytes into andesites, andesites into basalts, &c., &c.

Plutonic Rocks	Dyke Rocks	Effusive Rocks: Palæo-volcanic	Effusive Rocks: Neo-volcanic
Granites	Muscovite-Granite (Aplite) Granite-Porphyries	Quartz-Porphyries	Liparites Pantellerites
Syenites	Syenite-Porphyries Syenitic Lamprophyres	Quartzless-Porphyries	Trachytes Basic Pantellerites
Elæolite Syenites	Elæolite-Porphyries		Phonolites Leucitophyres
Diorites	Diorite-Porphyrites Dioritic Lamprophyres	Porphyrites	Dacites Andesites
Gabbros and Norites		Augite-Porphyrites and Melaphyres	Basalts
Diabases			
Theralites			Tephrites Basanites
Peridotites		Pikrite-Porphyrites	Limburgites Augitites
			Leucite Rocks
			Nepheline Rocks
			Melilite Rocks

A student who has attempted, with plenty of good sections to work on, to draw a definite line between trachytes and andesites, or augite-andesites and basalts, will probably not easily again fall into the error of believing in hard-and-fast types!

Dr. Hatch has at once indicated two main points which will strike petrologists as open to criticism in Rosenbusch's system: the "dyke rocks," and the subdivision of the effusive rocks into "palæo-volcanic" and "neo-volcanic." With regard to the former it deserves to be pointed out that it has not been found possible to classify any representatives of the diabases and gabbros under the head of dyke rocks at all; and one feels that very considerable force has been used, in some other cases, in order to get the rocks under this division into their proper "pigeon-holes."

Something of the same sort of strain and artificiality is felt in some cases with regard to the two divisions of the effusive rocks, and here again it is, perhaps, the equivalents of the diabases and gabbros which most strongly exemplify this feeling—viz. the augite-porphyrites and melaphyres, and the basalts.

Many passages, in several parts of the book, show how fully conscious Rosenbusch is of the weak places there are in his system, as there must always be weak places in every system in a young and rapidly growing science like microscopic petrology. One does not know which most to admire—the wonderfully wide research and knowledge, and the skill and painstaking care and labour, with which the system of classification has been evolved out of the great amount of material to hand, or the great modesty with which it is presented to us.

It will be a thousand pities if a translation of the book does not before very long find its way into the hands of all English-speaking petrologists. A. B.

Manchester, March 19.

"The Mechanics of Machinery."

ANY errors—or what seem such—in a work of so high character and repute as Prof. Kennedy's "Mechanics of Machinery" may be conveniently noticed in NATURE; and therefore no further reason need be offered for the following remarks.

(1) "If, then, a body is moving with a linear velocity of v feet per second about a centre (permanent or virtual) at radius r feet, it is undergoing a radial acceleration of $\frac{v^2}{r}$ foot-seconds per second, and the centrifugal force corresponding to this acceleration will be $\frac{v^2}{r}$ pounds per unit of mass . . . ." (p. 228).

Surely there is some confusion here between the virtual or instantaneous radius, and the radius of curvature; for it is of course the latter which indicates the radial acceleration.

It has always seemed to me that the common expression that a body is turning "about," or, as Prof. Kennedy sometimes puts it, "round," its virtual centre is very apt to mislead. All that we are entitled to say is that at any given instant one point is at rest; and that all other points are moving in directions at right angles to the lines joining them with that point, and with velocities proportional to those lines. This being true also in the simple case of motion in a circle we are apt to use the same language to express it, with the inevitable suggestion of the *curvature* being in correspondence. It need not be said that the curvature may be zero (as when a circle rolls inside one of twice its diameter); or that it may be *away from* the centre (as when the former circle is more than twice the diameter of the second). The beginner would find it hard to realize the latter case when he has been taught to speak of the body "turning round" its virtual centre. I do not know that any better description can be adopted, but it ought to be introduced with emphatic cautions that it is merely a convenient device of description. In any case it seems to me that the old term "instantaneous centre" is more likely to keep the truth before us than the "virtual centre" preferred by Prof. Kennedy.

(2) In a series of interesting discussions about train resistance, the following passage occurs: "The brake resistance is 1200 pounds, but it has to be overcome through a distance π times as great as that moved through by the train as a whole . . . . ;" this brake resistance having been described above as "the frictional resistance at the periphery of each wheel."

I cannot follow this. Surely if the circumference of the wheel be x feet, by the time the train "as a whole" has run over a rail-length of x feet, the brake has slid over a wheel-circumference of x feet also.[1]

This need hardly have been noticed, but that the examples seem always very carefully chosen, not as fancy problems, but as being in accordance with practical experience. Either, therefore, the common impressions as to the time and distance requisite for stopping must be wide of the mark, or the value assumed, in this and a number of other examples, for the brake resistance, must be about three times too small.

(3) "If, for instance, the brakes had not acted promptly, and had been put very hard on at the end, the velocity and acceleration curves might have been as dotted, when the maximum acceleration occurs almost at the end, a state of affairs very uncomfortable for the passengers" (p. 205).[2]

Is this so certain? I mean, is there any reason to suppose that a sudden change of *acceleration*, not of *velocity*—for of this there is no question with any conceivable brake system—would be felt as disagreeable?

The question must, one would think, have often presented itself to speculative and scientific engineers; but as I do not remember to have seen it discussed one would like to get their opinion on the point. The way it strikes me is this. We cannot practically suppose the acceleration *put on* instantaneously, for the brake needs time to work; but we can get as near as Nature allows to the instantaneous when it is *taken off*. That is, if the brakes are left on to the end, the velocity continues to diminish

[1] In the *Errata* we are told to omit this passage; but as the premises and the conclusion, between which it formed the necessary connection, are left unaltered, the need for it is as great as before. How else, but by such an inference, can the conclusion be reached?

[2] The curve of velocity here is a parabola, or nearly so, representing (on a distance scale) a nearly constant "acceleration," with a constantly decreasing velocity.

down to zero, and at the instant the train comes to rest the constant (negative) acceleration abruptly ceases.

How would this show itself in our feelings? If I were sitting with my back to the engine, leaning against the wall of the carriage, I should feel a slight mutual pressure between my back and the wall. This would remain constant to the end, and then abruptly cease. It would be but slight (for any possible brake acceleration must be but a small percentage of that of gravity) in comparison with that which we feel when we lie down. Would its abrupt termination—there being by supposition no sudden change of velocity—be really unpleasant?

To take a fanciful example. If, as I sit in my chair, gravity were suddenly annihilated (for me): I should note the cessation of pressure, and, in so far as my body is elastic, there would be some change of conformation. The pressure in the blood-vessels would also be changed, &c. But, dealing with even such a large acceleration as this, would the instantaneous change be at all comparable with that of a sudden trifling change of *velocity?*

Anyone who has been in a lift at the moment the cord broke might be able to tell us what all this feels like: but he must be careful to distinguish between the sensations due to the first moment of his passage from those due to the last.

The Definition of Force and Newton's Third Law.

PERHAPS your correspondents now engaged in discussing the value of dynamic terms could extend the range of their controversy a little, and deal with a subject of great importance which no text-books touch.

It seems to me that the definition of force as that which causes or alters motion is not reconcilable with Newton's law which asserts that every force is always opposed by an equal and opposite force.

How can a force opposed by an equal and opposite force perform work, or affect the motion of anything? We have here either a fallacy or an indefiniteness, and the matter is worth clearing up because it incessantly worries students who think.

March 23. NEMO.

Green Colouring-matter of Decaying Wood.

ANYONE who lives in a fairly wooded part of the country must be familiar with the fact that at certain stages of decay fallen branches of trees are often to be observed among the dry forest-litter coloured more or less through their tissue with various shades of green. After an examination of thin sections with the microscope, I am unable to trace this to any saprophytic organism. Chemical analysis, on the other hand, reveals the presence of *iron* as the base of the green colouring-matter (using fairly strong nitric acid as a solvent), which—so far as the evidence at present goes—seems to be some organic salt of iron, the organic acid being probably furnished by the slow decomposition of the woody tissue. In the hope that some further light may be thrown on the origin of the green-colouring matter of many Tertiary green earths, I would ask the favour of being allowed to solicit references to any foreign literature of the subject with which any of the numerous readers of NATURE may be acquainted.

A. IRVING.

Wellington College, Berks, March 17.

THE HITTITES, WITH SPECIAL REFERENCE TO VERY RECENT DISCOVERIES.[1]

I.

OF late much has been said concerning the Hittites, and, as might be expected in relation to such a subject, there have been fanciful hypotheses and wild vagaries, repugnant alike to the scientific method and the scientific spirit. But most persons, one would suppose, who have given serious attention to the subject, must have become convinced that there is a great vacancy in that map of the past which ancient history presents. Mighty kings, dynasties enduring, it may be, through thousands of years, great peoples who had made no slight advance in civilization, have passed away without leaving any chronicle equal even to those which were extant concerning Egypt and Assyria before the decipherment of the hieroglyphics and the cuneiform characters. The recent change in public opinion concerning the Hittites is not due merely to the discovery of monuments and inscriptions in various parts of Asia Minor: a large proportion of these had been known to exist for a considerable time, some for a very long time. It must be referred rather to the recognition of an identity or similarity of character in these monuments and inscriptions. And thus has arisen the idea of an empire stretching from the Euphrates to the Ægean Sea. It is, however, doubtful whether—if we use the word "empire" in such a sense as we employ it when we speak, for example, of the Empire of Russia or the Empire of China—there is any ground for believing that a Hittite Empire ever existed. Most likely there were in Asia Minor many States, or even single cities, which were usually to a great extent independent, and the peoples of which were not, perhaps, altogether homogeneous in race, but which, under pressure of the necessities of war, formed a federation. This view accords with the passages in the First and Second Books of Kings which speak of the "kings of the Hittites" (2 Kings, vii. 6) and of "all the kings of the Hittites" for whom Solomon's merchants brought up out of Egypt chariots and horses (1 Kings, x. 28, 29). The testimony of these passages in relation to the greatness of the Hittite peoples has been till recently but little regarded.

That the Hittites thus spoken of in the Old Testament are to be identified with the Khita of the Egyptian monuments, and with the peoples of the land of Khatti in the Assyrian records, is coming out more and more clearly; and as an especial link joining together the peoples thus designated by the Egyptians and Assyrians may be mentioned the city of Carchemish. Holding the Upper Euphrates, the Hittites stood between the Egyptians and the powerful and warlike peoples of Mesopotamia. On a superficial view this may seem not to be the direct route from Egypt to Mesopotamia; but to lead an army by the apparently more direct way across the Syrian desert would have been difficult or wholly impracticable. Moreover, it would not have been easy for an army to make the passage of the Euphrates towards the mouth of the river. But by the upper course of the Euphrates, at or near the site of Jerablûs, the river could be crossed with comparative ease. On the site of Jerablûs (from which the British Museum obtained a few years ago most of the Hittite monuments now in the collection) stood in all probability the renowned city of Carchemish. This identification, attributed to Mr. Skene, was accepted by the late Mr. George Smith, who visited the place shortly before his death. It was this city of Carchemish (not to go back further in Assyrian or Babylonian history) of which Tiglath-Pileser, about 1100 years before Christ, says, "The city of Kargamis, belonging to the country of the Khatti, I smote in one day. Their fighting-men I slew, their movables, their wealth, and their valuables I carried off." He records further that he pursued the portion of the Hittite army which fled; that he crossed the Euphrates in boats covered with bitumenized skins; and that he returned triumphantly to his city of Ashur. The conflict between the Hittites and Assyrians was, however, destined still to continue for 400 years, during which time, though repeatedly sustaining defeat, the Hittites made again and again a determined resistance. It was the fortune of Sargon to end the conflict by the capture, in 717 B.C., of Carchemish and its king, Pisiris.

Previous Egyptian monarchs had engaged in conflict with the Hittites with more or less conspicuous success; but it was the renowned son of Seti, the great Rameses II., about 1330 B.C., whose war with the Khita, and the great battle fought with them at Kadesh, appear to have

[1] Based on Lectures delivered by Mr. Thomas Tyler at the British Museum in January 1888.

been regarded as the most honourable and glorious. This, at any rate, would seem likely, from the care manifested in transmitting to posterity a record of these achievements. The Egyptian laureate, Pentaur, no doubt with a measure of poetical licence suited to his office, described how the Hittite commander, Khita-sar, summoned to the war all the peoples from the uttermost ends of the seas, countless in number, covering mountains and valleys like grasshoppers; and among this multitude were the people of Carchemish. In order that the "sinews of war" might not be deficient, Khita-sar "had not left silver nor gold with his people; he had taken away all their goods and possessions to give to the people who accompanied him." The details of the conflict show a high degree of military organization on the part of the Hittites; and this is in accordance with the position that they had long attained a considerable measure of civilization. According to the Egyptian records, however, they were defeated, and a great part of their army slain, some perishing in the waters of the Orontes, on the banks of which river the battle was fought. It seems sufficiently clear, however, that the Hittites, and "the miserable king of the hostile Khita," as Pentaur calls him, had proved themselves no contemptible foes, and that, defeated though they may have been, their power was very far from being entirely broken. This may be gathered from the treaty of offensive and defensive alliance which was subsequently ratified between Rameses and the Khita. There was to be continual peace and brotherhood; no hostility was ever to arise. Rameses, moreover, eventually married the daughter of the Hittite chief, and made her his queen.

The great sculpture and painting on the walls of the temple at Abu-Simbel, far up the Nile, which represents the war of Rameses with the Khita, and the battle of Kadesh, gives in a point of detail an interesting piece of evidence tending towards the conclusion that the Khita are to be identified with those who sculptured the monuments now known as Hittite. There are depicted on two at least of the monuments in the British Museum, which were obtained from excavations at Jerablûs or Carchemish, heads of kings or other persons in authority bearing the appendage known as the "pig-tail." We are accustomed

1. 2. 3.

FIG. A.—1. "Pig-tail" from Jerablûs monument in the British Museum. 2. Type of head at Eyuk. 3. Head of Khita warrior at Abu-Simbel (after Rosellini).

to associate the "pig-tail" especially with the Chinese, though they derived this mode of head-dress from the Manchu Tartars at a comparatively recent period. And, *primâ facie*, one is not unnaturally inclined to regard the pig-tail on the Jerablûs monuments as having a connection more or less identical—that is to say, a connection with the Manchu Tartars or with some cognate people. The sculptors of the Jerablûs monuments seem to have done their best to show that the pig-tail is a veritable lock of hair, and not a mere appendage of the tall conical cap. On what has been called the doorway inscription in the British Museum, to show that hair is intended, the "pig-tail" is ribbed or marked across; and there is a similar transverse marking of the hair of kings and other persons on the Assyrian monuments. Turning to the great painting at Abu-Simbel, already alluded to, we find that a certain proportion of the Khita warriors are represented as wearing the pig-tail, though this is not the case even with all the kings and princes. A prince, for example, who has fallen into the water of the Orontes, is destitute of this ornament. And even the great Khita-sar, the commander of the Khita, though he had the conical cap, does not seem to have worn the pig-tail.

The indications are clear that the pig-tailed heads on the Jerablûs monuments represent, in accordance with what has been already said, kings or persons of superior dignity. Other heads with ordinary long hair may be taken to be those of persons of inferior rank—subjects or servants. And, in the Abu-Simbel painting, the pig-tailed riders in the chariots are evidently the superiors of the persons beside them wearing long hair. Generally the soldiers with long hair act as shield-bearers or charioteers, while it is the chief warrior who wears the pig-tail.

On two, also, of the bas-reliefs at Eyuk, a place in Asia Minor not far from the River Halys, the wearing of the pig-tail is clearly represented, though the superiority or predominance of the wearers is not equally apparent. On one bas-relief there are six figures, apparently in marching order, all of which probably bore originally the pig-tail, though the monument is now much decayed. It is not, however, very difficult to make out a remarkable Mongolian type of countenance. This is especially to be seen in the figure of a man ascending steps or a ladder, as represented by Perrot and Guillaume ("Exploration Archéologique de la Galatie," plate 62).

Having regard, however, to the monuments from Jerablûs in the Museum, and to the Egyptian painting at Abu-Simbel, the inference seems pretty clear that the wearers of the pig-tail had gained the predominance in some of the Hittite cities, and that they were of a stock different from that of the general population in those particular cities. With the evidence which we at present have, it would be hazardous to say that this was the case in all the Hittite cities. Indeed some facts already alluded to render such a general conclusion extremely improbable.

The general Hittite population was most likely in great part, or principally, Semitic.[1] It is in accordance with this view that their great deity was Set or Sutech—a name repeated ten times, in connection with different cities, in the catalogue of the gods of the land of Khita, in the treaty with Rameses—and the treaty makes mention also of Astartha, or Ashtoreth, as "of the land of Khita"; and here, again, we have unquestionably a Semitic deity. Moreover, of the worship of Ashtoreth there is other important evidence on the Hittite monuments. There are, besides, names of Hittite cities which are unmistakably Semitic; as Carchemish, which can scarcely be explained otherwise than as meaning "the fortress of Chemosh." Then there is Pitru, or Pethor, as well as Hamath and Kadesh. Looking at these names alone, there would be a strong *a priori* probability that the speech of the inhabitants of these cities was Semitic. No doubt there are many names of Hittite persons and places, mentioned in the Egyptian and Assyrian records, with respect to which we must adopt the opinion of Brugsch that they are at least not purely Semitic.[2] The designation of the leader of the Khita or Hittites, Khita-sar, has, it is true, the word *sar*, which is Semitic for "prince," but the Semitic order is reversed. In a purely Semitic formation we should not expect to find "Khita-prince," or "of-the-Khita prince"; the order would probably be the same as ours, "Prince of the Khita." The presence of those wearers of the pig-tail suggests an explanation of the order of the words in Khita-sar, and of

[1] M. Perrot observes:—"Or les Cappadociens, qu'Hérodote appelle Leuco-Syriens ou Syriens blancs, étaient de race sémitique; c'est un fait attesté tout à la fois par les historiens et par le témoignage des médailles, qui nous montrent encore un idiome sémitique parlé au-delà de l'Halys, de Tarse à Sinope, dans la cours même du quatrième siècle avant notre ère" (Perrot et Guillaume, *op. cit.*, vol. i. p. 335). Mr. Pinches, of the British Museum, tells me that several Cappadocian tablets in the cuneiform character have been discovered. Six of these are in the Museum, and one at least is in part Semitic. The others, together with one in the Bibliothèque Nationale, at Paris, have, with one exception, hitherto resisted the attempts at decipherment which have been made.

[2] "History of Egypt," English translation, vol. ii. p. 5.

various other forms, as the Hittite names Pais and Pisiris, and of names ending with the termination *-beg*, as Sathekh-beg, or Suki-beki. The wearing of the pig-tail agrees with the reversal of the order in Khita-sar, since, in accordance with the Mongolian idiom, the order would be reversed; and, having regard to such names as Genghis, Usbeg, &c., there is no difficulty in accounting for the ending in Pisiris and Sathekh-beg.

We may come, then, rationally to the conclusion that men of a race cognate with the Mongols gained the supremacy in some of the Hittite cities; that this ascendancy had its influence on some proper names, and perhaps on other words, but did not change the language of the entire population. If this had been previously Semitic, it remained such. The wearers of the pig-tail did not require their subjects to arrange their hair in the same fashion; and, similarly, they did not attempt to change their language. If they had made the attempt, it would in all probability have been abortive.

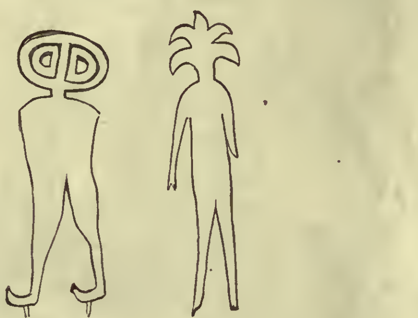
Allusion has been made to the rock-sculptures found at various places through the length and breadth of Asia Minor. Among these, pre-eminence must certainly be assigned to the very remarkable bas-reliefs at Boghaz-Keui, in Cappadocia, a place not far distant from Eyuk, already mentioned, and also near the Halys. Here, where there was, no doubt, originally a chasm or rift in the rocks, closed at one end, the surface of the rocks seems to have been prepared, and a sort of gallery formed. On the two sides of this gallery some sixty or seventy figures have been executed, forming what may be regarded as two processions, which meet on a grand tableau, engraved on the rock at the closed end, in the persons of a male and female figure of much greater height than the rest. Each of these figures seems to be presenting to the other a sort of flower or plant, an arrangement similar to what is to be seen on a seal very lately discovered at Tarsus. The male figure, in the Boghaz-Keui bas-relief, stands on the bended heads of two persons clad in long robes, who in all probability are priests. Each of these figures wears, like that above, a pointed cap, and the curious triangular ornamentation of the skirts of their dresses is very noticeable. The principal male figure has in his hand a sceptre terminating in a ball, and beside him is an animal, said to be a bull, also wearing a pointed cap. If the animal is really a bull, it was probably introduced partly to show by con-

FIG. B.—Central bas-relief at Boghaz-Keui.

trast the relatively gigantic size of the male figure standing beside it. Behind the principal figure is a long procession of some forty other figures, nearly all of which are evidently male, and among them are two winged deities, one of these being apparently the same god that is, or was recently, to be seen on a bas-relief at Jerablûs. Twelve figures in the extreme rear are in the act of running. They have conical caps, but differ from the sceptre-bearing kings, if we may so call them, at the front, in the grand tableau. These hindmost figures we may take to be common soldiers. It is, however, a procession of female figures to the right of a spectator in the rock-gallery to which the principal interest belongs. Each of these, from the more gigantic female figure in the grand tableau to the twentieth in the rear, has on her head a tall cap or crown. This is the so-called "mural crown." In its origin this mural crown probably represented the wall of a city; and the figure bearing it was most likely originally the personification of a city. If, however, this was its origin, it must have become in time diverted from its original use; and, having regard to the male procession, it cannot be regarded as likely that each of the female figures represents a distinct city. Each of these figures has what has been called a *bâton* or stick. But it is very noticeable that this so-called *bâton* is in most, probably in all, cases distinctly curved; a fact which—so it seems to me—probably denotes that it is an unstrung bow. If this is the case, we shall then have a procession of female warriors. Their attire in other respects would be consistent with the idea of their being priestesses, and, if so, the combination of warrior and priestess would precisely accord with one well-known view of the Amazons. It is remarkable, too, that the place where these sculptures are found is not very far from the locality by the River Thermodon and the Black Sea, which the Greeks assigned as the head-quarters of the Amazons. What, then, is the general view to be taken of this remarkable bas-relief? Some have thought that the whole idea is religious, and that at least the two figures meeting in front of the two processions are deities. But how is it, then, that these figures are without wings, seeing that there are winged deities in the male procession? Their mere greatness of size would not show that they are other than persons of kingly and queenly rank. I should not think, however, that the artists who executed this sculpture were commemorating any contemporary event. Probably they were concerned with some notable event in the past, when a king and queen met to ratify an

alliance, or for some other purpose. If the Amazons are, as is commonly thought, merely legendary persons, having no real existence, this sculpture at Boghaz-Keui may yet be looked upon with probability as tending to show that, in what may be called their own country, the story of these female warriors was believed. On the whole, it seems likely, in view of the evidence of this bas-relief, that the story rests on a substantial basis of truth. There is also, I may add, in the Hamath inscriptions, what looks very much indeed like the indication of female warriors armed with club and sword.[1]

Before passing from this Boghaz-Keui sculpture (other interesting bas-reliefs which are there I cannot now discuss), I must refer to the fact that in several instances curious symbols are held in the hands of several of the personages in the processions, or are placed near them. The floral or vegetable symbols held in the hands of the principal personages are surmounted by a remarkable oval figure. This oval object Prof. Sayce regards as a symbol of deity; and the vegetable or other figure beneath he takes for the name of a god. That the name of a god could be indicated by characters such as these seems to me a thing not easily credible; and the inscriptions give very strong reasons for regarding the oval object as a symbol denoting, not deity, but a city.[2] The more probable view seems to be that these figures surmounted by the oval object are the distinctive standards



1. 2.

FIG. C.—1. Standard, with symbol of "city" at Boghaz-Keui. 2. Mandrake after Visconti ("Iconographie Grecque") from manuscript of Dioscorides.

of cities. Unfortunately in the places where these standards occur the sculptures have suffered much from the effects of weather and of time; and the question has been complicated by the differences in the representations given by M. Texier and by MM. Perrot and Guillaume. The representations of the latter, based to a great extent on photographs, are no doubt by far the more accurate. M. Perrot seems to have thought that all these symbols are related to the mandragora or mandrake, a view which I venture to think very improbable. The oval symbol, with its curious marking, is certainly not the fruit of the mandrake, which is round and pendent, not oval and erect. But there is one place in the grand tableau where, I should say, the mandrake is clearly intended.[3] One of these is the symbol borne by the male figure immediately behind what I may call the queen. This figure bears in his hand, as a standard, the mandrake root with the ends turned up into feet. The ancients not only attributed aphrodisiacal and fecundating properties to the mandrake-root, but they also considered that it resembled the body of a man. Pythagoras is said to have spoken of the mandrake as "of human shape." And the difficulty about the feet was easily got over by a little manipulation.[1] There may possibly be some connection between this single male figure with the mandrake standard behind the queen, and what was said by the Greeks as to the relations of the Amazons with the males of a certain city separated from them by a mountain. I should add that the male figure immediately behind the king has the pole of the standard and the oval above, but the intervening figure is gone. It is probably still the standard-pole with the last figure to the reader's left in the central tableau. And possibly, too, at Karabel, the Hittite characters are to be understood as depicted on a standard.

(*To be continued.*)

[1] Under an indication of sex scarcely to be mistaken, is an arm with a hand grasping a club and a sword or dagger.

[2] This was, I believe, the view of Prof. Sayce, before he recognized the Hittite character of the Boghaz-Keui sculptures.

[3] There is evidence also equally clear on the other bas-reliefs at Boghaz-Keui which I do not here discuss.

[1] In the drawing in a manuscript of Dioscorides, of the fifth century, in the library of Vienna, and in Visconti's engraving, the mandrake root is grasped by a female figure. An artist, who is painting the mandrake, is actually accentuating the feet.

TIMBER, AND SOME OF ITS DISEASES.[2]

VI.

If we turn our attention for a moment to the illustrations in the first article, it will be remembered that our typical log of timber was clothed in a sort of jacket termed the cortex, the outer parts of which constitute what is generally known as the bark. This cortical covering is separated from the wood proper by the cambium, and I pointed out (p. 184) that the cells produced by divisions on the outside of the cambium cylinder are employed to add to the cortex.

Now this cortical jacket is a very complicated structure, since it not only consists of numerous elements, differing in different trees, but it also undergoes some very curious changes as the plant grows up into a tree. It is beyond the purpose of these articles to enter in detail into these anatomical matters, however; and I must refer the reader to special text-books for them, simply contenting myself here with general truths which will serve to render clearer certain statements which are to follow.

It is possible to make two generalizations, which apply not only to the illustration (Fig. 20) here selected, but also to most of our timber-trees. In the first place, the cortical jacket, taken as a whole, consists not of rigid lignified elements such as the tracheids and fibres of the wood, but of thin-walled, soft, elastic elements of various kinds, which are easily compressed or displaced, and for the most part easily killed or injured—I say for the most part easily injured, because, as we shall see immediately, a reservation must be made in favour of the outermost tissue, or cork and bark proper, which is by no means so easily destroyed, and acts as a protection to the rest.

The second generalization is, that since the cambium adds new elements to the cortex on the inside of the latter, and since the cambium cylinder as a whole is travelling radially outwards—*i.e.* further from the pith—each year, as follows from its mode of adding the new annual rings of wood on to the exterior of the older ones, it is clear that the cortical jacket as a whole must suffer distension from within, and tend to become too small for the enlarging cylinder of rigid wood and growing cambium combined. Indeed, it is not difficult to see that, unless certain provisions are made for keeping up the continuity of the cortical tissues, they must give way under the pressure from within. As we shall see, such a catastrophe is in part prevented by a very peculiar and efficient process.

Before we can understand this, however, we must take a glance at the structural characters of the whole of this jacket (Fig. 20). While the branch or stem is still young, it may be conveniently considered as consisting of three chief parts.

(1) On the outside is a thin layer of flat, tabular cork-cells (Fig. 20, *Co*), which increase in number by the activity

[2] Continued from p. 279.

of certain layers of cells along a plane parallel to the surface of the stem or branch. These cells (*C.Ca*) behave very much like the proper cambium, only the cells divided off from them do not undergo the profound changes suffered by those which are to become elements of the wood and inner cortex. The cells formed on the outside of the line *C.Ca* in fact simply become cork-cells; while those formed on the inside of the line *C.Ca* become living cells (*Cl*) very like those I am now going to describe.

(2) Inside this cork-forming layer is a mass of soft, thin-walled, "juicy" cells, *pa*, which are all living, and most of which contain granules of chlorophyll, and thus give the green colour to the young cortex—a colour which becomes toned down to various shades of olive, gray, brown, &c., as the layers of cork increase with the age of the part. It is because the corky layers are becoming thicker that the twig passes from green to gray or brown as it grows older. Now these green living cells of the cortex are very important for our purpose, because, since they contain much food-material and soft juicy contents of just the kind to nourish a parasitic fungus, we shall find that, whenever they are exposed by injury, &c., they constitute an important place of weakness—nay, more, various fungi are adapted in most peculiar ways to get at them. Since these cells are for the most part living, and capable of dividing, also, we have to consider the part they play in increasing the extent of the cortex.

(3) The third of the partly natural, partly arbitrary portions into which we are dividing the cortical jacket is found between the green, succulent cells (*pa*) of the cortex proper (which we have just been considering), and the proper cambium, *Ca*, and it may be regarded as

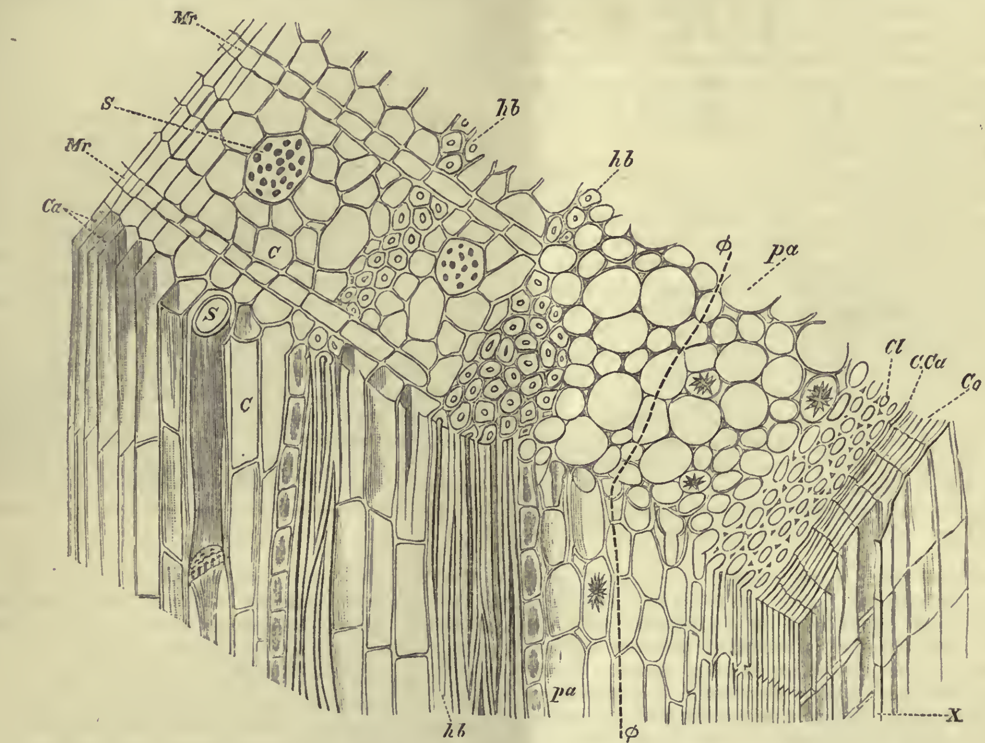


FIG. 20.—A piece of the cambium and cortical jacket of a young oak, at the end of the first year. It may be regarded as consisting of three parts, in addition to the cambium (*Ca*). Beginning from the outside, we have: (1) cork-cells (*X*), formed from the cork-cambium (*C.Ca*): the cells developed on the inside of the latter (*Cl*) are termed collenchyma, and go to add to the cortex. (2) The cortex proper, consisting of parenchyma-cells (*pa*), some of which contain crystals. (3) The inner or secondary cortex (termed *phloem* or bast), developed chiefly by the activity of the cambium (*Ca*): this phloem consists of hard bast fibres (*hb*), sieve-tubes (*S*), and cells (*c*), and is added to internally by the cambium (*Ca*) each year. It is also traversed by medullary-rays (*Mr*), which are continuations of those in the wood. The dotted line (φ) in the cortical parenchyma indicates where the new cork-cambium will be developed: when this is formed, all the tissues (e.g. *pa*, *Cl*), lying on the outside of the new cork will die, and constitute (together with the cork) the true *bark*.

entirely formed directly from the cambium-cells. These latter, developed in smaller numbers on the outside, towards the cortex, than on the inside, towards the wood, undergo somewhat similar changes in shape to those which go to add to the wood, but they show the important differences that their walls remain unlignified, and for the most part very thin and yielding, and retain their living contents. For the rest, we may neglect details and refer to the illustration for further particulars. The tissue in question is marked by *S*, *c*, *hb* in the figure, and is called *phloem* or bast.

A word or two as to the functions of the cortex, though the subject properly demands much longer discussion. It may be looked upon as especially the part through which the valuable substances formed in the leaves are passing in various directions to be used where they are wanted. When we reflect that these substances are the foods from which everything in the tree—new cambium, new roots, buds, flowers, and fruit, &c.—are to be constructed, it becomes clear that if any enemy settles in the cortex and robs it of these substances, it reduces not only the general powers of the tree, but also—and this is the point which especially interests us now—its timber-producing capacity. In the same way, anything which cuts or injures the continuity of the cortical layers results in diverting the nutritive substances into other channels. A very large class of phenomena can be explained if these points are understood, which would be mysterious, or at least obscure, otherwise.

Having now sketched the condition of this cortical jacket when the branch or stem is still young, it will be easy to see broadly what occurs as it thickens with age.

In the first place, it is clear that the continuous sheet of cork (*Co*) must first be extended, and finally ruptured, by the pressure exerted from within: it is true, this layer is very elastic and extensible, and impervious to water or nearly so—in fact it is a thin layer or skin, with properties like those of a bottle cork—but even it must give way as the cylinder goes on expanding, and it cracks and peels off. This would expose the delicate tissues below, if it were not for the fact that another layer of cork has by this time begun to form below the one which is ruptured: a cork-forming layer arises along the line ϕ, and busily produces another sheet of this protective tissue in a plane more or less exactly parallel with the one which is becoming cracked. This new cork-forming tissue behaves as before: the outer cells become cork, the inner ones add to the green succulent parenchyma-cells (*pa*). As years go on, and this layer in its turn splits and peels, others are formed further inwards, and if it is remembered that a layer of cork is particularly impervious to water and air, it is easy to understand that each successive sheet of cork cuts off all the tissues on its exterior from participation in the life processes of the plant: consequently we have a gradually increasing *bark* proper, formed of the accumulated cork-layers and other dead tissues.

A great number of interesting points, important in their proper connections, must be passed over here. Some of these refer to the anatomy of the various "barks"—the word "bark" being commonly used in commerce to mean the whole of the cortical jacket—the places of origin of the cork-layer, and the way in which the true bark peels off: those further interested here may compare the plane, the birch, the Scotch pine, and the elm, for instance, with the oak. Other facts have reference to the chemical and other substances found in the cells of the cortex, and which make "barks" of value commercially. I need only quote the alkaloids in Cinchona, the fibres in the Malvaceæ, the tannin in the oaks, the colouring-matter in *Garcinia* (gamboge), the gutta-percha from *Isonandra*, the ethereal oil of cinnamon, as a few examples in this connection, since our immediate subject does not admit of a detailed treatment of these extremely interesting matters.

The above brief account may suffice to give a general idea of what the cortical jacket covering our timber is, and how it comes about that in the normal case the thickening of the cylinder is rendered possible without exposing the cambium and other delicate tissues: it may also serve to show why bark is so various in composition and other characters. But it is also clear that this jacket of coherent bark, bound together by the elastic sheets of cork, must exert considerable pressure as it reacts on the softer, living, succulent parts of the cortex, trapped as they are between the rigid wood cylinder and the bark; and it is easy to convince ourselves that such is the case. By simply cutting a longitudinal slit through the cortex, down to near the cambium, but taking care not to injure the latter, the following results may be obtained. First, the bark gapes, the raw edges of the wound separating and exposing the tissues below; next, in course of time the raw edges are seen to be healed over with cork—produced by the conversion of the outer cells into cork-cells. As time passes, provided no external interference occurs, the now rounded and somewhat swollen cork-covered edges of the wound will be found closing up again; and sooner or later, depending chiefly on the extent of the wound and the vigour of the tree, the growing lips of the wound will come together and unite completely.

But examination will show that although such a slit-wound is so easily healed over, it has had an effect on the wood. Supposing it has required three years to heal over, it will be found that the new annual rings of wood are a little thicker just below the slit; this is simply because the slit had released the pressure on the cambium. The converse has also been proved to be true—*i.e.* by increasing the pressure on the cambium by means of iron bands, the annual rings below the bands are thinner and denser than elsewhere.

But we have also seen that the cambium is not the only living tissue below the bark: the cortical parenchyma (*pa*), and the cells (*c*) of the inner cortex (technically the phloem) are all living and capable of growth and division, as was described above. The release from pressure affects them also; in fact, the "callus," or cushion of tissue which starts from the lips of the wound and closes it over, simply consists of the rapidly growing and dividing cells of this cortex, *i.e.* the release from pressure enables them to more than catch up the enlarging layer of cortex around the wound.

An elegant and simple instance of this accelerated growth of the cortex and cambium when released from the pressure of other tissues is exhibited in the healing over of the cut ends of a branch, a subject to be dealt with later on; and the whole practice of propagation by slips or cuttings, the renewal of the "bark" of Cinchonas, and other economic processes, depend on these matters.

In anticipation of some points to be explained only if these phenomena are understood, I may simply remark here that, obviously, if some parasite attacks the growing lips of the "callus" as it is trying to cover up the wound, or if the cambium is injured below, the pathological disturbances thus introduced will modify the result: the importance of this will appear when we come to examine certain disturbances which depend upon the attacks of Fungi which settle on these wounds before they are properly healed over. In concluding this brief sketch of a large subject, it may be noted that, generally speaking, what has been stated of branches, &c., is also true of roots; and it is easy to see how the nibbling or gnawing of small animals, the pecking of birds, abrasions, and numerous other things, are so many causes of such wounds in the forest. H. MARSHALL WARD.

(*To be continued.*)

NOTES.

ON Friday, the 23rd inst., Sir Henry Roscoe drew attention in the House of Commons to the Woolwich regulations, the mischievous nature of which we have repeatedly exposed. Sir Henry Roscoe was cordially supported by Sir Lyon Playfair; and Mr. Stanhope, we are glad to say, dealt with the subject in a fair and conciliatory spirit. He promised to discuss the matter with men of science, and the result, we may hope, will be that new regulations will soon be drawn up, securing that scientific candidates shall not be placed at a disadvantage as compared with students of language and literature.

IN replying to Sir Henry Roscoe, Mr. Stanhope made a statement to the effect that the regulations now in force for Sandhurst, which were issued in 1884, were recommended by upwards of fifty head masters. We have before us the Report of the Head Masters' Conference for 1883, in which the recommendations of their Committee are printed, and these recommendations differ in certain important respects from the regulations actually adopted by the War Office. The head masters appear, from their suggestions, to have desired to retain a more important place for Latin and Greek than those subjects occupy in the War Office regulations; and they also attached a higher value to higher mathematics. On the other hand, they placed modern languages and experimental science on a lower but relatively less unequal footing than the War Office has done. Although, therefore, in consequence of the position of classics, the actual value of science was, on the whole, perhaps not better under the head masters' suggestions than under the regulations issued by the War Office, it is hardly correct to speak of the head masters as having recommended a scheme of which the predominating fault is, as

we think, the undue difference in the marks allotted to modern languages as compared with the experimental sciences. Moreover, even if Mr. Stanhope were right, it would not follow that the head masters contemplated the application of their suggestions in all respects to the scientific branches of the Army, since the needs of those branches are so obviously different in certain matters. We quite recognize the necessity pointed out by the Secretary of State for War, that the system of the Royal Military Academy (Woolwich) and that of the Royal Military College (Sandhurst) should be as much as possible assimilated to each other. But for that very reason the needs of the Woolwich cadets in the case of science should have been more carefully considered in the framing of the Sandhurst regulations. No one will contend that scientific capacity is a bad thing for a Sandhurst cadet, and since it is admittedly of direct and very great importance to secure scientific capacity on the part of Woolwich cadets, it appears reasonable that, in the case of science subjects, the needs of the Woolwich system should be chiefly regarded, if in this respect the two systems must be made similar.

TEN Fellows of the Royal Society have died in less than four months—a large number when we take into account that the annual death-rate is barely fifteen. Six out of the ten gave an average age of seventy-nine.

THE annual general meeting of the Chemical Society was held yesterday. Mr. Crookes, F.R.S., the President, read a report on the state of the Society, and an address on elements and meta-elements. The medal founded, for triennial award, by Dr. Longstaff, was conferred on Dr. W. H. Perkin, F.R.S. The President, in presenting the medal, expressed the pleasure he felt in thus testifying, in the name of the Society, to the value of Dr. Perkin's interesting and important researches on the magnetic rotary polarization of compounds in relation to their chemical constitution. Mr. Crookes also took the opportunity of congratulating Dr. Longstaff on the fact that although on the eve of his eighty-ninth birthday he is still hale and hearty.

THE half-yearly general meeting of the Scottish Meteorological Society was held yesterday in the hall of the Royal Scottish Society of Arts, Edinburgh. In their Report the Council state that, in addition to the routine work of the Office, the Secretary's time has been occupied with the preparation of the Report on the Ben Nevis observations from the opening of the Observatory in November 1883 to the end of December 1887, and in seeing these observations through the press. The work, which is to appear as an extra volume of the Transactions of the Royal Society of Edinburgh, is in a state of forwardness, the whole of the observations proper of the Observatory being now through the press. The Council also note that the physical and biological researches have been conducted on the *Medusa* during the winter months with characteristic vigour, and with a success so great as to point to the solution of the questions raised by the herring and salmon fisheries, while at the same time an entirely new light has been cast on the circulation of the water in our fresh and salt water lochs, and generally on the problem of oceanic circulation.

AN influential Committee has been formed at Edinburgh for the purpose of collecting subscriptions for a memorial of the late Prof. Kelland. An appeal has been issued to his former students and others, and it ought to meet with a prompt and generous response. Prof. Kelland, as the Committee remind those whom they have addressed, was not only an excellent and most successful teacher of mathematics, loved and honoured by the students of forty sessions at the University of Edinburgh, but one of the most effective recent promoters of the cause of education in Scotland. The precise nature of the memorial will to some extent depend upon the amount subscribed; but it will be essentially a foundation bearing the name of Kelland, such as a Scholarship, or even a special Lectureship, in connection with the Chair of Mathematics at the University of Edinburgh.

THE Irish Exhibition, which is to be held at Olympia, Kensington, from June 4 next to October 27, ought to be one of very great interest. The intention is that the English public shall have an opportunity of obtaining a clear view of the predominant industries of Ireland. It is also proposed to exhibit some of her historical and antiquarian treasures. The profits are to be given in aid of Irish technical and commercial schools.

THE eighth German Geographentag, which was to have been held at Berlin in April, has been postponed. The Committee, in announcing this decision, explain that the festivities which might, as usual, be connected with the meeting would not be in accordance with the feeling excited in the capital by the death of the Emperor William.

THE *Standard* of Wednesday, March 21, printed some extracts from the letters of Cowper, the poet, which may serve to show that the climate of England has not deteriorated, bad as it has lately been. In a letter dated March 19, 1788, Cowper writes to his friend Bagot:—"The spring is come, but not that spring which our poets have celebrated. So I judge, at least, by the extreme severity of the season—sunless skies and freezing blasts, surpassing all that we experienced in the depth of winter. How do you dispose of yourself in this howling month of March? As for me, I walk daily, be the weather what it may, take bark, and write verses. By the aid of such means as these I combat the north-east wind with some measure of success, and look forward—with the hope of enjoying it—to the warmth of summer." On May 6 he says to Lady Hesketh:—"I am just recovered from a violent cold, attended by a cough. I escaped these tortures all the winter; but whose constitution or what skin can possibly be proof against our vernal breezes in England? Mine never were nor will be." Yet only three weeks afterwards (May 27) he exclaims to the same correspondent:—"How does this hot weather suit thee, my dear, in London? As for me, with all my colonnades and bowers, I am quite oppressed by it." It would be interesting if some one could provide particulars as to the weather of any of the former '88 years.

THE *American Meteorological Journal* for February devotes an article to the works of Prof. William Ferrel, now seventy-one years of age. His first meteorological papers were published in the form of essays in 1856, and were reprinted and extended, under the title of "Motions of Fluids and Solids on the Earth's Surface," as one of the professional papers of the Signal Service. In this paper the explanation of the trade winds is altogether different from that usually given. His latest contribution—"Recent Advances in Meteorology" (see NATURE, vol. xxxvi. p. 255)—is the best summary of the principles and results of meteorology in existence. Ferrel's views received considerable attention in France soon after publication, but in this country and in America they have only attracted notice more recently. His mathematical papers on the motions of the ocean are not less important than those on the motions of the atmosphere. The article is accompanied by a good portrait of Prof. Ferrel.

WE have received from Dr. Van der Stok the rainfall observations made in the East Indian Archipelago during the year 1886. Observations are now taken at 102 stations, several additions having been recently made, including an important station on the Key Islands, in longitude 132° 45′ E.; the district now represented extends over 37° of longitude. The data published include the monthly and yearly values for the year 1886, and the means for a number of years, the number of days of rainfall, and the greatest falls in twenty-four hours. The value of the work

would be much enhanced by the addition of charts showing the distribution in space and time, and by some discussion of the results. It has been shown by M. Woeikof that the rainfall of stations close together differs materially. For instance, at Batavia the proportion of rainfall in the wettest and driest months is 8 to 1, while at Buitenzorg, only 25 miles distant, the proportion is only 2 to 1. The work contains a short account of the position of every station.

THE Central Physical Observatory of St. Petersburg has published a memoir on the rainfall of the Russian Empire (506 pp. 4to) with an atlas. The data used in the calculations are brought down to the year 1882, and include observations taken at 450 places, embracing altogether 3112 years. The tables contain individual monthly and yearly values, and the means for the whole period, rainfall frequency, and maximum falls in twenty-four hours. The influences of the form of gauge and exposure on the amounts of rainfall, and of the method of reckoning days of rain, are fully discussed. The amount taken as representing a rainy day is ·004 inch, while in England it is ·01 inch. It is shown that the difference in the methods of counting rainy days materially interferes with the calculations based upon rainfall frequency.

A SERIES of highly interesting experiments upon the vapour-density of ferric chloride have lately been completed by Drs. Grünewald and Victor Meyer. The chlorides of aluminium and indium have already been shown by Nilson and Pettersson, and by V. and C. Meyer respectively, to possess the molecular formulæ $AlCl_3$ and $InCl_3$; it therefore became most important to determine, if possible, whether the molecule of the corresponding chloride of iron possessed, as has been so generally supposed, the constitution Fe_2Cl_6, or $FeCl_3$. The pure ferric chloride for use in the experiments was obtained by gently heating fine iron wire in a stream of dry chlorine gas and re-subliming the product, thus obtaining the salt in beautiful hexagonal plates, exhibiting a fine green colour by reflected, and a purple tint by transmitted light. The first determination was carried out in a bath of vapour of boiling sulphur (448° C.). At this temperature, the lowest at which vapour-density estimations are possible, the volatilization is very slow, but occurs without the slightest decomposition. And yet the vapour-density obtained was considerably lower than that required by the formula Fe_2Cl_6, showing that at no temperature does ferric chloride possess the molecular formula Fe_2Cl_6, but must of necessity consist of molecules corresponding to the simpler formula $FeCl_3$. On repeating the determinations at higher temperatures in baths of phosphorus pentasulphide (518°) and stannous chloride (606°), and in a platinum apparatus heated in a Perrot furnace to temperatures of 750°, 1050°, and 1300°, the numbers obtained gradually approached the vapour-density of $FeCl_3$, the only unfortunate circumstance being that decomposition into ferrous chloride and chlorine occurred as the temperature was increased. However, on repeating the observations in an atmosphere of chlorine, results almost identical with the former ones were obtained; hence there can be no doubt that the true formula of ferric chloride is not Fe_2Cl_6, but $FeCl_3$. It follows from this as a matter of course that the former view as to the tetrad nature of iron must be laid aside. It will be of great interest, in view of this somewhat unexpected result, to learn the results of the determinations of the vapour-density of the lower chloride of iron, which, we understand from Prof. Meyer, are being undertaken by Profs. Nilson and Pettersson.

A THIRD edition of "Practical Amateur Photography," by Mr. C. C. Vevers, has just been issued. This little manual is intended to serve as a text-book for the beginner and a handy work of reference for the advanced photographer, and care has been taken to make it eminently practical.

AN interesting book on "Tank Angling in India," by Mr. H. Sullivan Thomas, has been published at Madras and in London (Hamilton, Adams, and Co.). Anglers in India will find in the little work—in which there are some fairly good illustrations—an immense amount of information about paste-baiting, live-bait picketing, live-bait with a float, worm and prawn fishing, localities suitable for tank-fishing, stocking ponds, the mainspring of fish-life, and names, description, and habitat of fish.

IN No. 124 of the Proceedings of the Royal Society of Edinburgh (session 1886–87) many valuable papers are printed. Among the contents we may note: the sense of smell, being Part III. of Prof. Haycraft's treatise on "The Objective Cause of Sensation"; on transition resistance at the surface of platinum electrodes, and the action of condensed gaseous films, by Mr. W. Peddie; researches on the problematical organs of the Invertebrata, by Dr. A. B. Griffiths; the salinity and temperature of the Moray Firth, and the Firths of Inverness, Cromarty, and Dornoch, by Dr. H. R. Mill; on the minute oscillations of a uniform flexible chain hung by one end, and on the functions arising in the course of the inquiry, by Dr. E. Sang; notes on the biological tests employed in determining the purity of water, by Dr. A. W. Hare; glories, halos, and coronæ seen from Ben Nevis Observatory, extracts from log-book, by Mr. R. T. Omond; on glories, by Prof. Tait; rectilineal motion of viscous fluid between two parallel planes, by Sir W. Thomson; and the thermal windrose at the Ben Nevis Observatory, by Mr. A. Rankine.

AT a recent meeting of the Wellington (New Zealand) Philosophical Society a paper was read by Mr. E. Tregear on "The Origin of Fire" according to Polynesian folk-lore. Mr. Tregear read from Sir George Grey's work the Maori legend of the procuring of fire from the old fire-goddess Mahuika by the hero Maui who had the power of becoming a bird at will, and compared this with the Samoa version in which the fire-deity is a male person, from whom Maui procures fire, having vanquished him in a personal encounter. In the legend of another of the islands the place of Mahuika as fire-deity is taken by the great Polynesian god Tangaroa. From the fact that in these legends the path by which fire was reached was always downwards into the centre of the earth, Mr. Tregear suggests that it was probable that the ancestors of the Polynesians had experience of natural fire drawn from volcanic sources, but to Maui is due the discovery in Polynesia of fire by friction. With regard to Maui himself there is great difficulty in the parent-names. The assumption by him at will of the form of the dove or of the hawk is consistent with the belief in the ancient world of the various shapes assumed by deities when desirous of accomplishing their purposes. The "seed of fire," an expression used in traditions for the inflammable nature of certain kinds of timber, was a common idiom in ancient Continental nations. Fire-worship continued to have its devotees in Europe until comparatively recent times; and the sacred fire was always "new fire" which had not previously been used for any purpose, being kindled by friction. A legend is preserved in Eastern Polynesia of the descent of the Maori people from a race whose name is the same as that of the fire-kindling instrument used in India, and it is remarkable that the deity who forges the thunderbolts in India is probably identical in name with the thunder-god of the Maoris.

DR. GEORGE M. DAWSON has contributed to the Transactions of the Royal Society of Canada (vol. v. section 2, 1887) a valuable series of notes and observations on the Kwakiool people of Vancouver Island. Referring to the question as to the best means of doing good service to the Kwakiool, Dr. Dawson says it is primarily essential to establish among them

industries which will remove the temptation now felt to drift to the larger settlements and towns. The Kwakiool, with other Indians of the coast, already cultivate in a desultory manner small crops of potatoes, on such minute patches of open ground (generally the sites of old villages) as are to be found along the shore. Their bent, however, is not that of an agricultural people, and the densely-wooded character of their country calls for labour, herculean in proportion to the unsystematic efforts of these people, before it can be cleared and reclaimed for agriculture on any large scale. They are excellent boatmen and fishermen in their own way, and Dr. Dawson has no doubt that under favourable conditions they would readily learn to build boats, make nets, and cure fish in such a manner that the product would be marketable. To effect these objects the most essential step, in Dr. Dawson's opinion, is the establishment of industrial schools, where the younger people may be separated from their old associations and instructed in various callings appropriate to their condition and surroundings.

We have received the Report of the Rugby School Natural History Society for the year 1887. This is the twenty-first issue. The editors point out that owing to various causes a perhaps unusually large number of the meetings were taken up with lectures. Among the contents are two exceptionally interesting papers: one on "Specialization," by Mr. E. Solly, and one on "Natural History in Southern Germany," by Mr. E. E. Austen.

Mr. E. Stanford has issued a pamphlet, by Mr. F. A. Velschow, of Copenhagen, on "The Natural Law of Relation between Rainfall and Vegetable Life, and its Application to Australia." The object of the paper is to show why, in the author's opinion, the regularity of the downpour of rain "depends directly on one particular quality appertaining to vegetable life." He also undertakes to prove that "vapour rarefies the atmosphere instead of increasing its specific gravity, as is now supposed."

The last Calendar of the Imperial University of Japan, to which we have already briefly referred, shows in a very striking manner how the Japanese are beginning to rely upon themselves for instruction in matters relating to higher education. The following figures will show to what extent the Japanese now avail themselves of European assistance in their University:—(1) Law Department: 19 professors, assistants, and lecturers, of whom 5 are foreigners; (2) Department of Medicine: 53 professors and assistants, of whom 2 are foreigners; (3) Engineering Department: 33 professors, assistants, and lecturers, of whom 4 are foreigners; (4) Literature Department: 19 professors and lecturers, of whom 6 are foreigners; (5) Department of Science: 25 professors and assistants, of whom 2 are foreigners. The academical and other qualifications of the Japanese professors and lecturers appear in most cases to be all that could be expected from men holding their positions. The distribution of the foreign professors and lecturers in the University is, we believe, as follows: eight British, eight Germans, two Frenchmen, and one American. Not many years ago a large majority of the *employés* of the University of Tokio, as it was then called, were Americans; and of the present number of foreigners the majority appear to be employed in teaching foreign systems of law and foreign languages. We notice the appointment for the first time of a Professor of Sanitary Engineering, wherein the Japanese University is in advance of nine-tenths of the educational institutions of the West. It is also curious to notice that the Professor of Japanese Philology and Literature is an Englishman.

Ellis's "Irish Education Directory and Scholastic Guide" for 1888 has just been issued. The publication of the volume has been delayed in consequence of the many important changes made in the regulations of the medical licensing bodies in Ireland. During the past year the work has been carefully revised, and it contains full information as to the Irish Universities and professional schools, and the institutions of Ireland for promoting intermediate and primary education. There are also complete alphabetical lists of Irish colleges and schools, and copious alphabetical and classified indices.

The examination papers set in 1887 in connection with the Royal University of Ireland have been published in a separate volume as a supplement to the University Calendar for the year 1888.

According to *Allen's Indian Mail*, the principle of payment by results in the primary schools, has not been altogether successful in India. Last year it proved a failure in Kachar, and this year it is having its final trial in Assam. The teachers in charge of certain selected schools were offered their choice of fixed salaries or payment by results, and if they did not work the latter system successfully they were to revert to the former. The rules for payment by results have recently been revised, larger rewards being offered, and the scheme has been opened to all primary schools.

On Monday a deputation representing Islington, Hackney, and Stoke Newington, waited upon Mr. Anstie, Charity Commissioner, to confer with him about a proposed scheme of Technical Institutes for the North of London. Mr. Anstie was reminded that the Commissioners had suggested to a previous deputation that St. Pancras, Islington, Hackney, and Stoke Newington should combine in order to formulate an educational scheme which would benefit the North of London. Since that time three of the parishes—Hackney, Islington, and Stoke Newington—had met, but St. Pancras had declined to join them, and they now desired to know what assistance they could get out of the City Parochial Funds for their scheme. The deputation said it would be difficult to raise money, but, supposing that they raised £60,000 in Islington and Hackney, could the Charity Commissioners promise them one-half of that amount? Mr. Anstie replied that the Charity Commissioners' proposal to South London was to contribute pound for pound, to be applied rather to permanent endowments than to pay any preliminary expenses. The Commissioners were very anxious in any scheme that was proposed that provision should be made for children between the ages of 13 and 16 to continue their instruction, and they particularly wished to benefit the poorer classes. In fact, they were bound to do so under the provisions of the Act. If St. Pancras stood outside, then the Commissioners would have to treat with the three parishes alone. He urged them very strongly to use every effort to get as much money as possible. The Commissioners would look most favourably upon a scheme which contained in it the promise of the largest contributions.

During the approaching summer a new branch of the London Geological Field Class will make a detailed study of the Chalk formation under the direction of Prof. H. G. Seeley, F.R.S. The other branch under the same direction will follow the course of former years by investigating the principal geological features in the neighbourhood of London. Full particulars can be had by intending students on application to Messrs. G. Philip and Son, 32 Fleet Street, and from many booksellers in the suburbs.

The additions to the Zoological Society's Gardens during the past week include a Shining Parrakeet (*Pyrrhulopsis splendens*) from the Fiji Islands; two Banded Grass Finches (*Poëphila cincta*); two Bicheno's Finches (*Estrelda bichenovii*) from Queensland; two Mandarin Ducks (*Æx galericulata*) from China, purchased; a white-fronted Lemur (*Lemur albifrons* born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Pulkowa Catalogue of 3542 Stars for 1855.—Dr. Backlund has given in the "Mélanges Mathématiques et Astronomiques" of the St. Petersburg Academy, tome vi., pp. 563–99, a comparison of the star places of the Pulkowa Catalogue of 3542 stars for 1855, with those of the other Pulkowa star catalogues, including the unpublished one for 1875 by Herr Romberg, as well as with the catalogues of Becker, Boss, and Resphigi. This catalogue, which forms part of vol. viii. of the Pulkowa observations, contains the mean places of 3542 stars observed with the meridian-circle of that Observatory during the years 1840–69. It includes all the Bradley stars north of S. Decl. 15°, with the exception of the Pulkowa fundamental stars, which have not been included because the catalogue-places depend on their positions as determined with the transit-instrument and vertical circle. And as the definitive positions of the present catalogue depend on the two catalogues of fundamental stars for 1845 and 1865, it appears that the system of the catalogue for the epoch 1855 will be practically identical with that of the mean of the two catalogues above mentioned. Dr. Backlund's comparisons give a very favourable view of the accuracy with which the relative positions of the stars have been determined, the probable error of an R.A. in the 1855 catalogue being ± 0″·034 for a star south of N. Decl. 30°, and of a declination ± 0″·30; but they also show that the problem of the determination of absolute positions is in a far less satisfactory state. A further comparison of the Pulkowa 1855 catalogue has been made by Herr Seyboth (*Astr. Nach.* 2808), the catalogue with which it has been compared being that of the Cape Observatory for 1880. The agreement appears to be as close as could be expected considering the unfavourable position at either Observatory of several of the stars used; the Pulkowa star places south of the equator show, however, some discordance from those obtained at the Cape as also from those of Boss's standard catalogue. From a comparison of the fundamental stars only, Herr Seyboth finds for the probable error of the Cape places ± 0·021s. in R.A., and ± 0·38s. in Decl.

The Constant of Precession and the Proper Motion of the Solar System.—The completion of Auwers' re-reduction of Bradley's observations, and of the definitive catalogue based thereupon, taken together with the catalogue of 3542 stars and the two fundamental catalogues referred to in the preceding note, has furnished M. L. Struve with the means for a very important investigation, which he has recently published in vol. xxxv. of the *Mémoires* of the Imperial Academy of St. Petersburg. The epoch for Bradley's catalogue being 1755, and the mean date of the three catalogues just mentioned, 1855, M. Struve had at his disposal the places of all Bradley's stars north of S. Decl. 15° for two epochs a century apart. The differences of these places would be due to a combination of three causes: the actual proper motions of the stars, the movement of the solar system, and the error in the constant of precession employed; and they therefore furnish the means of determining both the true value of the precession constant and the direction and rapidity of the motion of translation of the solar system. In his discussion of his materials, M. Struve has followed the method adoped by Sir G. Airy in his treatment of the same problem (Memoirs R.A.S., vol. xxviii.), and determined all his unknowns at the same time. As after excluding all those stars which rest upon but one observation of Bradley, together with a few others omitted for special reasons—seven for their large proper motion,—there still remained 2509 stars, with 2181 proper motions in R.A., and 2345 in Decl., without some method of grouping, the equations of condition would have been too numerous for manipulation. M. Struve has therefore marked off seven zones, each 15° in breadth, and divided these by lines of right ascension into 120 spherical trapezia of nearly equal areas. Each group has been weighted according to the number of the stars it contains, and also according to their magnitudes, so as to reduce the influence of the brighter stars. The solution of the equations of condition by the method of least squares shows very nearly the same correction to the adopted constant of precession,—that of Prof. O. Struve, of 1841, viz. 50″·3798,—from the proper motions in right ascension as from those in declination, the resulting value for the constant being 50″·3514, not so small a value as Nyrén's, 50″·3269, but smaller than those of Bessel, Dreyer, and Bolte. The equating of X, Y, and Z to zero in the normal equations gives a result substantially the same, and proves that the constant can be considered as independent of the motion of the solar system.

For the speed of translation of the solar system, M. Struve finds $q = + 4''\cdot3642$; for the co-ordinates of the apex of the motion, A = 273° 21′, and D = + 27° 19′. Comparing the various determinations which have been made by other astronomers, he is disposed to adopt as a mean position of the apex—A = 266°·7, D = + 31°·0. For q, the displacement of the sun in 100 years as seen from an average star of the sixth magnitude, a number of investigators, O. Struve, Dunkin, Gyldén, and Mädler, have found values not greatly differing from 5″; but others, Ubaghs, Airy, Rancken, and Bischof, obtain very different results, varying from $q = 1''\cdot45$ by Ubaghs, to $q = 49''\cdot5$ by Bischof. Taking 0″·011 as the mean parallax of a star of the sixth magnitude, $q = 5''$ would represent an annual motion of about five radii of the earth's orbit, or a velocity of a little over 15 miles per second. It is clear, however, that we are yet far from being in a position to regard these estimates of velocity as more than provisional.

The chief difficulty in these investigations lies in our ignorance of the actual distances of the stars from us, and even of their relative distances. M. Struve has assumed the following mean values of ρ—the distance of the star from the sun—for each order of magnitude, the sixth magnitude being taken as unity:—

m.		m.	
1	0·13	5	0·70
2	0·23	6	1·00
3	0·36	7	1·49
4	0·51	8	2·25

and adopting 8″ for the secular proper motion of a sixth magnitude star, the scale represents to some extent the proper motions actually observed. M. Struve has also discussed the question of the rotation of the entire sidereal system in the plane of the Milky Way, but his results do not afford any support to the hypothesis, and it has been neglected in the general investigation. At the end of the memoir M. Struve has given the means for the calculation of the general and planetary precessions, together with their secular variations. An appendix furnishes a list of those Bradley stars for which the Pulkowa catalogues gave proper motions sensibly different from those deduced by Auwers from the Greenwich and Berlin observations.

Comet 1888*a* (Sawerthal). — Dr. B. Mattheissen gives (*Astr. Nach.* No. 2830) the following ephemeris from Finlay's elements for this object:—

For Berlin midnight.

THE ROYAL METEOROLOGICAL SOCIETY'S EXHIBITION.

FOR several years past the Royal Meteorological Society has organized an Exhibition of Meteorological Instruments in connection with its ordinary meeting in March. The first Exhibition, which was held in 1880, was of a general character; the subsequent ones, however, have been devoted to the following special subjects, viz. hygrometers, anemometers, travellers' instruments, thermometers, sunshine recorders and radiation instruments, barometers, and marine meteorological instruments.

The subject selected for this year's Exhibition was atmospheric electricity, including new meteorological instruments. The Exhibition was held in the rooms of the Institution of Civil Engineers, 25 Great George Street, Westminster, from March 20 to 23, and was of a most interesting character. The catalogue embraced 155 exhibits, which were arranged under the following heads:—Electrometers, lightning conductors, lightning protectors for telegraph purposes, objects damaged by lightning, &c.; alleged thunderbolts, new instruments, photographs of flashes of lightning, and photographs, drawings, &c.

The Astronomer-Royal exhibited all the apparatus for atmospheric electricity which was formerly in use at the Royal Observatory, Greenwich. These instruments were mounted so as to show the manner in which they were actually arranged for observation.

The Kew Committee also exhibited a number of electrometers which were employed by Sir Francis Ronalds at the Kew Observatory from 1843 to 1851. These are fully described in the Report of the British Association for 1844. Several forms of Thomson's portable electrometer were also shown. The electricity in this instrument is collected by means of a burning fuse at the extremity of a vertical wire. Prof. F. Exner, of Vienna, sent his portable apparatus for the determination of the normal potential in the open air and while travelling.

Numerous patterns of lightning conductors were exhibited by Messrs. J. W. Gray and Son, Messrs. R. Anderson and Co., Messrs. John Davis and Son, and also by the Lightning Rod Conference. Models of churches, houses, chimney-shafts, &c. showed the systems adopted for securing protection from damage by lightning. Messrs. Siemens, Brothers, and Co., also exhibited their apparatus for testing the efficiency of lightning conductors.

The Postal Telegraph Department showed a number of lightning protectors which are used for protecting telegraph instruments.

The Exhibition contained many objects damaged by lightning, including lightning conductors, telegraph instruments and line wire, and portions of trees struck by lightning. The most interesting exhibit, however, was that showing the clothes of a man torn off his body by lightning on June 8, 1878, while standing under a tree. These comprise a flannel jacket, flannel under-vest, trousers, stockings, garters, boots, and watch; also a portion of the bark from the tree.

A valuable collection of meteorites was also shown, the specimens being from various parts of the world, and one showing the Widmanstätten figures. A number of alleged "thunderbolts" were also exhibited. These were of an amusing character; the specimens being in reality nothing more than a large nodule of sandstone, a cannon-ball, a piece of coal, clinkers, &c. Mr. Symons, at the meeting of the Society, showed that these were really of a terrestrial, and not a celestial, nature.

One of the special features of the Exhibition was the very interesting collection of more than fifty photographs of flashes of lightning which have been collected from all parts of the world. These show that lightning does not take the zigzag path as depicted by artists and painters. The lightning really takes a very sinuous and sometimes erratic path. Some of the photographs had been enlarged specially for the Exhibition, and showed up to great advantage. In some cases the photographs showed the lightning to be not merely a line of light, but to have a perceptible breadth, somewhat resembling a piece of tape waved in the air. A large number of the photographs were taken in London during the great thunderstorm of August 17, 1887. One of the photographs taken by Mr. E. S. Shepherd shows the remarkable phenomenon of a *dark* flash.

Mr. Symons exhibited three diagrams of lightning made by Mr. James Nasmyth, F.R.S., in 1856, showing (1) Nature's lightning; (2) painter's lightning; and (3) forked lightning. On comparing these drawings with the photographs of lightning, it is at once apparent what a keen eye Mr. Nasmyth must have had, for the agreement is exceedingly close.

Several new meteorological instruments were exhibited. Mr. W. H. Dines showed a maximum wind pressure anemometer. This has a circular plate, which is always kept face to the wind, at the back of which is a vessel containing shot. The pressure of the wind forces back the plate, and allows shot to fall from the higher to the lower part of the vessel. As soon as the weight of the shot in the lower vessel is equal to the whole pressure on the plate, the plate resumes its normal position, and the opening through which the shot falls is closed. The weight of the shot in the lower vessel gives the maximum pressure since the instrument was last read. Mr. G. H. Larkins showed some rain-band spectroscopes with Tripe's arrangement. The improvements in this instrument over the ordinary form of direct-vision spectroscope are: (1) that it gives uniform light and dispersion, and also better definition of the lines; (2) that as the slit is of uniform width, observations made with this form of instrument are comparable with each other; and (3) that the focussing tube can be fixed by a revolving clamp and kept ready for use.

Dr. Marcet exhibited Prof. Colladon's instrument for illustrating the formation of waterspouts. This consists of a large glass vessel, at the bottom of which has been scattered some dust somewhat heavier than the water. The motion given to a handle turns a wheel which imparts to the water a circular motion. The dust is then drawn up from the bottom in a column, and looks exactly like a waterspout or a sand pillar.

Mr. J. B. Jordan showed one of his new pattern photographic sunshine recorders (in which he now obtains a straight record instead of a curved one), and also that devised by Dr. J. Maurer, of the Swiss Central Observatory, Zurich.

Mr. G. M. Whipple exhibited his repeating cloud camera, which has been designed for obtaining a series of four photographs of the same cloud at short intervals of time, in order to show rapid changes of form.

Numerous photographs of damage by lightning were shown, as well as several records of atmospheric electricity taken at the Greenwich and Kew Observatories during thunderstorms and snowstorms. Messrs. Norman May and Co., exhibited two beautiful photographs taken from the top of the Worcestershire Beacon (1390 feet above sea-level), about 700 feet above the general level of the fog which covered the whole of the surrounding country, on January 12 last. Above the fog there was bright sunshine.

Mr. R. Abercromby and Mons. C. Moussette each exhibited some very fine photographs of clouds; and Mr. J. S. Dyason showed a number of sketches of skies in colour.

WILLIAM MARRIOTT.

THE BOTANICAL DEPARTMENT, NORTHERN INDIA.

UP to the year 1874–75, the Botanical Gardens at Saharanpur and the Botanical Officer in charge of them were Imperial, *i.e.* were under the control of the Supreme Government. In 1875, under the scheme of decentralization by which the independent powers of local Governments were considerably increased, the charge of the Saharanpur (Botanical) Institute became provincial, and passed under the authority of the Lieutenant-Governor of the North-Western Provinces and Oudh.

In 1887 the subject of reorganizing the Botanical Survey in India was taken up in connection with the memorandum, dated February 10, 1885, by Mr. Thiselton Dyer, Director of the Royal Gardens, Kew, and after consultation with the Government of the North-Western Provinces and Oudh and the Superintendents of the Botanical Gardens, Howrah and Saharanpur, the Government of India determined that the most important step which it was desirable to take in order to bring the hitherto unexplored regions of India under botanical survey was to expand the circle, for the botanical investigation of which the Saharanpur Officer was responsible, so as to bring the greater part of Upper India within the sphere of his duties. In order to effect this object it became necessary to restore the Saharanpur Botanist to his former position as an Imperial officer. A further reason for this change was found in the necessity for maintaining, at the disposal of the Government of India, the services of a Botanical Officer with a specially trained staff for the purpose of accompanying expeditions in the neighbourhood of or beyond our north-western frontier. These duties have now been attached to Mr. Duthie, the officer who holds the Saharanpur appointment.

The transfer took effect from April 1, 1887. But the Gardens, with the assistant, Mr. Gollan, who was brought out in 1879, were not placed under Imperial control, but still remained provincial. The Imperial Botanist is therefore now divorced from the Curatorship of the Gardens, which has passed, under the general control of the Director of the Provincial Department of Agriculture, into the hands of the former assistant. The Botanical Officer retains his occupation of the house and Botanical Museum (with the Herbarium), but has no longer any connection with the practical management of the surrounding gardens.

The Botanical Officer retains under his control the whole of the native staff connected with the Museum and its Herbarium, as well as the native artist (now drawing Rs. 100 a month), who was trained at the Bombay School of Art specially for the Saharanpur Institution.

THE NEW SIBERIAN ISLANDS.[1]

THE Expedition of MM. Bunge and Toll, who have explored the lower Yana and the islands of New Siberia during the last two years, was sent out by the Russian Academy of Sciences. Hedenstrom's description of the masses of petrified wood which is found on these islands, and the information gathered from the hunters as to the richness of the archipelago in remains of Quaternary mammals, were the chief inducements for sending out the Expedition.[2] The Expedition consisted of Dr. Bunge, who had just terminated his two years' stay at the Sagastyr Polar station at the mouth of the Lena; Baron Toll; two Cossacks, four Yakuts, and two Tunguses. After having explored the region at the mouth of the Yana during the summer of 1885,[3] and spent the winter at the Kazatchie settlement, twenty miles to the south of Ust-Yansk, the Expedition started in the spring for the New Siberian Islands, and for better exploring them divided into two parties. Dr. Bunge undertook the exploration of the southern islands of the archipelago, and especially of the small Lyakhoff Island, while Baron Toll explored the northern islands (Kotelnyi, Thaddeus, and New Siberia), usually called the Anjou Islands.

Owing to some misunderstanding Dr. Bunge did not find his reindeer on the small Lyakhoff Island, which was his chief station; and, until June 14, he was compelled to limit his explorations to a few excursions only. He saw large flocks of ducks coming from the north—that is, from what is an open sea on our maps, while several species of *Larus* and *Totanus* came from the south. As a rule, few birds cross to Little Lyakhoff Island in their migrations; only geese come by the end of June, and as they moult on the shores of the small lakes and ponds of the island, they are killed in great numbers by the hunters.

The winter lasts on the Little Lyakhoff Island until the first part of June, and returns again in October. On October 16 the frost was already $-37°$ C., but even during the summer 10° C. over zero is considered a very hot temperature; and in July there were thirteen days with snow, fifteen with fog, four with rain, and one snowstorm.

And yet organic life develops with astonishing rapidity. The first flowers were seen on June 11, and Dr. Bunge's collection of phanerogams numbers seventy species; but all plants are dwarfs, hardly reaching a few inches, while the soil, even in the best situated places, thaws only to the depth of 16 inches. The water of the small ponds is so much warmed by the rays of the sun, that temperatures of from 10° to 16° C. were observed, and therefore worms and Crustacea rapidly develop in the ponds. The insects are few; even the mosquitoes do not plague men and cattle as they do on the continent; still, two butterflies were caught. As to mammals, herds of reindeer come every year from the continent to the islands, but in smaller numbers than formerly; they are followed by wolves. The snow fox is very common, but the common fox and hare are exceedingly rare visitors to the islands. The Polar bear has become of late very rare, and hunters attribute this to the fact that the ice has remained unbroken for several yeas past. They affirm that the ice around the coasts has not moved since the year when Nordenskiöld sailed through in the *Vega*, and Dr. Bunge doubts whether it will soon be possible to repeat the same journey.

The chief interest of the island is in its masses of fossil bones buried in the frozen soil. Bones of the mammoth, rhinoceros, *Bos moschiferus*, two other species of *Bos*, several species of *Cervus*, very many bones of *Equus*, and several others, were found, and brought in by Dr. Bunge. The rocks of which the island is built are granite and sedimentary rocks without fossils.

Baron Toll's expedition was much richer in results. It appears from his surveys that the Kotelnyi Island extends much farther east than is shown on our maps, and that it is connected with Thaddeus Island by a sandy beach. It would be most interesting to know how far this circumstance is due to the upheaval of the islands, which is sure to go on like the upheaval of all the northern coast of Siberia. But the most important discovery is, that the masses of fossil wood which were found on Thaddeus Island proved to be Tertiary, and not Quaternary, as has hitherto been supposed. They belong to layers of Tertiary coal, and fossil *Sequoiæ* were found amidst them. We have thus a new proof that the great Tertiary continent which possessed a warm climate, well known from Oswald Heer's description, included not only Greenland, Spitzbergen, and Novaya Zemlya, but also the New Siberian Archipelago, more than 90° of longitude to the east of Novaya Zemlya. Geology must explain the existence of this warm climate beyond the 75th degree of latitude, at a period so closely preceding that of the glaciation of the northern hemisphere.

Finally, Baron Toll, after having made rich zoological, botanical, and palæontological collections—Silurian, Devonian, and Triassic deposits being found on the Kotelnyi Island,—reached the northern extremity of the island under the 76th degree of latitude, and thence he saw the land which was seen eighty years ago by Sannikoff, and has since periodically appeared on, and disappeared from, our maps. It exists, and it is situated nearly a hundred miles (150 versts) due north, off the northern extremity of the Kotelnyi Island.

If we take into account the facts that there are serious reasons for admitting the existence of a land to the north of Novaya Zemlya,[1] and that the existence of Sannikoff's Land is now again

confirmed, we must recognize that the discovery of Franz Joseph's Land was but a first step towards the discovery of the Arctic archipelagoes which undoubtedly exist under and within the 80th degree of latitude. P. A. K.

EARTHQUAKES IN THE LEVANT.[1]

THE Island of Zante, in the Ionian Group, to the north-west of the Gulf of Arcadia, is a centre from which no fewer than seven submarine cables radiate, and Mr. Forster has taken advantage of his position as manager of the station to make some interesting observations of the connection between interruptions of the cables and the occurrence of earthquakes, which are more frequent, he says, in the Levant than in any other part of the world, except Japan. The notes of what he has himself observed are valuable and suggestive, but unfortunately he has made them a peg on which to hang a theory that the "true and only reason for seismic disturbances" is that landslips and subsidences occur in ocean beds. Soundings of the bed of the Mediterranean, made chiefly in the interest of cable-laying, have brought to light extraordinarily rapid variations of depth. In one case, Mr. Forster tells us, the repairing ship of his company found a difference of 1500 feet between the bow and stern soundings. "We know of mushroom-shaped mountain ranges, abrupt and precipitous table-lands, immense marginal shelves and overhanging cliffs. . . . We know by soundings that many of these tottering masses are hanging over precipices from 3000 to 5000 feet in height, and that the erosion of the water at the base of the inverted cone-shaped rocks eventually causes them to slide over." Mr. Forster admits that a secondary cause of earthquakes may be "explosions owing to the filtration of water through the crevices and chasms that a denudation of so large an extent must necessarily cause." He has done good service in drawing attention to a cause of earthquakes which seismologists may have been disposed to under-rate, but he overstates his case outrageously in making this explanation cover every example. "I am prepared, of course," he says, "to encounter a torrent of objections to the acceptation of my theory as the sole cause of seismic disturbances" (*sic*), and this is well.

By way of supporting the theory he has written a long, rambling, inconsequent pamphlet, the manner and matter of which we may illustrate by quoting a paragraph that is neither better nor worse than its neighbours :—

"If, therefore, we are to believe that the process of cooling our planet, which began so many thousands of centuries ago, is gradually and surely condensing the nucleus of liquid or solid fire in its centre, it is reasonable to assume that the bed of the Mediterranean, by virtue of its more recent formation, should be more subject to the effects of the contraction of the upper crust than other parts which have gone through these periods already ; because it is evident that the contraction which originally commenced began equally so over the whole surface of the earth's sub-crust, and was, through some unknown reason, abruptly suspended in certain parts which only subsided and very suddenly when the cooling action was once more renewed."

Or this, which the author himself puts in italics :—

". . . *The severity of the concussion is always precisely proportionate to the bulk of the falling mass, the depth of its fall, and the nature of the matter constituting it, and on to which it falls.* . . ."

We commend the following to the attention of electricians, as coming from one of their own number :—

"By 'freeing' a cable, it is understood that the end opposite to the testing-station is detached from the apparatus and left free in the air ; and, provided the cable be electrically perfect, no deflection of the magnetic needle will appear at the testing-office when the cable is joined up through a delicate galvanometer to 'earth.' If, however, the cable thus insulated is lying near to or in the direct radius of a volcano, or near to any hot springs, the increased temperature would cause a thermopile to be set up, and by induction through the insulating material its presence would be plainly manifest."

The fact that in certain earthquakes the author made this test and found no current, is used as an argument to show the "absolutely local nature" of what in another place he calls the "*centri*" of the shocks.

What is of real value are his positive observations of certain cases where the rupture of a cable or the production of a bad fault in it took place at the moment an earthquake occurred, and of cases where, when the cable came to be repaired, the contour of the ocean bed was found to have undergone a distinct change, the cable being, in more than one instance, actually buried below the new surface. The great earthquake which destroyed Filiatra in August 1886, shook the telegraph office at Zante so sharply that the clerk rushed out. On returning to his Morse instrument, he found, by the paper band which was still running, that a message coming from Candia had been interrupted at the time of the shock, and tests taken immediately after showed a dead break 23 miles from Zante. Other cables, following a more northerly course, were not disturbed. In another instance a cable was broken at once in two places, 2 miles apart, apparently by a subsidence of the ground between. Once, when the Zante-Trepito cable was broken by an earthquake 7 miles from Zante, the repairing ship discovered "that the break had occurred in a depth of about 2000 feet of water, where about 1400 feet originally existed, and it was impossible to haul in the broken end, firmly jammed down by the mass which had fallen over and upon it."

If Mr. Forster had contented himself with telling the story of facts like these, which have come within his own observation, the seismologist would have felt nothing but gratitude. But these grains of wheat are only reached after wading through an intolerable deal of wordy chaff. The gist of the pamphlet is to be found in the last fifteen or twenty pages, and we advise the reader who wishes to save his patience to go to them at once. We conclude by quoting an interesting passage where Mr. Forster describes two natural phenomena of Cephalonia, about which one would like to know more :—

"Not far from Lizuri, which is on the western side of the Bay of Argostoli, is a moving rock which, unchanged by the roughest or the calmest sea, rocks to and fro with the regularity of a pendulum. It is separated from a fixed mass of rock against which it opens and shuts in its perpetual motion ; at one time it will jam a knife placed in the crevice, from which, in a few seconds, extraction is impossible, whilst the next moment you can easily insert your bent hand when its maximum aperture has been reached. This phenomenon has been carefully examined by many scientific men ; divers have been sent below to ascertain if it be the result of a detached rock from a neighbouring cliff having fallen on to another, and thus becoming very finely balanced, as all logan stones usually are. However, it was not only shown to be a perfectly solid rock, but it does not require the motion of the water to sway it, as so often we find it erroneously stated, the motive power for swaying it being furnished from an absolutely inexplicable cause. Nearly opposite to this rocking stone the other remarkable phenomenon is to be found, consisting of a body of water, equal in bulk to about half a million gallons per day, running in from the sea at four points on the coast somewhat rapidly for a certain distance until it gradually becomes sucked into the earth and disappears. By conducting the water into an artificial canal for a few yards, and by collecting the four points of supply into one, enough motive power is obtained to drive two mills. The stream, after being thus utilized, is allowed to follow its own course, and is lost among the rocks. . . . [It] has no visible outlet."

Forster, Manager and Electrician to the Eastern Telegraph Company, Zante. Dedicated, by Special Authority, to His Majesty George I., King of the Hellenes. Pp. 68. (London : Waterlow and Sons, 1887.)

THE MINERAL CONCRETION OF THE TEAK TREE.[1]

AT the last meeting of the Nilgiri Natural History Society Mr. Lawson showed a specimen of a whitish mineral substance found in a teak tree growing in the Government Plantation at Nilambúr. This peculiar secretion is not altogether unknown to officers in the Forest Department, and its composition has on more than one occasion been investigated by chemists.

In 1870 the fact of calcareous masses occurring in timber was brought to the notice of the Asiatic Society of Bengal by Mr. R. V. Stoney, who stated (*vide* P.A.S.B., May 1870, p. 135) that many trees in Orissa had pieces of limestone or calcareous tufa

[1] A Paper read by David Hooper at a meeting of the Nilgiri Natural History Society, Ootacamund, November 7, 1887.

in their fissures, but principally Asan (*Terminalia tomentosa*, W. and A.), Swarm (*Zizyphus rugosa*, Lam.), Sissu (*Dalbergia sissu*, Roxb.), and Abnus (*Diospyros melanoxylon*, Roxb.).

In 1880, Mr. V. Ball, in making a geological survey in the Central Provinces, met with this concretion, and thus alludes to it in his "Jungle Life in India":—"Some white marks on the cut stumps of an Asan tree caught my eye, and these on examination proved to be sections or laminæ of calcareous matter which alternated with the ordinary rings of woody growth. The rocks about were gneisses and schists, and I could discover nothing in the soil to account for the peculiarity. In some cases irregularly shaped pieces seven inches long by two inches thick were met in the trunks at a height of about six feet from the ground. By the natives the lime is burnt and used for chewing with *pan*. On examination it was found there was no structure in these masses which would justify a conclusion that they had been formed by insects. Some included portions of decayed wood seemed to be cemented together by the lime."

Major-General Morgan, late Deputy Conservator of Forests, Madras, speaks of it in the following terms in his "Forestry of Southern India":—"It is a curious fact that in the Wynaad, though there is no free lime in the soil, yet Teak (*Tectona grandis*) and Blackwood (*Dalbergia latifolia*), if wounded near the ground, contrive to absorb large quantities of lime. It may be seen, incrusting the tree on the surface as far as four feet in height, from three inches to a foot in width, and two or three inches in thickness. The lime is so hard that it destroys circular saws, and the Carumburs use it for chewing with betel."

Abel, in 1854, thus described it: "The wood of teak, which grows in the South of India and other tropical countries, frequently exhibits cracks and cavities of considerable extent lined with a white crystalline deposit consisting chiefly of hydrocalcic orthophosphate, $CaHPO_4,H_2O$, with about 11·4 per cent. ammonio-magnesium phosphate" (Chem. Soc. Q.J. xv. 91.)

This white deposit in the wood of teak has also been examined by Thoms, who found it to consist of monocalcic orthophosphate, $CaHPO_4$ ("Landw. Versuchs. St." xxii. 68, xxiii. 413). More recently still Prof. Judd has found in teak a specimen of crystalline apatite, a well-known mineral containing a large proportion of calcium phosphate.

"The formation of this deposit indicates that the wood itself must contain a considerable quantity of phosphoric acid, and the analysis shows this is really the case, as the ash of teak wood is composed as follows:—

CaO	MgO	FeO	K_2O	Na_2O	SiO_2	SO_3	P_2O_5	CO_2	Cl
31·35	9·74	0·80	1·47	0·04	24·98	2·22	29·69	0·01	0·01

The percentages of carbon and hydrogen are higher than in most woods, and this together with the richness in calcium phosphate and silica may perhaps account for the great hardness of teak" (Watts' "Dict. Chemistry," 3rd Supp. p. 1894).

The sample from Nilambúr was in the form of a rounded flattened cake about ten inches in diameter and two or three inches in thickness; dirty white in colour, with a rough gritty surface. A sample was made for analysis by breaking off portions from different parts of the cake and reducing the whole to a fine powder. The powder examined under the microscope was mainly in an amorphous condition similar to prepared chalk, with a dark-coloured gummy matter, and a small quantity of crystalline quartz sand. The following is the composition:—

Calcium carbonate	70·05
Tricalcic orthophosphate	2·89
Quartz sand	9·76
Organic matter	14·30
Moisture	3·00
	100·00

The analysis shows that the principal compound is calcium carbonate, and the concretion approaches nearer the chalk or limestone formation than that of the apatite or phosphatic found by other investigators. An examination of deposits from other trees might show greater differences than these, but it seems enough has been done to prove that the calcium element forms the base.

The sand, probably blown up as dust and made to adhere by the organic matter, is a mechanical ingredient. The deposit contained no salts of sodium or calcium soluble in water, nor any ammoniacal compounds; this would stand to reason, as the heavy rain to which this district is subjected would scarcely leave anything soluble on the trees.

A sample of the soil from the Teak Plantations, the same as that in which the ipecacuanha is being cultivated, has also been examined. It is a light reddish brown sandy loam with quartz. In a dry state it contains 79 per cent. of silica and silicates, about 5 per cent. of organic matter, the same of iron oxide and alumina, and 0·217 per cent. lime as oxide.

The scanty amount of lime present in the soil, and the large amount found in the tree, show what an enormous quantity must have been taken up by the sap. I have shown elsewhere that a full-sized cinchona tree contains about ten ounces of lime (as slaked lime), not concentrated by abnormal development in one place, but distributed in all its parts. A teak tree from its size and ash contents would have a much larger supply than a cinchona, and yet, it seems, is able to excrete it in some abundance. In what manner this takes place is not easy to determine. The calcium enters the plant in a soluble form as sulphate. The calcium unites with oxalic and other acids and is precipitated, while the sulphuric acid parts with its sulphur to form organic compounds. A wound in the tree is liable to render these processes abnormal by causing the vegetable acids to ferment by exposure to the air and to yield carbonic acid as one of the products, and this meeting with the calcium in the ascending sap exuding from the wound might convert it into an insoluble calcium carbonate which would harden in the cavity of the tree and form the deposit.

THE NEW YORK AGRICULTURAL STATION.[1]

THE special report of the Director, Dr. E. Lewis Sturtevant, extends over the first fifty-seven of a volume of 480 pages, and within their limits are to be found the general conclusions arrived at during the past year. The remainder of the *brochure* consists of the detailed reports of the horticulturist, the botanist, and the chemist. After an analysis of the rainfall and temperature of 1887, which appear in general climatic conditions to have borne a great resemblance to what we ourselves experienced, the Director calls special attention to the importance of soil moisture, and surface cultivation as a means of conserving it. He shows the vast importance of checking evaporation from the surface by preserving a finely pulverized condition of the top soil. This he calls a "soil mulch," and states that "it protects the capillary outlets from surface exposure."

"The extent of the conservation of water through the prevention of evaporation by cultivation, as measured by the lysimeters in 1885 from May to September inclusive, with a rainfall of 14·42 inches, as between bare soil and cultivated soil, was about 1·4 inch, and as between cultivated land and sod-land about 2·5 inches. The rational direction, therefore, to the farmer for carrying out intercultural tillages must be to use an implement as a means to an end, *i.e.* the maintaining of a mulch of loose soil upon the field. . . . The intercultural tillage should be applied whenever the upper soil has regained, through the effect of rains, its connection with the lower soil, and the capillary tubes become extended to the surface. Following the same line of argument, the evil effects of weeds are attributed to their appropriation and transpiration of moisture from the soil rather than to their robbing the plant of food constituents. This conclusion will be brought home to anyone who notices the dry condition of the soil in near proximity to tree roots."

The remarks upon feeding cattle with a view to milk and to beef production are interesting, but the system of experimenting upon single animals is not to be commended. The conclusion forced upon the Director, that "individuality is sufficient to mask the influence of food," is patent to anyone, and should demonstrate the absolute need of carrying out any feeding experiments upon a large number of cattle simultaneously. Average results may then be expected upon which practice may be based.

The Director pours a flood of cold water upon the system of plot experiments in the field. Under the head of "Conclusions" he says:—"These field trials indicate the utter unreliability of field experiments, and should convince the public of the lack of certainty which attends all general conclusions gained by this process. I trust the time may arrive when this plat work, instead of being forced upon experiment stations, will be condemned." Certainly

[1] Sixth Annual Report of the Board of Control of the New York Agricultural Experiment Station (Geneva, Ontario Co.) for the year 1887.

after obtaining no increase by the application of 1400 pounds of a fertilizer, over what had been obtained from a dressing of 400 pounds per acre, there might appear some cause for complaint. We cannot, however, indorse Dr. Sturtevant's opinions. Plot experiments may be made fairly representative of larger areas, and upon them various treatments of soil and crop may be compared. No doubt great care should be taken in carrying out such experiments; but surely a series of plots of $\frac{1}{4}$, $\frac{1}{10}$, or $\frac{1}{20}$ acre each might be and are made to teach most useful lessons. Dr. Sturtevant might well pause to consider that if such experiments are of no value the value of other experiments might be doubted, and the public, to whom he appeals, might think fit to rescind a grant amounting to £4000 a year for the purpose of carrying out his researches. The volume abounds in tables of analyses of fodder and grain crops. A large portion (200 pages) of the middle is occupied by a descriptive catalogue of varieties of beet, carrot, radish, turnip, onion, celery, spinach, squash, tomato, &c., mostly very wearisome, and savouring more of the catalogue of the seedsman than of the results of scientific work.

Downton. JOHN WRIGHTSON.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, January.—Researches on the influence of magnetism and temperature on the electric resistance of bismuth and its alloys with lead and tin, by Ed. van Aubel. These protracted experiments have been undertaken in order to determine the variations of electric resistance due, not only to magnetism and heat, but also to molecular structure, with a view to discovering the causes of the disturbances and completing our knowledge of the phenomena first observed by Hall. In the present paper, a first contribution to the study of the subject, the author deals mainly with the diminution of the electric resistance of bismuth and its alloys under increased temperature. He shows that the anomaly cannot be due to the presence in the metal of foreign elements such as arsenic, tin, lead, or iron. The state of greater or less tension of the bismuth itself also seems to have no influence. But the study of some bismuth wire obtained by the soldering of the filings of this metal under a pressure of several thousand atmospheres constantly exhibits a considerable increase of resistance when the temperature is raised.—Experimental researches on the vision of the Arthropods, third part, by Felix Plateau. This part deals with the vision of caterpillars, and with the *rôle* of the frontal ocelli in the perfect insects. The very numerous experiments here described and carried out under the most varied conditions, tend to the general conclusion that in insects possessing both compound and simple eyes (ocelli), the former are of some service, while the latter are quite useless, and should consequently be grouped in the category of rudimentary or atrophied organs. In the case of caterpillars the vision is defective, not extending distinctly beyond one centimetre, and is supplemented by the antennæ and the fine hairs covering the body. Perfect insects when completely blinded almost invariably fly in a straight line vertically, which, against the opinion of Forel, is attributed to the more intense light of the higher regions, to which the whole surface of the body is susceptible. The primitive "dermatoptic sensation" is revived, and acts in a feeble way as a substitute for the later developed ocular vision of which the animal has been deprived.—On the molecular work of the organic liquids, by P. De Heen. It is shown that the author's formula of 1882, that for the organic fluids belonging to one and the same homologous series the molecular work is fairly constant, has been mainly confirmed by subsequent research.—This number of the *Bulletin* also contains a valuable paper by Louis Henry on the volatility of the carbon compounds, the result of several years' research.

Rivista Scientifico-Industriale, February 29.—On the peronospora of the grape-vine, by Prof. G. Cuboni. The two phases of this disease are fully described for the first time, and the disease itself is carefully distinguished from black-rot and other analogous forms of blight with which it is often confounded. A mixture of sulphur with 3 or 4 per cent. of the sulphate of copper is proposed as the best remedy if applied at an early stage.—Prof. E. Canestrini concludes his experiments on some effects produced by induction sparks. In one instance the leaves of some perennial plants were found to be covered with dark spots similar to those frequently observed on plants struck by lightning. But the results of these researches, like others of a similar kind, have obviously no more than a relative value, depending as they do on the intensity of the induced currents.

Journal of the Russian Chemical and Physical Society, vol. xix. No. 8.—Isomery in the series C_nH_{2n-2}, by A. Favorsky.—On the laws presiding at reactions of direct addition, by J. Kabloukoff.—Short notes by MM. E. Sokoloff, Joukovsky, and Gorboff.—Experimental researches into the oscillations of electrical force in electrolytes, by A. Sokoloff; it is the third of a series of elaborate papers on the subject, especially with regard to the capacities of voltameters.—On the measuring of specific heat by the method of mixtures at a constant temperature, by N. Hesehus.—End of a full bibliography of all books and articles printed in Russia on chemistry and chemical technology during the year 1886.

Journal of the Russian Chemical and Physical Society, vol. xix. No. 9.—On the speed of formation of acetic ethers of monatomic alcohols, by N. Menshutkin, being a first paper of a new series of researches where the compound influence of the surrounding medium in which the reaction is going on has to be studied.—Notes by MM. Matweieff and Spiridonoff.—On the empirical formula of cholic acid, by P. Latchinoff, being an answer to the criticisms against the new formula ($C_{25}H_{42}O_5$) proposed by the author.—On the gelatinous state of albuminoid bodies, by W. Mikhailoff, being the first of a series of papers intended to summarize elaborate researches on the subject, in accordance with the principles laid down by Lieberkühn and his followers.—On the number of parameters which determine the displacement of a kinematic chain, by P. Somoff. Taking up the view of Reuleaux, who recorded each mechanism as a kinematic chain, the author shows the necessity of considering the degree of freedom left to each part of the chain in its displacements in various mechanisms.—On the dependence of the colour of bodies on the angle of incidence of the rays of light, by W. Rosenberg.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 15.—"Report of the Observations of the Total Solar Eclipse of August 29, 1886, made at Grenville, in the Island of Grenada." By H. H. Turner, M.A., B.Sc., Fellow of Trinity College, Cambridge. Communicated by the Astronomer-Royal.

The first part of the paper gives details of the general arrangements made for observation—the selection of a site, the erection of the instruments, and a hut to cover them; and refers to the unfavourable conditions under which the observations were made. The second part gives the results of the observations. These were of two kinds.

(1) Before and after totality the order of appearance and disappearance of a number of bright lines in the spectrum of the chromosphere and inner corona was watched. The lines selected were those observed by Mr. Lockyer in the Egyptian eclipse of 1882, and the observations were undertaken with a view to the confirmation of his results.

The lines are denoted for convenience by small letters as follows:—

	λ.		λ.		λ.
a	4870·4	*e*	4917·9	*h*	4932·5
b	4871·2	*f*	4919·6	*i*	4933·4
c	4890·0	*g*	4923·1	*k*	4956·5
d	4890·4			*l*	4970·0

With this nomenclature, a table given by Mr. Lockyer in a short account of his results (Roy. Soc. Proc., vol. xxxiv., 1883, pp. 291, &c.) shows that lines *g* and *l* are seen by Tacchini in prominences, while *a*, *b*, *c*, *d*, *e*, *f*, and *k* are seen in spots.

Mr. Lockyer saw *g* and *i* 7 minutes before totality,
and in addition *k* and *l* 3 ,, ,,
and all the lines 2 ,, ,,

In my own observations I saw *g* 3 minutes before totality,
and in addition *i* 40 seconds ,,

while the moment of appearance of all the lines was indistinguishable from the commencement of totality.

After totality clouds obscured the sun for a short time; but on their clearing the visibility of *g* and *k* was noted; *i* could not be seen.

The three lines *g*, *i*, and *k* were extremely short, and did not

appear to extend beyond the chromosphere before and after totality.

The unfavourable conditions under which the observations were made as compared with Mr. Lockyer's—with a low sun and through passing clouds, and an atmosphere charged with moisture which doubtless diminished the light in this region of the spectrum considerably—perhaps account in some measure for the striking difference in vividness of the phenomena. The solar activity was also much nearer minimum in 1886 than in 1882. As far as they go, however, the observations are confirmatory of Mr. Lockyer's, except in the visibility of the line *k* after totality. This line was not noted before totality, and it is possible that the observation may be spurious, although the evidence for it is as good as that for all the observations, which were found to be generally of a difficult character. The instrument used was a 6-inch refractor by Simms, with a grating spectroscope; the grating being $1\frac{1}{2}$ inch square, ruled with 17,000 lines to the inch. The second order of spectrum was used.

(2) During totality I was directed to look for currents in the corona. I can only report a negative result. The structure of the corona appeared in a 4-inch refractor, with a power of 80, to be radial to the limb throughout, and no striking differences in special localities were noticed.

Appended to the paper are two drawings which do not attempt to give more than the distances to which the coronal rays extended in various directions. One was made by Mr. St. George with an opera-glass, and the other by Lieut. Smith with the naked eye; but in the latter case the observer's eyes had been specially covered fifteen minutes before totality, and the brighter portions of the corona were screened from him by a disk of angular diameter three times that of the moon. He consequently traced the rays much further than Mr. St. George, though, allowing for this difference in conditions, the drawings are fairly accordant.

"On the Ultra-Violet Spectra of the Elements. Part III. Cobalt and Nickel." By Profs. Liveing and Dewar.

The authors compare the results obtained by the Rutherfurd grating which they used in measuring the wave-lengths of the iron lines with those obtained wlth the larger Rowland's grating used for measuring the wave-lengths recorded in this paper, and find them closely concordant. They next compare the measures of wave-lengths of the cadmium lines obtained by them by means of a plane Rowland's grating and a goniometer with an 18-inch graduated circle with those obtained by Bell with a large concave grating of 20 feet focal length. The result of the comparison is that the plane grating gives measures which agree very closely with those given by the concave grating, while the former gives more light and is better for complicated spectra, such as those described in this paper, because the overlapping spectra of different orders are not all in focus together as they are when a concave grating is used.

The authors give a list of 580 ultra-violet lines of cobalt and 480 lines of nickel. They find a certain general resemblance of the two spectra, but no such exact correspondence as the close chemical relationship of the two metals would render probable. They point out that the coincidences of lines of the two metals are hardly, if at all, more in number than would have been the case if the distribution of the lines had been fortuitous. They give a map of each spectrum to the same scale as Ångström's normal solar spectrum.

Linnean Society, March 15.—W. Carruthers, F.R.S., President, in the chair.—On a ballot being taken, the following were elected Fellows of the Society: Messrs. J. W. Taylor, W. Gardiner, and David Sharp. The following were admitted Fellows of the Society: Messrs. A. G. Renshaw and A. E. Shipley.—Mr. J. Harting exhibited the frontal portion of the skull of a red-deer stag, which, although an adult animal, had never possessed horns, and made some remarks on the occasional occurrence of this abnormality. The stag in question was one which had been shot some years ago by the late Emperor of Germany in the Royal forest of Göhrde, in Hanover. A discussion followed in which the President, Mr. Seebohm, and Dr. Hamilton took part.—The first paper of the evening was then read by Mr. George Massee, entitled "A Monograph of the *Thelophoreæ*," and drawings of several of these Fungi were exhibited. The paper was criticized by Mr. A. W. Bennett and Prof. Marshall Ward.—In the absence of the author, a paper by Mr. E. A. Batters, describing three new marine Algæ, was then read by the Botanical Secretary, Mr. B. Daydon Jackson, who exhibited the drawings made to illustrate the paper. After some critical remarks from the President, Mr. Harting pointed out the indirect influence of the Gulf Stream in causing a deposition of northern sea-weeds upon the north-east portion of the English coast, where some of the species described had been found.

Zoological Society, March 20.—Mr. Henry Seebohm in the chair.—Mr. G. A. Boulenger read a note on the classification of the Ranidæ, in which, after speaking of the difficulty hitherto experienced in dividing this large group satisfactorily, he called attention to Peters's discovery that in certain forms a small additional phalanx is present between the ultimate and what is normally the penultimate phalanx. The author therefore proposed to separate the family Ranidæ into two groups, according to the presence or absence of this peculiar digital structure.—Mr. G. B. Sowerby gave the description of sixteen new species of shells, amongst which were two species of the genus *Lima* from Hong Kong and Japan; a remarkable species of the rare genus *Malletia* from the Bay of Bengal; a very distinct species of *Cypræa* from Japan; and one of the largest species yet known of the genus *Columbella*.—Mr. F. E. Beddard read some notes on a freshwater Annelid, of which he had obtained specimens from a tank in the Society's Gardens. Mr. Beddard referred these specimens to a new species of the genus *Æolosoma*, which he proposed to called *Æ. headleyi*.—Prof. Newton, F.R.S., communicated (on behalf of Mr. Scott Barchard Wilson) the description of *Chloridops*, a new generic form of Fringillidæ, based on a specimen obtained on the west coast of the Island of Hawaii, Sandwich Group, which he proposed to name *Chloridops koua*. Unfortunately the single example yet obtained was of the female sex.

Geological Society, March 14.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the gneissic rocks off the Lizard, by Howard Fox, with notes on specimens by J. J. H. Teall. The rocks may be classed under three heads: (1) the coarse gneisses or Mên Hyr type, (2) the light-banded granulitic gneisses or Wiltshire type, and (3) the transition micaceous rocks of "Labham Reefs," type intermediate between (2) and the mainland schists. The first are seen in Mulvin, Taylor's Rock, Man-of-war Rocks, the Stags, Mên Par, Clidgas, Mên Hyr, and Vasiler; the second in Sanspareil, the Quadrant and adjoining reefs, Labham Rocks, &c.; and the third in the Labham Reefs. The inclination of the divisional planes appeared conformable with that of the rocks of the mainland. The gneisses and granulites of several of the islands are traversed by numerous dykes of prophyritic basic rock, seen in Taylor's Rock, Man-of-war Rocks, Sanspareil, Quadrant Rock and Shoals, and Clidgas. These dykes have been disturbed by movements subsequent to their intrusion. They sometimes strike across the foliation-planes of the gneiss, and send veins into the latter rock; at other times the strike is parallel to that of the foliation-planes; the two modes of occurrence are occasionally observable in different portions of the course of the same dyke, *e.g.* in one traversing that part of the Man-of-war group known as the Spire. This dyke is also noticeable from the fact that it appears to be traversed by veins of gneiss. The dykes vary in width from 18 inches to several feet. In his notes on the specimens, Mr. Teall arranges the rocks in four groups. Prof. Bonney spoke in high terms of the value of the work done, as it was in a region accessible with difficulty, which time did not permit him to explore when working at the rocks of the mainland.—The Monian system, by the Rev. J. F. Blake. The reading of this paper was followed by a discussion in which the President, Dr. Hicks, Prof. Hull, and Prof. Bonney took part.

Royal Meteorological Society, March 21.—Dr. W. Marcet, F.R.S., President, in the chair.—The President delivered an address on atmospheric electricity. He first alluded to Franklin's experiments in America in 1752, who succeeded in obtaining the electricity of a storm-cloud by conducting it along the string of a kite sent into the cloud. De Romas, in Europe, repeated the experiment, and, having placed a wire within the twine his kite was attached to, obtained sparks of 9 or 10 feet in length. The characters of the two kinds of electricities were next described—the vitreous or positive, which was produced by rubbing glass, and the resinous or negative, obtained by rubbing sealing-wax or another resinous substance; and it was shown, by bringing suspended balls of pith within the in-

fluence of these electricities, that electricities of different kinds attract each other, and those of the same kind repel each other. De Saussure's and Volta's electroscopes were next described, pith-balls being used in the former and blades of straw in the latter for testing the pressure of electricity. With the object of measuring the force of electricity, Sir W. Thomson's electrometer was mentioned, in which the electricity is collected from the air by means of an insulated cistern letting out water drop by drop, each drop becoming covered with electricity from the atmosphere, which runs into the cistern where it is stored up, and made to act upon that portion of the instrument which records its degree or amount. The atmosphere is always more or less electrical, or, in other words, possessed of electrical tension, and this is nearly always positive; while the earth exhibits electrical characters of a negative kind. The effects of atmospheric electricity were classed by Dr. Marcet under three heads: (1) lightning in thunderstorms; (2) the formation of hail; (3) the formation of the aurora borealis and australis. He explained how clouds acquired their electrical activity by remarking that clouds forming in a blue sky, by a local condensation of moisture, became charged with positive electricity from the atmosphere; while heavy dark clouds rising from below nearer to the earth were filled with terrestrial negative electricity, and the two systems of clouds attracting each other would discharge their electricity, giving rise to flashes of lightning. In some cases a storm-cloud charged with positive electricity would approach the earth, attracting the terrestrial negative electricity, and when within a certain distance shoot out lightning which would apparently strike the earth; but it would just as well have struck the cloud, only there was nothing in the cloud to sustain any damage, while on the earth there were many objects lightning would destroy, to say nothing of its effects upon animal life. Thunder is the noise produced by the air rushing in to fill up the vacuum made by the heat of the lightning flash. There may be sheet lightning, zig-zag or forked lightning, or globular lightning. The latter is particularly interesting from its assuming a spherical form. Illustrations were given of objects struck by lightning, the most remarkable being, perhaps, the clothes of a working man which were torn into shreds, while the man himself was not seriously injured. Dr. Marcet next proceeded to show a flash of lightning, which he produced by throwing on a white screen the image of an electric spark 2 or 3 inches in length, enlarged by means of the lens of an optical lantern; forked lightning, 6 or 8 feet in length, with its irregular zig-zag course, was most clearly demonstrated. After alluding to the protecting power of lightning conductors and their construction, Dr. Marcet explained the formation of hail and waterspouts, and exhibited an instrument by Prof. Colladon, of Geneva, for showing the formation of waterspouts. He concluded his address with a few remarks on the aurora borealis and australis, the formation of which was illustrated by de la Rive's experiment, which consisted of successive discharges of electric sparks through a partial vacuum while under the influence of a powerful magnet; electric sheets of light were seen assuming the form of bands and possessed of a certain rotating motion.—Mr. G. J. Symons, F.R.S., read a short commuication on the non-existence of thunderbolts, and briefly described the history of several so-called thunderbolts, the specimens obtained being of an amusing character, thus clearly showing that they were of a terrestrial and not a celestial character.

Edinburgh.

Royal Society, February 20.—Sir W. Thomson, President, in the chair.—A preliminary note on the duration of impact, by Prof. Tait, was communicated. The results already obtained were got by means of a roughly made apparatus designed for the purpose of testing the method used. When a wooden block of 10 lbs. mass fell through a height of 18½ inches on a rounded lump of gutta-percha, the time of impact was found to be 0·001 sec., and the coefficient of restitution was 0·26.—A paper on a bathymetrical survey of the chief Perthshire lochs was read by Mr. J. S. Grant Wilson of H.M. Geological Survey. Lochs Rannoch, Tummel, Earn, and Tay, were specially dealt with. In the discussion which followed, Sir W. Thomson remarked that he did not consider that the ice had much to do with the formation of rock basins. Where it found a rock basin already in existence it might increase its dimensions.—Mr. H. M. Cadell, H.M. Geological Survey for Scotland, read a paper, of which an abstract appeared in our last issue (p. 488), on experimental researches in mountain building.—Mr. Peach communicated a paper by Dr. Ernst Stecher on contact phenomena of some Scottish olivine diabases.

March 5.—Mr. J. Murray, Vice-President, in the chair.—Mr. W. E. Hoyle communicated a paper by Mr. D. McAlpine on observations on the movements of the entire detached animal, and of detached ciliated parts of bivalve mollusks, viz. gills, mantle-lobes, labial palps, and foot.—The Chairman communicated a report on the fishes which he had obtained in deep water on the north-west coast of Scotland. The report was drawn up by Dr. A. Günther, F.R.S., Keeper of the Zoological Department, British Museum.—Prof. Haycraft read a paper by Dr. Carlier and himself on the morphological changes which take place in blood during coagulation.—A paper by Prof. Tait on the mean free path, and the number of collisions per particle per second in a group of equal spheres, was communicated. In this paper Prof. Tait cited De Morgan's definition of the term "mean," and pointed out the difference between the mean free path, properly so called, and the quantity to which that name is usually applied.—A preliminary note by the same author on the compressibility of glass at different temperatures was also read. The glass experimented upon was ordinary lead glass. At 8° C. the compressibility per atmosphere is 0·0000027, and increases by 0·00000002 per degree Centigrade of rise of temperature.

March 19.—Sir W. Thomson, President, in the chair.—Mr. George Seton read a paper on illegitimacy in the parish of Marnoch.—Dr. G. Sims Woodhead communicated some notes on the use of the mercuric salts as antiseptic surgical lotions.—In a paper on the effect of differential mass-motion on the permeability of gas, Prof. Tait gave the calculations which he promised in his reply to Prof. Boltzman published in the *Philosophical Magazine*.—The President read the second part of a paper by Mr. J. J. Coleman, on a new diffusimeter, and other apparatus for liquid diffusion, and discussed the determination of diffusivity in absolute measure from Mr. Coleman's experiments.—Sir W. Thomson also read an extract from a letter of the late William Froude to himself, dealing with the soaring of birds. Mr. Froude showed that in all cases soaring is dependent on the existence of upward air currents. In the case of a complete calm at sea, the upward current is produced by displacement as a wave passes underneath.—Mr. W. Peddie read a preliminary note on new determinations of the electric resistance of liquids by a method based upon Joule's law, and which therefore avoids any error which might be caused by transition-resistance or polarization.—Mr. C. A. Stevenson gave a notice of the recent earthquake in Scotland, with observations on those since 1882.

Paris.

Academy of Sciences, March 19.—M. Janssen in the chair.—On certain points connected with the theory of accidental errors, by M. Faye. It is argued that the arithmetical mean does not necessarily and in all cases give the most probable result. The law of error can be regarded only as a simple approximation to the truth, although so far valuable that it may be freely applied to all sorts of observations and measurements, provided they be exempt from systematic error. The danger lies in excluding all extremes which might have the effect of enabling the observer to draw any conclusion he pleases, or which squares best with some preconceived view. The same subject is discussed in a paper by M. J. Bertrand on the probable value of the smallest errors in a series of observations.—On a point in the theory of the moon, by M. F. Tisserand. The object of these remarks is to determine in Delaunay's theory of the moon the full scope and application of the theorem of the invariability of the great axis of the lunar orbit. The demonstration here induced from Delaunay's method is extremely simple, and leads to some further interesting inductions.—New theory of the equatorial *coudé*, by MM. Lœwy and P. Puiseux. The paper deals with the corrective terms depending on the inner glass and the axis of declination. In a future paper will be given the terms depending on the outer glass, together with the complete formulas of reduction.—On the absorption of saline substances by plants, by MM. Berthelot and G. André. The experiments here described are mainly confined to the sulphate of potassa, and will in future be extended to other substances with a view to elucidate the obscure processes by which plants derive their mineral elements from the soil. The solution of the

soil whence the roots derive the sulphate is shown to remain always richer than the solution penetrating into the vessels of the roots. Thus is confirmed the general law of this class of phenomena, and some important inductions are drawn from it in connection with the formation of the nitrates in certain plants.—On the relations of atmospheric nitrogen with vegetable humus, by M. Th. Schlœsing. Having previously studied the relations of vegetable earth with ammonia, carbonic acid, and oxygen, the author here extends his researches to its relations with atmospheric nitrogen.—On the actinometric observations made at Montpellier during the year 1887, by M. A. Crova. From these observations it appears that the calorific intensity, measured at noon, steadily increased from the beginning of winter nearly to the end of spring, attaining its monthly maximum (1·35 calorie) in May, and its absolute maximum (1·54 cal.) on the 24th of that month. Then it declined rapidly, its mean value during the summer being inferior to the means of other seasons. It rose, fell, and again rose in autumn, during which period it acquired a new maximum of 1·26. These observations confirm the general laws induced from the records of previous years, showing that, although the epochs of maxima and minima may often be exceptionally displaced, the maxima of radiation occur normally in spring, the minima in summer. Tables follow giving the mean annual intensities and other meteorological data for the five years 1883–87.—On the unification of the calendar, by M. Tondini. Reference is made to the recent steps taken by Italy for the purpose of promoting the universal adoption of the Gregorian calendar, which, thanks to the action of England, has already replaced the Chinese system in Japan under almost insurmountable difficulties.—Remarks accompanying the presentation of a model of the Fumat safety-lamp, adapted for use in mines subject to fire-damp, by M. Daubrée. This lamp, which has been for some time in use in the Grand Combe mines, has successfully withstood the severe tests to which it has been subjected by MM. Mallard and Le Châtelier, and seems to answer all the purposes of such an appliance quite as well as any other hitherto devised.—The meridian of Laghwat, by M. L. Bassot. The geodetic junction of Spain with Algeria, completed in 1879, has now been extended to Laghwat, 180 miles south of Algiers, and on the verge of the Sahara. This carries the great meridian for the west of Europe across 28° of latitude, from the northernmost point of Great Britain through France and Spain to about 33° N. latitude, on the confines of the desert. To the triangulation have been attached the astronomic stations Gelt-es-Stel and Laghwat itself, the latitude and longitude and an azimuth for each of these places having been accurately determined.—On the passage of the electric current through sulphur, by M. E. Duter. Sulphur, a very bad conductor at the normal temperature, is here shown to acquire a considerable degree of conductibility when raised to the boiling-point.—On the radiograph, by M. Louis Olivier. The instrument described under this name has been invented by the author as a self-acting recording photometer. At each revolution of the drum it closes an electric circuit, and thus automatically shuts off the luminous action at any desired moment. While serving in a general way as a registering apparatus for light, it is capable of venous applications in photography, meteorology, and physics.—On the hydrate of sulphurated hydrogen, by MM. de Forcrand and Villard. Having already made known the composition of this substance, $HS + 12HO$, and measured its tension of dissociation between $+0·5$ and 29° C., the authors here resume its study for the purpose of more accurately determining this tension at or about the temperature of 0°. This is found to be about equal to atmospheric pressure.—Experimental researches on chronic intoxication by alcohol, by MM. A. Mairet and Combemale. Having previously described the influence of chronic alcoholic intoxication on the nervous and muscular systems, the authors here study its effects on the heart, the respiratory and digestive organs, and the bodily temperature.

BERLIN.

Physical Society, March 2.—Prof. du Bois Reymond, President, in the chair.—Dr. Gumlich spoke on Newton's rings as seen by transmitted light. The speaker had calculated and experimentally verified the formulæ for the rings as seen by transmitted light, in the same way as many years ago Prof. Wangerin had treated the rings when seen by reflected light, and subsequently verified the results of his calculations experimentally in conjunction with Prof. Sohncke. The outcome of Dr. Gumlich's calculation was the same as that of Prof. Wangerin for the rings seen by reflected light. When the light is incident at right angles, the rings are circles lying in one plane: when the angle of incidence is less than a right angle, the rings lie on a surface of extremely complicated shape, which is characterized by a primary ordinate, and an oblique ordinate at right angles to the former, which do not coincide at the point of intersection. By means of an apparatus which the speaker showed and carefully described, he had experimentally tested the accuracy of his calculations, and found them fully confirmed. When the light is incident obliquely, the rings are no longer circles as they are when it falls on to and passes through the medium at right angles, but are now ellipses whose axes bear a ratio to each other which is dependent on the angle of incidence of the light. It was not found possible to obtain any definite results as regards the width of the rings, since this is very largely affected by temperature.—Dr. Sprung reported on a work which had been sent in by Dr. Müller-Erzbach treating of the determination of mean temperature by means of the weight of water which is vaporized. A bulb blown on the end of a glass tube is half filled with water and introduced into a wide-necked flask whose bottom is covered with sulphuric acid. Assuming the truth of Dalton's law of tensions, Dr. Müller has arrived at a formula by means of which the mean temperature of a space can be determined from the mass of water which is vaporized in a given time.—At the end of the meeting Prof. Lampe discussed a reply which had been recently made to a criticism of his on a piece of work done last year by Dr. Häussler, and showed how devoid of foundation the reply was.

THURSDAY, APRIL 5, 1888.

THE FORESTRY SCHOOL AT COOPER'S HILL.

THE Forestry School at Cooper's Hill is intended in the first place for the education of a certain number annually of young officers for the Indian Forest Department. The arrangements are, nevertheless, of such a kind that private students are admitted to the forestry course, in as far as space is available, and on condition that they conform to the rules.

It is in many ways advantageous that the Forestry School is attached to the Royal Indian Engineering College at Cooper's Hill. Although the course for forest students is necessarily different from that designed for engineering students, there are several subjects to be studied in common, and consequently the present arrangements admit of the forest students obtaining their training in surveying, descriptive engineering, and mathematics, for instance, in the excellent courses provided by the well-known Professors in the Engineering College.

The Forestry School itself consists of a block of buildings attached to the Royal Indian Engineering College, on the brow of Cooper's Hill, near Staines, and looking north over Runnymede and the Valley of the Thames. It is within a convenient distance from London, the traveller arriving at Egham (the nearest station on the London and South-Western Railway) in from forty-five to sixty minutes from Waterloo. Windsor Great Park is within a mile of the beautiful and spacious grounds in which the College stands, and the fine trees of all kinds to be met with in the neighbourhood give to the situation much that is desirable for a centre for the teaching of forest botany, and several parts can be made use of to a certain extent for illustrating subjects in forestry proper.

The building of the Forest School itself consists of large and small class-rooms, a museum, and the well-designed and appointed botanical laboratory. In this block the students pursue their main studies—botany, forestry, and entomology. Their other studies—engineering, surveying, mathematics, geometrical and freehand drawing, physics, geology, and one or two other subjects to be referred to presently—are pursued under the direction of the various Professors in the class-rooms and laboratories of the Royal Indian Engineering College, to which the Forestry School is attached.

The forest museum is a convenient, well-lighted room, rapidly filling with useful collections of specimens illustrating the chief departments of forestry. Among the most valuable and conspicuous objects in this splendid collection may be mentioned the series of European and Indian timbers, which are so disposed that the student has ready access to them, while the Professors are able to refer to them in lecturing, and thus to make the teaching, in the best sense of the word, practical. Then there is a remarkably complete and interesting collection of implements used in forestry, and there are models of timber-slides, apparatus for catching timber, and other forest works, also so disposed that every student can handle and examine them and learn their uses with facility. Another valuable feature in this museum is the series of economic products of Indian plants. This is of course not complete, but the greatest credit is due to all concerned for bringing together for such useful purposes so many instructive specimens of fibres, seeds, barks, fruits, food-materials, &c., from the chief representative Indian plants; and when it is remembered that the Forestry School is so young, in this country (it was started in September 1885), it is the more praiseworthy that the authorities have made such good use of their opportunities and time. The collections must no doubt receive numerous additions as time passes, for it is well known that a museum takes many years to bring within measurable distance of completeness, but the Cooper's Hill museum is already fairly filled, the nucleus of the collections having been derived from the late Indo-Colonial Exhibition, and from the Royal Gardens, Kew. It would require too much space to enumerate the remaining interesting features of these instructive series of forest objects: specimens of timber showing the changes due to abnormal growths, the healing of wounds, the various injuries produced by unsuitable environment or by the attacks of insects and other living organisms, and last, but by no means least, a unique collection showing the ravages of those fungi which injure timber-trees, collected by Prof. Robert Hartig, of Munich, and presented to the School, and a collection of the more injurious forest insects, presented by Herr Oberforstrath Judeich, of Tharand. There is also a small herbarium, of a particularly interesting character, containing an excellent series of Conifers and other trees.

The botanical laboratory has just been completed, and is, without doubt, one of the best designed small laboratories, for its purpose, that we have seen. It consists of an oblong room running east and west, and lighted from the north and east by windows arranged conveniently for work with the microscope. There are also tables and apparatus for experimental demonstrations in vegetable physiology; provision will exist for cultivating seedlings and plants at constant temperatures, for measuring growth, and for exhibiting the influence of light, gravitation, &c., on the growth of plants; and arrangements for showing the quantities of water given off from transpiring leaves, for developing plants in water-cultures, &c. The students are supplied with microscopes, reagents, and accessories, and are taught to familiarize themselves thoroughly with all modern appliances bearing practically on their studies.

The above-mentioned block of buildings also includes one small and one larger lecture-room, which are provided with necessary teaching appliances. The series of botanical diagrams especially are remarkably good, and in fact many of them are unique, being the private property of the Professor of Botany, and drawn and coloured by himself. Another feature which must not be overlooked is the projected botanic garden. This will consist of a series of seed-beds, &c., illustrating the raising of forest trees, and of beds of plants chosen from the most important natural families, in order that the students may familiarize themselves on the spot with their chief characteristics. This botanic garden is now in process of being laid out, and it will be ready for the use of students in a short time.

The courses of studies followed by the forest students are admirably adapted to the wants of practical men

whose lives will be largely spent in the creating, planting, preserving, and using of forest and other trees. Obviously, such a course must comprise several branches of teaching, the one thing common to all being that they bear upon the practical needs of the future forester. That the same training applies to a planter or estate-manager needs no remark, and portions of the course would be suited for others engaged in work in woodlands, and in the colonies, &c. The full course, as at present set forth in the syllabus of studies, is as follows.

The student begins work in September, and attends lectures regularly during two academical years. In engineering, he is taught the principles of road-making, and the building of forest bridges and other structures; he is also instructed in the practice and theory of surveying under the care of the Professor of Surveying. In his first year he studies for two terms under the Instructor in Geometrical Drawing, and in his second year receives lessons in the keeping of accounts. To these subjects may be added freehand drawing, and a modern language. In addition to these more technical subjects, the student attends certain short courses in mathematics and in applied mathematics, under the Professors of these sciences; he also studies physics—in lectures, as well as in the laboratory—entomology, and geology. A short course on organic chemistry is now being commenced.

The rest of his work consists in the special training as a forester, and it may safely be stated that there is no other centre in the Empire where so thorough and excellently designed a curriculum for a forester or planter can be obtained. The two subjects of forestry and botany are under the care of separate Professors. Dr. Schlich lectures on forestry, dividing his subject as follows:—In the first year he deals with the various soils, climates, and the regulating effects of forests on these; sylviculture, artificial and natural woods; the tending, thinning, pruning, &c.; the protection of forests against man and other animals, and especially insects, and against injurious plants, climatic influences, &c. During the second year the student is instructed in the utilization of forests; the technical qualities of woods; the felling, shaping, transportation, &c., of timber; the utilization of minor forest produce; the preservation of wood; sawmills; charcoal, &c. He then passes to the study of working plans, and especially the arrangement of cuttings; surveying and mapping forests; measurement and determination of ages of trees and forests; and the methods of regulating the yield of forests. The final course of lectures is on forest law. In addition to the lectures, the students also make occasional excursions, under the direction of Dr. Schlich; the neighbourhood of Windsor Forest facilitating this important object, and enabling the Professor of Forestry to make his teaching thoroughly practical.

In botany, under the management of Prof. Marshall Ward, the students are instructed by means of lectures, and practical work in the laboratory and in the fields and woods of the neighbourhood. The course in botany is designed to train foresters, not technical botanists: its aim is throughout practical, and directed to teaching the students exact and thorough knowledge of the life-phenomena of the trees and plants which it will be their duty to rear, and take care of, and utilize in the future. Commencing with a short course of thoroughly practical instruction in the elementary biology of plants selected as illustrative types of the vegetable kingdom, the young student is taught the use of the microscope and how to apply it practically in examining the tissues of plants. He is then instructed in the organography and anatomy of plants, learning (not only in lectures, but also in the laboratory and in the field) what the organs of plants *are*, and what they *do*; so that roots, stems, leaves, buds, bulbs, tubers, tendrils, thorns, &c., become to him not mere abstractions, but objects on which his attention will be continually fixed as active parts of plants. The study of cells and their contents, of epidermis and stomata, of vascular bundles and other tissues—of wood, bark, cambium, and so forth—is carried on thoroughly, not only that the forester may know the principles by which to classify and recognize timbers and forest products, and learn their uses, but also that he may understand what these various parts of the plants do in nature: how heart-wood is formed, how the timber grows and may be improved, how wounds may be healed over, how the roots take up substances from the soil, and how the plant makes use of them, and so forth. The student concludes his first year's study in botany (in the early summer) by familiarizing himself with the names and systematic position of the plants in the neighbouring fields and woods, especial attention being paid to the important trees and shrubs, and their relations to the forest flora of India.

During his second year, the student is instructed in the physiology of plants—how they feed, respire, and chemically change substances in their interior; how they grow, and are affected by light, gravitation, temperature, moisture, &c.; how they are reproduced, hybridized, and so on; the effects of various agents in the production of wood, in influencing the fertility, and so forth. The course is completed by the study of the diseases of plants, and especially of timbers, and how their effects may be minimized or healed.

As special features of the greatest importance, it should be mentioned that the senior students pay periodic visits to the magnificent gardens, museums, and plant-houses at Kew, under the direction of Prof. Marshall Ward, in order that their knowledge of the important economic plants and their products shall be real. They see the plants growing, learn to familiarize themselves with their peculiarities and habits and uses, and are thus not strangers to them when they land in India. Secondly, the young foresters are taken abroad, and taught what life in the forest really is. At the completion of their first year's studies, they accompany the Professor of Forestry to Scotland, or to the New Forest, or to the Forest of Dean, as may be decided for the year; and at the end of their second year they are taken to the Continent for three or four months' practical work in Germany and France, to examine the systems pursued in the large and more systematically managed forests of those countries, and thus to study the art of forestry in practice under conditions more resembling those met with in the huge and valuable forests of India.

During the summer of 1887, for instance, the young officers who are now in India were taken to Bavaria, under the direction of Dr. Schlich, accompanied by Prof. Marshall Ward and Mr. Gamble. They visited the

magnificent museum and laboratories of the Forestry School at Munich, the Forest of Freising, the willow nurseries and plantations at Oberberghausen, the spruce forests at Hohenaschau, and the timber depot at Traunstein. They then proceeded to the Austrian forests of the Salzkammergut; and later to the Forest School and school forests at Nancy, the cork oaks and pine forests in the Esterel, and the *Pinus maritima* forests on the west coast of France, used for the preparation of turpentine as well as for timber.

With this practical tour, the training of the young forester in Europe stops, and he departs for India to assume the new duties and large responsibilities of his life as a forest officer under the Imperial Government.

THE BALTIC AMBER COAST IN PREHISTORIC TIMES.

Die prähistorischen Denkmäler der Provinz Westpreussen und der angrenzenden Gebiete. Von Dr. A. Lissauer. (Leipzig: Engelmann, 1887.)

THE prehistoric antiquities of that part of the Baltic coast that lies about the mouth of the Vistula have something more than a local interest. The old Prussian shore—the land of the Æstii of Tacitus and Cassiodorus, of the Estas of King Alfred—had already in very early times a European importance in its connection with the widely ramifying amber commerce of antiquity, of which this was in historic times the richest field of production. The present work by Dr. Lissauer, the President and founder of the Anthropological Section of the Natural History Society of Danzig, is peculiarly welcome as giving in a thoroughly scientific form a summary of the results of the archæological discoveries made in recent years relating to the prehistoric period in the province of West Prussia and its border districts. The author has divided the work into several sections, corresponding to the Neolithic, Hallstatt, and the successive Iron Age periods, and has accompanied each with an excellent synoptic list of the various individual finds.

Of the earlier Palæolithic Age there are, of course, no remains in this Baltic tract, which was still covered with an ice-sheet at a time when primæval man had already begun to tenant the caves of Cracow. As the ice retreated there was formed the great glacier stream at present represented by the Vistula, but which then prolonged its course to the west, and, joining with the Elbe, poured its waters into the German Ocean. The physical event which in this region dominates all the succeeding history is the breaking through of the Vistula at Fordon, near Bromberg, and the formation of the new channel by which it poured itself henceforth into the Gulf of Danzig; and this, geologically speaking, was a comparatively recent consummation. The author has reproduced an elaborate calculation of Jentzsch, based on the formation of the delta and the average amount of sediment conveyed by the waters of the Vistula, according to which the breaking through of that river to the north must have taken place approximately about 3000 B.C. That the Neolithic immigration into the Old Prussian land from the south must have taken place at an early period is seen from the local distribution of these remains, which tends to show that the ice and snow still lingered on the higher parts of the country. On the other hand, from the fact that Neolithic settlements are peculiarly abundant in the old bed of the Vistula itself, Dr. Lissauer concludes that this immigration did not take place till well after the date when the river had taken its new course. Here, too, as elsewhere, we find the same entire revolution in the character of the Neolithic fauna as contrasted with the Palæolithic group of the Polish caves for example. Not a single representative remains. No reindeer bones even have been discovered on the Neolithic sites of the lands of the Lower Vistula, though the remains both of aurochs and of bison have been found.

Among the most interesting and characteristic objects that appear in association with the Neolithic deposits of the Lower Vistula are certain rude representations of human and animal figures cut out of amber. These remarkable productions, perforated as if for suspension, and engraved with fine lines, are more frequent to the east than to the west of the Vistula mouth; but one of the most striking, a figure of a boar, ranked by Virchow amongst the best relics of the plastic art that have reached us from the Stone Age, was found in the neighbourhood of Danzig. These amber men and animals have been the object of a special study by Dr. Tischler, of Königsberg, whose researches into the prehistoric remains of East Prussia are the complement to those of Dr. Lissauer in the Western Province. In his admirable papers on the Stone Age in East Prussia, Dr. Tischler has shown that these figures are characteristic of an extensive East Baltic region; they have been found in the same shapes and with the same perforations, but cut out of bone and stalagmite instead of amber, in the Polish cave of Pod-kochanka; and, what is still more remarkable, bone figures of analogous character have been discovered amidst the remains of a Neolithic station, described by the Russian explorer Inostranzeff, on the shores of the Lake of Ladoga. From these and other parallels, Dr. Tischler has been able to establish the existence of a distinct East Baltic Stone Province extending from the Oder to the Lake of Ladoga, and in all probability to the Onega shores, and including not only the provinces of East and West Prussia but the greater part of Poland. The relation of these northern "idols" to the clay figures of men and animals found in the Swiss lake-dwellings, in the pile settlements of Laibach, and some of the prehistoric sites of Hungary and Transylvania, where one has been found of alabaster; and the relation again of these latter to the "Pallas" of Dr. Schliemann's Trojan excavations, or the rude "Carian" and Cypriote figures, suggest wide and far-reaching inquiries on which it is impossible here to embark.

Of the Bronze Age, pure and simple, there are very scanty remains in these East Baltic coast-lands; though there are sufficient examples, both of Hungarian and West Baltic forms, to show that before the close of the period in Central and North-Western Europe its arts were already taking root in this region. Dr. Lissauer's remarks on what he terms the "so-called Bronze Age," but which, in the greater part of our Continent at least, represents a very well defined stage of culture, reflect an attitude of mind not yet wholly extinct amongst German scholars. How far the Hallstatt culture can in this district be regarded as the immediate successor of that of Neolithic times is a

question, however, of comparatively secondary importance. The main fact with which we have to deal is that it is only in the transitional age that takes its name from the great Salzkammergut Cemetery, and when iron was already coming into use, that we have the evidence of intimate and extended relations between the Amber Coast of the Baltic and the lands to the south and south-east. The importance of this fact in its bearing on the early course of the amber trade does not seem to me to be clearly brought out by Dr. Lissauer. Montelius, however, has conclusively shown that throughout the earlier and purer Bronze Age in Central and North-Western Europe the source of the amber supply was not the East Baltic, but the coast of Jutland and the mouths of the Elbe and Weser, where, as Müllenhoff has demonstrated on purely literary grounds, lay the Amber Islands of Pytheas. The main course of this early commerce, as indicated by the connection of the Bronze Age forms discovered, was up the course of the Elbe; and the first appearance of an intrusive southern culture at the Vistula mouth in Hallstatt times shows that it was not till this comparatively recent period that the Baltic amber route was opened up. But, when once this, then probably as now, far more prolific field was known, southern commerce showed more and more a tendency to follow this route, to the final desertion of the older line to the north-west. Among the most characteristic evidences of the trade relations thus established between the Old Prussian Amber Coast and the Mediterranean may be cited the discovery of a "cordoned" bronze bucket of the class common to Northern and Southern Italy, and of which large finds have come to light in Southern Hungary,—a class of objects which there seems no longer any warrant for qualifying, as Dr. Lissauer does, as "Etruscan," but which, as Helbig has shown, may very well represent an old Chalcidian fabric. A whole succession of finds of Greek coins further mark in somewhat later times the continued intercourse with the south. Dr. Lissauer apparently accepts the much-disputed Schubin find of Archaic coins of Athens and Erchomenos, and though the inclusion in this sixth century hoard of two later pieces of Athens and Miletus, and a modern Siamese coin, render the circumstances of the find open to grave suspicion, the later series of discoveries of coins of Thasos, Macedon, &c., extending from Hungary to Gothland, throws a retrospective light on the probable direction followed by one branch of this Baltic commerce. It appears equally clear, however, both from archæological and historic sources, that another line crossed the Julian Alps to the head of the Adriatic, finding in all probability its southern continuation by the East Adriatic coasting route. This, it will be remembered, was the route followed by those who, in Herodotus's account, conveyed the mysterious gifts of the Hyperboreans to the Delian shrine of the Sun-god—a mission which seems to have an inseparable connection with the "Sun-stone" Islands of Eridanos's mouth and the Phaethontid maidens.

Among the most interesting and characteristic features of the Hallstatt period in West Prussia are the "face-urns," or cinerary vases with human features rudely modelled on their neck; and Dr. Lissauer is probably on the right track when he compares them with the early vases of the same kind discovered by Fräulein von Torma in the Valley of the Maros in Transylvania. That they have any relation with the "face-urns" of Etruria seems out of the question, especially since the appearance of the monograph of Prof. Milani, tracing the evolution of the developed Tuscan type from an earlier class of cinerary vases with funeral masks attached to them. But the parallels from the Maros Valley may be more plausibly regarded as supplying an intermediate link in space and time between the face-urns of the Baltic coast and those of prehistoric Troy. In other respects the ceramic forms that occur in West Prussia and its borderlands during this period, such as the "twin" and painted vases, show strong southern and south-eastern affinities; while the occurrence amongst the ornaments of *Cypræa moneta* and *Cypræa annulus* from the Red Sea and Indian Ocean point to still more extensive eastern relations. Cowry ornaments, it may be worth observing, are of frequent occurrence in the prehistoric cemeteries of the Caucasian region, and there is here perhaps an indication of old Pontic communications by the Dniester or Dnieper Valleys—lines of intercourse which Dr. Lissauer does not seem to have kept sufficiently in view.

The Hallstatt culture on the Old Prussian shore is in its turn cut short by that to which we in England give the name of "Late Celtic," but which on the Continent passes by the name of La Tène from the Swiss station of that name. The Roman taste for amber ornaments subsequently gave a great impulse to the commercial intercourse between south and north *viâ* the Pannonian frontier station of Carnuntum, and we have abundant evidence of the progress of Roman provincial arts on the Lower Vistula. The finds of Roman coins become more and more frequent, and culminate in the reign of Severus, after which time they as suddenly fall off. There can be little doubt, as Dr. Lissauer has suggested, that this sudden break in the commercial relations with the south is due to the great migration of the Gothic tribes, who had before this time established themselves in this part of the Baltic coast, to their new seats on the shores of the Black Sea and Trajan's Dacia. Into the depopulated lands west of the Vistula the new tide of Slavonic settlement now poured, while the older branch of the Litu-Slavic race, the Æstii or "Old Prussians," still held their own on the Amber Coast to the east of the river-mouth, as we know from the offerings made by them to King Theodoric. The last section of Dr. Lissauer's work is directed to this Wendish period of East Baltic history, to the "Burgwall" and the "Bergwall," the pile-dwellings, the characteristic pottery and ornaments of the primitive Slavonic race, and to the monuments of their rising commerce with Byzantium and the Arabian East. To a somewhat later date, perhaps, may be assigned the curious stone figures included by Dr. Lissauer in an appendix to his Neolithic section, and as to the date and origin of which he refrains from conjecture. There can, however, as the author himself admits, be no reasonable doubt that they belong to the same category of monuments as the well-known *Kamienne baby* or "stone wives" of the Russian steppes. They extend, in fact, in an unbroken zone through Poland and Lithuania to the steppes of the Dnieper and the Sea of Azoff, and find their analogies in Central Asia and in the rude stone figures on the Siberian

kurgans. As to the ethnic character of the people who spread them over this vast Scythian region, we have the direct testimony of the traveller Rubruquis, who, when visiting the Polovtzi or Kumans—the scourge of mediæval Russia—actually witnessed their erection over the grave-mounds or kurgans of that race. Their Turko-Tataric origin is indeed entirely borne out by their physiognomy, which, as I have myself had occasion for observing in various parts of Southern Russia, is of an unmistakably Mongolian cast, and their dress and accoutrements thoroughly bear out this identification, the head-gear in some instances being identical with that still worn by some Tekke-Turkomans. Individual divergences of type in some of the western examples may of course show that these Mongolian images were imitated by Wendish or Old Prussian, Polish, or Lithuanian hands. Two things, however, may be regarded as certain: that the stone figures of the steppes are of Turko-Tataric origin, and that the date of their Baltic reproductions is considerably later than Neolithic times.

ARTHUR J. EVANS.

VOLTAIC ELECTRICITY.

Voltaic Electricity. By T. P. Treglohan, Head Master, St. James's Science and Art Schools, Keyham, Devonport. (London: Longmans, Green, and Co., 1888.)

ONE occasionally hears of the evil effects of cram and bad teaching which the system of examination and payment by results so extensively made use of by the Science and Art Department is supposed to encourage. If such books as the above are in general use by teachers or candidates, it cannot be denied that the evil is very serious.

There is little of reasoning or explanation anywhere; but, instead, there are strings of statements which would, if they were accurate, consist of ready-made answers for such questions as may be set for the first stage or elementary course of voltaic electricity. At the end of the book will be found the elementary questions in voltaic electricity for the last twenty years, with numbers attached showing the pages where the answers may be found.

The book professes to be largely experimental, and the student is urged to make the apparatus and to try the experiments described. A few extracts will show how utterly misleading it is in this respect.

If the tongue is placed between a penny and a half-crown, "a feeble spark is seen as contact is made between the two metals."

"The missing Zn" (owing to the action of a voltaic cell) "is found in the cell, either in the liquid or at the bottom, as a grayish-coloured deposit."

"This" (the bichromate) "was a strong cell, and was tolerably constant; but, after a short time, was weakened in consequence of crystals of chrome alum forming in the liquid. To prevent this crystallization, the liquid must be frequently disturbed, either by lifting the plates out of it, or by some other means."

After speaking of the Daniell, Bunsen, and Grove, the author describes the Leclanché as "another very constant cell."

To show that zinc and carbon have a greater E.M.F. than zinc and copper in a cell, a condenser and two electroscopes are recommended to be used. In the figure the plates are shown separated and connected each to the zinc or copper and to one electroscope, of which the leaves are widely divergent. The student is not told that the connections must not be so made, nor is any practicable method of making the experiment described.

"In brine the positive and negative elements have the same relative order as in dilute acids; but in ammonia the relation is reversed, and those that were negative in the former case will be positive in the latter."

"It is found that the wire attached to the Cu, C, or Pt has free statical electricity apparent at its terminal, which repels the glass rod rubbed with silk, and that attached to the Zn free statical electricity, which repels the sealing-wax rubbed with flannel."

This extraordinary statement appears five times in a few pages.

Three or four Grove's cells are "necessary" to electrolyze acidulated water; the hydrogen gas collected in one of the tubes of a voltameter explodes "with a tolerably loud report." When a solution of common salt is electrolyzed, "the sodium of the salt and the hydrogen of the water" (appear) "where the current leaves the cell."

"Another simple experiment is to send the current through a solution of iodide of potassium. A brown substance—iodine—is seen at the anode, and the metal potassium at the cathode."

It is doubtful what some passages mean, as for instance, the paragraph:

"If any number of plates be used together, the E.M.F. of such a cell would be the result of the difference of potential of the two plates which are furthest apart in the electromotive series."

Frequently, the language is more than careless; thus, after speaking of sulphuric acid and sulphate of copper, the author says *other* binary compounds; and, after describing the action of a solenoid, he says coils and helices *also* exhibit magnetic properties.

Those expressions of doubtful meaning—intensity and quantity—are freely used, as is the word potential, which fortunately has not its meaning explained. The names of some of the units are met with for the first time in the sentence: "Current strength is calculated in amperes, electromotive force in volts, and resistan*ces* in ohms." Not a word of explanation is given.

NATURAL HISTORY OF VICTORIA.

Prodromus of the Zoology of Victoria. Decades 1–15. By Prof. F. McCoy. (Melbourne, 1878–87.)

JUST ten years ago, Prof. Frederick McCoy decided, under instructions from the Victorian Government of the day, to commence the publication of a series of short descriptions, accompanied by coloured figures, of the indigenous members of the different classes of the animal kingdom. These were to be published in parts containing ten plates in each, which have appeared with commendable regularity to the present time. As the fauna of Victoria was not as well known as its flora, it was a necessary preliminary, in order to effectually carry out such a scheme, to have a large number of drawings made, as opportunity arose, from the living or

quite recent examples of many species of reptiles, fish, and the lower animals, the true characters of which, in many cases, were but imperfectly known, from their having been described from often badly-preserved specimens.

The value of such a work will be readily granted, and the energy of the Victorian Government will be duly appreciated by those of us in the mother country who know the difficulty there would be in our obtaining Government sanction for the publication of like descriptions of the animal inhabitants of these islands.

Of all the forms described and figured in these decades, the originals are preserved in the National Museum at Victoria. The first volume was completed with the tenth decade in 1885, and it forms a large octavo volume of 100 plates and over 200 pages, with a classified index. Since then, Decades 11 to 15 have been published, bringing the date to last year.

On this important work, which we fear is not so well known in this country as it ought to be, we venture to make the following remarks. Of the century of plates forming Vol. I., fifty-four are illustrative of vertebrate forms, and forty-six of invertebrate ones. Of these latter no less than twenty-eight are exclusively of Polyzoa, which seems to us a somewhat unfair treatment of the other groups. We cannot object to it on the score of the advancement of science, but we think we justly may, so far as the usefulness and interest of these decades are for the public. Another criticism, and we have done: the references to where the species have been described are for the most part useless. For example, to the species figured on the 100th plate, *Goniocidaris tubaria* (Lam.), where we find "*Cidarites tubaria* (Lamk.), Anim. sans Vert.," there is not another word added, and this reference is not only defective but erroneous. This is a subject that ought to be attended to: we do not demand a full and detailed synonymy, but would, in such a publication, be content with just such information as would enable a student to see where the generic and the specific names adopted by the author were to be found first described; and to give this, few would be better qualified than Prof. McCoy.

With scarcely an exception, the plates have been exceedingly well executed; those on insects by A. Bartholomew demand a special word of praise, and the same artist has also done full justice to the fishes and the Mollusca, the plates representing the "tuberculated argonaut" being nearly perfect. Another artist whose work we may allude to is Dr. Wild, well known in connection with the *Challenger* Expedition; among the drawings executed by him, that of the Australian fur seal, a group with the adult male, female, and a cub, is worthy of praise.

The descriptive details vary, as might be expected, in interest; sometimes we have most interesting and full accounts of the life-history of the species, as notably in the cases of the fur seals just referred to, of the case moths (Metura), the bell frog, the great cicada, and others too numerous to mention; and were our space unlimited we would gladly show how all-sided is the information to be gained from these decades. The following will serve as an example. A common moth, first described from New South Wales by Lewin as *Phalænoides glycine*, from the larvæ feeding on the leaves of a leguminous plant (*Glycine bimaculata*), is equally common in the colony o Victoria, but there the larvæ fed on *Gnaphalium luteo-album*, a common weed. Since the planting of vineyards this moth has increased in enormous numbers, and the larvæ have completely abandoned their original food, and now devour only the leaves of the grape vine, on which the moth multiplies beyond measure. It is a puzzle how the female moth was guided to deposit her eggs on a plant of so different a character from that which she had been accustomed to, and which must have been to her unknown. The injury done to the vineyards of Victoria by this insect is enormous, and would seem, in spite of many remedies, to be increasing. Insectivorous birds will not eat the marauding larvæ; and children, who might keep down the plague by hand picking, must, by law, attend their schools.

We hope to again notice these decades on the completion of the second volume. In the meanwhile we have said enough to call our readers' attention to the value and interest of the information which they contain; and we congratulate Prof. McCoy and the Victorian Government on their publication. E. P. W.

OUR BOOK SHELF.

Technological Dictionary. In 3 vols. English-German-French, French-German-English, German-French-English. Third Edition. (London: Trübner and Co., 1888.)

THE inventions and discoveries of the present century have introduced a very considerable number of new words into the various languages of the world, but more especially into the European languages. As these words do not occur in ordinary dictionaries, special dictionaries embodying them are necessary to a great number of persons. Thus, to facilitate communication in commercial transactions between one country and another, and to enable students of science and technology to profitably consult works written in languages other than their own, they are indispensable. As regards the three principal languages of Europe, this want is supplied by the work before us, the third edition of which has recently been completed by the publication of French-German-English, and German-French-English volumes. The third edition of the English-German-French volume was published in 1878. The first edition dates as far back as 1852, and since then the work has been thoroughly revised and new matter added.

The work embraces the terms employed in the arts and sciences, engineering, architecture of every description, navigation, astronomy, meteorology, mining, artillery, &c. In addition to the terms relating to the various appliances, processes, and substances, there are also those applied to the different orders of people concerned with them, from the "doffer" of the spinning mill to an "Admiral of the Fleet." Teachers of scientific and technological subjects will also find the equivalents of the great majority of the terms they find it necessary to employ, the names of chemicals and minerals included. The work is wonderfully comprehensive, and the arrangement is all that could be desired.

The best authorities have been consulted, and tedious processes adopted, with the view of obtaining indisputable accuracy, and this has practically been accomplished. No effort has been spared to make the work deserving of the important place in literature which it should naturally occupy, and no recommendation of ours is necessary. It certainly ought to be available for reference in all libraries of any importance. A. F.

Transactions of the Sanitary Institute of Great Britain. York Congress, 1886.

THE valuable work done by the Sanitary Institute cannot be altogether gauged by the annual volumes of Transactions, one of which now lies before us. It must be remembered that, besides the reading of papers and holding of discussions on subjects of sanitary interest, the Sanitary Institute endeavours, by means of its Congresses and annual Exhibitions, to arouse the interest of the inhabitants no less than of Town Councils and municipal authorities in the health and well-being of the towns visited. That such visitations have a beneficial influence, by awakening public interest in measures of sanitary reform, both local and general, can hardly be doubted; and, as pointed out by Sir Spencer Wells in his Presidential Address, if further legislation on sanitary matters is not to be ridiculous, it must be accompanied by increased knowledge on the part both of the persons charged with administering the Sanitary Acts as well as of the public themselves.

The modern science of hygiene is hybrid, embracing as it does special branches of most of the leading sciences—medicine, engineering, architecture, geology, chemistry, meteorology, &c. The subjects treated of by means of papers in such a Congress must be very varied, and such we find to be the case; but as far as possible the papers are relegated to one of three sections, where their merits will be best understood and most adequately discussed. The standard of the papers submitted to the York Congress is fully up to the average, many of them treating of subjects of wide interest, or having important bearings on the prevention of disease and maintenance of the public health.

Science Sketches. By David Starr Jordan. (Chicago: A. C. McClurg and Co., 1888.)

IN this neat and handy little volume we have a very interesting and intellectual collection of sketches and addresses more or less scientific. Some of the articles, which, as the author tells us, have been published before, have been freely retouched or re-written; but the papers on "The Dispersion of Fresh-water Fishes," "The Evolution of the College Curriculum," and the address on "Darwin" appear for the first time. The subjects treated are of various kinds, so that anyone who takes up the book will be sure to find in it something that will interest him. The appendix contains a list of the scientific papers of the author, and we hope it will not be long before we are favoured with another such book as the above.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Coral Formations."

SINCE writing the letter published in NATURE, March 22 (p. 488), I have checked Mr. Ross's figures. The result is somewhat surprising. Instead of 8400 tons of carbonate of lime removed from $12\frac{1}{2}$ square miles of lagoon representing a sheet half an inch thick, it really only amounts to a film of that area $\frac{1}{252}$ of an inch thick.

At this rate per annum it would in round figures take eighteen thousand years to dissolve out a lagoon a fathom deep, or a *million* years for the creation of a lagoon 60 fathoms deep. When we consider that this could only happen on the impossible assumption of the atoll remaining stationary for a million years, while no accumulation of coral sediment or organic calcareous growth took place in the lagoon, it is at once seen, on the showing of its own supporters, how impotent is the solution theory to account for the formation of lagoons in atolls.

To represent the figures in a familiar way, I may point out that the film removed annually would be a little less in thickness than one of the pages of "Prestwich's Geology." A volume of 36,000 pages (18,000 leaves), minus covers and well pressed, would be a fathom thick. No one acquainted with my geological work will accuse me of being parsimonious of geological time, but this is really beyond my mark altogether.

Mr. Irvine asks (NATURE, March 29, p. 509): "Can Mr. Reade give any observations or figures in support of his view of the rate of accumulation of oceanic calcareous deposits?"

If Mr. Irvine will refer to Mr. Murray's paper (NATURE, vol. xxii. p. 352), he will see that the pelagic life in a square mile of ocean water 100 fathoms deep is estimated by him to represent sixteen tons of carbonate of lime.

I am not aware of the length of life of such organisms, but if they lived on an average *only one day*, and the whole of their tests were rained down on to a submarine peak at the rate of sixteen tons per diem, *and none were dissolved by sea-water*, it would take twenty-nine years to accumulate 1 inch in thickness of solid carbonate of lime in this pelagic cemetery. In this way, if anything so improbable were to happen, a submarine peak half a mile below the range of coral growth might be levelled up into a suitable platform in 900,000 years. I could add much more, but respect for your valuable space bids me conclude.

T. MELLARD READE.

Park Corner, Blundellsands, April 3.

"The Dispersion of Seeds and Plants."

IN support of the views expressed in Mr. D. Morris's interesting article on the above subject (NATURE, March 15, p. 466), I beg to be allowed to state the following facts. In the Island of Porto Rico, the *Panicum barbinode*, called there "malojilla," has been cultivated for many years in the low humid lands, and it is a current opinion among farmers that it is reproduced by means of the animals feeding on it. Some fruit-bearing trees and shrubs, which are a favourite food for the wild *Columba leucocephala* and *Columba corensis*—among them the *Solanum stramonifolium*, the *Bucida Buceras*, the wild coffee, *Coffea occidentalis*, the palm-tree, *Oredoxa regia*—appear in some mountains and regions where they were formerly unknown, and there is no doubt that they have sprung from fruits and seeds transported by these pigeons. The *Anona muricata* (soursop), the *Anona reticulata* (custard apple), the *Carica papaya* (papaw tree), whose hard seeds are sometimes uninjured by the processes of mastication and digestion, are also believed to be planted accidentally by birds, and sometimes by hogs, horses, and other Mammalia. They grow all about in pastures where these animals are fed. The statement made about the orange-tree in Jamaica also holds good for Porto Rico. Very few orange-trees were planted in the interior of the country, and the tree is now wild in all that zone by the agency of birds in great part. There is no doubt, as Mr. Morris says, that birds and cattle have been the means of distributing plants all over the island.

ANTONIO J. AMADEO.

"Balbin's Quaternions."

NATURE of December 15, 1887 (p. 145), which has lately reached me, contains a notice of a treatise on Quaternions, by Prof. Valentin Balbin, in which the reviewer alludes to the "slight alterations" introduced into the notation of quaternions by Messrs. Houel and Laisant, and apparently visits them all with equal condemnation.

To me it appears that a distinction should be made between the two points in which the French notation differs from the English. The use of letters in different type to denote different kinds of quantities, the same type being always reserved for the same kind, seems to render the processes sometimes clearer and the results more immediately and easily available for students. In spite, therefore, of the ugliness of the black-letter symbols, it would not perhaps be altogether a loss if English mathematicians would adopt this part of the French scheme.

The other change introduced by M. Houel, that of the order of the factors, writing $q\,q'$ where Hamilton writes $q'\,q$, seems, on the contrary, to be an entirely retrograde step. That, as a rule, the symbol for the operator should be written before that of the operand, is a necessity in all modern symbolic processes. The alteration can only lead to confusion. In my "Text-book of Algebra" I have suggested that while the symbol $a \times b$

should be read, a multiplied by b, the symbol $a.b$ or ab should mean a multiplied into b, so that $a \times b$ and $b.a$ or ab are identical. Perhaps a compromise might be effected on this basis in the notation of quaternion multiplication.

The "unnamed French mathematician" who is quoted in the notice in question as asserting that quaternions have no sense in them, is stated by M. Laisant to have been M. Prouhet, and to have expressed this opinion in the *Nouvelles Annales de Mathématique* (1863, p. 333), in reviewing the first work published in French on quaternions, the author of which was M. Allégret. W. STEADMAN ALDIS.

Auckland, New Zealand, February 20.

Mr. Crookes and the Transformation of Heat-Radiations into Matter.

PROF. CLIFFORD, in the *Fortnightly Review*, June 1875, wrote as follows:—"But if the ether did absorb light, what would this mean? Vibratory motion of solids, which is really a molecular disturbance, is absorbed by being transformed into other kinds of molecular motion, and so may finally be transformed to the ether. There is no reason why the vibratory motion of the ether should not be transformed into other kinds of ethereal motion; in fact, there is no reason why it should not go to the making of atoms" ("Lectures and Essays," by W. K. Clifford, vol. i. p. 246).

Mr. Crookes, in his Presidential Address to the Chemical Society, March 28, brought forward a somewhat similar hypothesis, for he says:—"If we may hazard any conjecture as to the source of energy embodied in a chemical atom, we may, I think, premise that the heat-radiations, propagated outwards through the ether from the ponderable matter of the universe, by some process of Nature not yet known to us, are transformed *at the confines of the universe* into the primary—the essential—motions of chemical atoms, which, the instant they are formed, gravitate inwards, and thus restore to the universe the energy which otherwise would be lost to it through radiant heat."

The hypotheses will be seen to be exactly alike, except for the speculation introduced by Mr. Crookes of the transformation taking place "at the confines of the universe." What do we know of the confines of the universe? Nothing. Are we *now* to begin building up hypotheses on such foundations—foundations concerning which we know nothing, and are not likely to know anything *for some time*? HUGH GORDON.

Royal Institution, March 31.

Green Colouring-matter of Decaying Wood.

MR. IRVING writes (p. 511): "After an examination of thin sections" of the decaying wood "with the microscope, I am unable to trace this to any saprophytic organism."

I have at the present time a coccus, I suppose, growing on the surface of nutrient gelatin, which is stained a beautiful green, highly fluorescent, by the colouring-matter absorbed by it from the micro-organisms. The cultivation is in a test-tube of nutrient gelatin inoculated by scratching the surface of the gelatin with a needle which had been rubbed on a colony, isolated by plate-cultivation, and obtained from a bad water.

The growth, a greenish-white, is entirely on the surface—so entirely that the scratches made in inoculating the gelatin are still visible, three weeks after the inoculation, and the gelatin is perfectly transparent.

Under these circumstances it is quite certain if I made sections of the green gelatin no micro-organisms would be found in them.

It may be that the decaying wood is stained in the same way by colouring-matter absorbed by the sap or the moisture of the wood by micro-organisms growing on its surface.

It is a fact, I believe, that the colouring-matter formed by chromo-genic micro-organisms does not reside in their structures but in the interspaces between them, so it would naturally be absorbed by any solvent they were in contact with, while the organisms themselves might remain entirely on the surface, as they do in the case of my gelatin.

This may explain why Mr. Irving has failed to find micro-organisms in the sections he made. Further, if the colour of his green wood is caused by the same micro-organism which stains my gelatin green, it is a very small one, so small that, with a 1/15-inch oil-immersion object-glass, and a No. 12 compensating eye-piece of Zeiss, I find it very difficult to decide what shape it is, but I think it is not spherical.

I think Mr. Irving will find references to the literature of chromo-genic micro-organisms in Crookshank's "Manual of Bacteriology." HENRY ROBINSON.

The University Chemical Laboratory, Cambridge.

Comet *a* 1888 (Sawerthal).

I SAW comet Sawerthal to-day at 3.40 a.m., with power 20 on a $4\frac{1}{4}$-inch refractor. It was about 50′ immediately below θ Pegasi, and had a bright broad tail, which I could only distinguish to a length of 65′, on account of the twilight, moonlight, and the comet's low altitude. I thought the tail was slightly curved, concave to south; it pointed on the average to a little above ν Pegasi, or at a position-angle of about 260°. The total light of the head was considerably fainter than θ Pegasi, and considerably brighter than ν, so that it would be from 4 to $4\frac{1}{2}$ mag.; but owing to the unfavourable conditions I could not see it with the naked eye. T. W. BACKHOUSE.

Sunderland, April 3.

THE HITTITES, WITH SPECIAL REFERENCE TO VERY RECENT DISCOVERIES.[1]

II.

THE monuments at Boghaz-Keui and Eyuk are on the east of the River Halys; and it seems doubtful whether there is evidence that the country inhabited by the Hittites extended much, if at all, beyond a line drawn from Sinope on the Euxine to the most westerly bend of the Halys, and continued through the peninsula to the Mediterranean. No doubt sculptures with Hittite characteristics have been found further to the west, as at Giaour-kalessi, in Phrygia, and at Karabel, near to Smyrna and to the coast of the Ægean; but as yet it does not appear certain that these sculptures denote permanent occupation, or that they are more than monuments of successful military expeditions. The Euphrates may be taken as marking vaguely the eastern boundary of the Hittite land. To the south, in Syria, the Hittite country certainly extended as far as Kadesh, a site on or near the present Lake of Homs.

It is with the inscriptions and the engraved seals found in, or connected with, the district I have indicated that Hittite researches are mainly concerned. The few characters on the monument at Karabel are too far obliterated to be, for the present, of much importance. In 1812, Burckhardt visited Hamah, the ancient Hamath, in Syria. He saw in the corner of a house in the bazaar "a stone with a number of small figures and signs, which appear to be a kind of hieroglyphical writing, though it does not resemble that of Egypt" ("Travels in Syria," Lond., 1822, p. 147). But, as Dr. Wright remarks, "so little interest was taken in his discovery, even by professional explorers, that Porter, in Murray's 'Hand-book,' so late as 1868, declares 'there are no antiquities in Hamah'" ("Empire of the Hittites," 2nd ed., p. 1). There were, however, other inscriptions at Hamah besides that noticed by Burckhardt, and the stone bearing one of these was supposed to possess mysterious properties, efficacious for the cure of spinal disease, so that "deformed persons were willing to pay for the privilege of lying upon it, in the hope of a speedy cure" (Burton and Drake, "Unexplored Syria"). After sixty years, or nearly so, from the time of Burckhardt's discovery, attention was called to the Hamath inscriptions, first by Mr. J. A. Johnson, United States Consul at Beyrout, and subsequently (1872) by Capt. R. F. Burton and the late C. F. Tyrwhitt Drake, in the work just quoted. In 1872, however, Dr. Wright was successful in obtaining casts of the Hamath inscriptions, while the originals were trans-

[1] Based on Lectures delivered by Mr. Thomas Tyler at the British Museum in January 1888. Continued from p. 514.

mitted in safe custody to Constantinople. The arrival of Dr. Wright's casts in this country was naturally followed by attempts at the decipherment of the hieroglyphics, though some of those who made these attempts had previously concerned themselves with the imperfect representations given by Burton and Drake in the work already mentioned. About the same time (1872) attention was called to the inscription then existing at Aleppo, but since unfortunately destroyed. Not very long afterwards an interesting bas-relief at Ibreez, in Lycaonia, accompanied by an inscription, was brought anew under notice by the Rev. E. J. Davis; and in 1876 Prof. Sayce observed with reference to this inscription, "The Hamathite hieroglyphics appear to have been an invention of an early population of Northern Syrians. Their occurrence in Lycaonia is probably due to Syrian conquest." Still later, and in view of the sculptures of Boghaz-Keui and Karabel, together with other monuments, Prof. Sayce took a much wider view, extending Hittite presence and influence through Asia Minor. Not long after taking this more extended view of the Hittites, the same scholar made a discovery of no small importance with regard to the decipherment of the inscriptions: I allude to the discovery that certain characters on the seal of Tarkutimme were Hittite hieroglyphics (*Academy*, August 21, 1880). The true nature of these hieroglyphics had not been previously seen, though, together with the cuneiform inscription round the circumference, they had been discussed by the late Dr. Mordtmann.

The history of this now celebrated seal is certainly remarkable. About the year 1860, a convex silver plate bearing the inscriptions just alluded to was presented for sale at the British Museum. Doubt was entertained concerning the genuineness of this silver plate as an antiquity, and the purchase was declined, though an electrotype copy was made and preserved. On account of the prolonged interval which has elapsed, the precise ground of doubt is not now altogether clear. It seems not unlikely, however, that the decision as to the spuriousness of the plate was arrived at after several considerations had been duly weighed. The silver of the plate may have seemed too well preserved for an object of so great antiquity, unless, indeed, it had been in some special manner sealed up and protected in a vase or other receptacle. Then the character of the engraving was probably regarded as inconsistent with the idea of its having been cut originally in silver, and especially in a comparatively thin silver plate, the engraving being rather that of stone, on which material, indeed, a seal was much more likely to be engraved. And another important fact, as agreeing with this view, is a flaw which appears on the right hand of the central figure, and which suggests the fracture or chipping of stone rather than the abrasion of metal. On these grounds, probably, the conclusion was arrived at that the plate was not a genuine antiquity.[1] Most likely it was a cast or electrotype from an ancient stone seal, this seal having been retained by the discoverer—whoever he may have been—with the view of obtaining eventually a larger profit by its sale. Proceedings of this kind are not unknown at the Museum. But where the original seal then was, or now is, has never been known; and the silver plate offered at the Museum has likewise disappeared from view. But this disappearance is of little importance to science, if the genuineness of the inscriptions can be fully proved.

In favour of this genuineness it must be urged as improbable that any from among the few Assyriologists who were to be found in Europe nearly thirty years ago would have co-operated in forging the seal. Moreover, there are two difficulties in the way of believing in such a forgery. First, the cuneiform legend has peculiarities which distinguish it from any other known type of cuneiform writing, as was observed by Dr. Mordtmann. Then there is an interspace over the head of the standing figure, which might seem, at first sight, to be interposed between the beginning and end of the cuneiform legend. It occurs, however, in the middle of a word. For this interspace a possible reason may be derived from the recently-discovered Yuzgât seal; but its occurrence does not suggest the idea of forgery by a scholar conversant with the cuneiform characters. Supposing, however, that these difficulties are put aside, there remains the much stronger argument furnished by the characters in the central space, which are certainly Hittite. Now, and for some time past, great interest has been displayed in relation to Hittite inscriptions; but in and about the year 1860 the case was far otherwise. There was then no temptation to forge these Hittite inscriptions on the seal, even if it had been possible to do so. But it may be doubted whether at the time in question it would have been possible to find and bring together the various Hittite characters. Besides, it is not difficult to discern a concinnity and agreement between the cuneiform and Hittite adverse to the idea of forgery, and consistent only with the opinion that the seal is, with its inscriptions, a veritable bilingual.

FIG. D.—Bilingual seal of Tarkutimme (enlarged).

About the time already mentioned (1860), Dr. Mordtmann examined at Constantinople a convex silver plate, then in the possession of M. Jovanoff, probably the identical plate which was offered at the British Museum. Concerning this plate, Dr. Mordtmann wrote, with date "Constantinople, December 6, 1861," a contribution to Grote's "Münzstudien," entitled "Sceau de Tarkoumdimmi, roi de Tarsous"; the designation "Tarkoumdimmi, roi de Tarsous," being Dr. Mordtmann's reading at that time of the cuneiform inscription on the seal. He noticed also, very appropriately, the resemblance of the name on the seal to the names Tarcondimotus, Ταρκονδίμοτος, as found in Tacitus, Strabo, and Dio Cassius, names employed to denote a father and son, Cilician kings who reigned in the time of Augustus. Dr. Mordtmann mentioned, also, that Plutarch gives, instead of the longer form, the shorter name Ταρκόνδημος, a name approaching still closer to that on the seal, expressing, however, at the same time the opinion that the king to whom the seal belonged was of much earlier date.[1] As to the name of the place mentioned, Dr.

[1] The decision arrived at was probably in accordance with the view of Mr. Ready, who then was, as he still is, at the Museum. What has been said as to the style of engraving and the fracture was, most likely, suggested by him at the time, though he cannot now recollect the details of the matter.

[1] Prof. Sayce has called the seal "The Boss of Tarkondemos." But I do not see how in any way the seal can be suitably designated a "boss." And, even if it be conceded as certain that "Tarcondemos" represents the name given on the seal, still it is a Græcized form which cannot be used with propriety to denote a king who, according to Prof. Sayce's view, probably lived some 700 years B.C.

Mordtmann seems to have been first inclined to give *Zousous*, but, as no other authority for such a name could be found, he changed this conjecturally for *Tarsus*.

The Hittite characters Dr. Mordtmann regarded as, on the whole, emblems of the country, with its productions, over which the king ruled, and not as forming inscriptions, or an inscription. He made, however, some important observations with regard to the relation of these characters, as well as the figure and equipment of the king, with what was to be seen on other monuments. The boots with turned-up toes were found also at Boghaz-Keui, Eyuk, and Eregli, in Cappadocia (" Les Monuments d'Uyuk, de Bogaz-keuy, et d'Éregli, en Cappodoce"), as well as on the monument at Karabel, near Smyrna. The dagger was to be seen at Boghaz-Keui, and the spear at Karabel. The figure at Karabel, also, was without a beard, like that on the seal. At Karabel, too, were the same characters found between the head and the spear.[1] The accoutrements of the king were like those of the Cilician soldiers in the army of Xerxes, as described by Herodotus (lib. vii. ch. 91).

About ten or eleven years later, Dr. Mordtmann returned to the seal, and discussed it in the Journal of the German Oriental Society (*Zeitschr. d. deutsch. morgenländ. Gesellsch.*, vol. xxvi. p. 625). He then gave, as the name of the king, " Tarkudimme," and, though regarding the name of the place, " Tarsun," as tolerably well ascertained ("ziemlich gesichert"), yet he would not make, he says, any strong opposition if it should be preferred to substitute *zu* for the *tar*, forming the first syllable of this name. With regard to the Hittite characters, this article does not mark any very conspicuous advance, except that the animals' heads, which Dr. Mordtmann had previously regarded as the heads of horses, he now more accurately described as the heads of goats "Ziegenköpfe").

Though Dr. Mordtmann anticipated Prof. Sayce, not only in perceiving a relation between monuments (now recognized as Hittite) in different places in Asia Minor, but even in recognizing that certain characters on the seal were the same, or of the same kind, with those found on the Karabel monument, yet he did not perceive that these characters formed a Hamathite or Hittite inscription. It would have been scarcely possible for him to do this at the time; and this fact furnishes, in accordance with what has been said, one of the strongest arguments for the genuineness of the inscriptions on the seal. It was reserved for Prof. Sayce to detect that the seal presented a true bilingual, Assyrian and Hittite (*Academy*, August 21, 1880).

Although, as already stated, the Assyrian characters have peculiarities which distinguish them from any type of cuneiform writing otherwise known, nevertheless, with the exception of one important character, there is a tolerable agreement as to the way in which the Assyrian inscription is to be transcribed and read. If we begin with the first character after the vacant space over the king's head, this inscription, it seems to me, may be read thus:—

-me-e ▌ *Tar-ku-u-tim-me sar mat Zu-*

But if we begin, as we certainly ought to do, with the vertical wedge standing before the king's name, and denoting that the name of a man follows—represented here by a vertical black line—we have :

▌ *Tar-ku-u-tim-me sar mat Zu-me-e.*
"Tarkutimme king of the country of Zume."

The precise pronunciation of the second dental in the royal name it is impossible to determine with certainty. Some might prefer to read "Tarkudimme." But this is not of very much consequence. The difficulty to which I have adverted relates to the first character in the name of the country—the character immediately before the vacant space over the king's head. Prof. Sayce reads this as *er*, and gives as the name of the country *Er-me-e*, "Erme." To me the probability has seemed that the character should be read *su* or *zu*, the alternative reading which had been suggested by Dr. Mordtmann.[1] Certainly, with the reading *su* or *zu*, a symmetrical rendering of the Hittite inscription can be given, but with *er* this seems scarcely possible.

On comparing the spaces on the one and the other side of the figure of the king—for certainly this figure must be intended as a portrait of King Tarkutimme—it will be seen that the characters are repeated, though apparently with some variations in size and in the order of sequence. But these variations may be accounted for, if the exigencies of the space at the engraver's disposal are considered. On the left side of the king there is the greater space, and a division is effected by the king's arm and staff or spear. Consequently, in decipherment, the order observed on this side would seem to furnish the more satisfactory guidance. We may reasonably begin at the top, with the two characters above the king's arm; and these, it can scarcely be doubtful, represent the royal name Tarkutimme, inclosed and shut off as they are from the rest. How the name is to be divided between the two characters may seem not quite clear. Does the upper one denote *Tarku* and the lower *timme*, or should we divide *Tar-kutimme?* There are grounds on which the latter view seems the more probable. The Hittite hieroglyphics may possibly have been used by non-Semitic peoples, but at present the balance of evidence seems to be in favour of a Semitism more or less pure. On the Semitic hypothesis, and with the unequal division last given, both elements of the name admit of tolerably easy explanation. The first character seems certainly to be the head of a goat. There is little difficulty, in accordance with well-known vocal changes, including the substitution in Aramaic of *t* for *s*, in understanding how *tar* may represent the Hebrew *se'ar, sa'ir;*[2] and the second character likewise may be reasonably explained.[3] Beneath the arm is a tall cone which must certainly represent "king." This may be argued from the character being placed close to the king on both sides, as well as from its position on his left side immediately under the characters representing the royal name. It

[1] "Les mêmes caractères verticaux entre la tête et la lance que nous voyons figurés sur le sceau près de la main qui tient la lance et de l'autre côté près du grand obélisque." If anything more was intended than *characters of the same kind*, there seems to be a mistake.

[1] This conclusion was arrived at when, in 1880, my attention was first directed to the seal; and I then consulted three well-known Assyriologists. One of these was Dr. Strassmaier, who still adheres to the opinion then expressed. The very large number of texts which he has examined in the interval, while preparing his laborious and comprehensive contributions to Delitzsch and Haupt's Assyriological Library, gives his opinion the greater weight. He bases his opinion on the convergence of the two smaller wedges towards the larger horizontal wedge: strict parallelism would have been required to give the value *er*. Dr. Haupt, now Professor of Semitic Languages at the Johns Hopkins University, gave, if I recollect rightly, the value *su* rather than *zu*. Mr. S. A. Smith, who is editing and translating the Assurbanipal texts, also gives his opinion in favour of *su*.

[2] We ought also to remember in this connection that Tarsus was the chief city of Cilicia. According to the oldest authority which we have for the name (the black obelisk of Shalmaneser), the city was called *Tar-zi*. That this city should be called after the goat can scarcely seem unlikely, if we recollect how famous Cilicia was for its goats with thick and long hair, out of which Cilician cloth was made—a cloth of which, according to some, St. Paul was a weaver.

[3] In his contribution to the "Münzstudien," Dr. Mordtmann spoke of this character as "un objet difficile à reconnaître, mais qui ressemble au *pudendum muliebre*." And afterwards, in the *Z.D.M.G.*, he used similar language: "ein schwer zu bestimmendes Symbol, vermuthlich ein pudendum muliebre." Supposing this to be the object intended, there is no difficulty in understanding its bearing in a Semitic dialect the name *kutimme*. First, there is the Assyrian *katamu*, with the Arabic *katama*, "to conceal," connected with which the word would have a sense nearly equivalent to *pudendum*. But, having regard to what has been said on *tar*, it may seem that we ought to look to the Aramæan; and here we have *ketham*, "signavit." with a derivative, "*kuthema*," nearly identical in form with *kutimme*. In Gal. vi. 17 (Pesh.), *kuthema* is used in the plural of the στίγματα, which the apostle says he bore in his body. The transition from this sense is not difficult. Dr. Mordtmann's is the only probable explanation of the symbol. Special and local causes may account for its forming part even of a king's name.

may here be observed that there was at Aleppo a Hittite inscription which unfortunately has been destroyed, and which, though it had evidently suffered from the weather and time, was in several respects of great interest. From drawings which were made from it, especially by the late George Smith, we are able, however, to form a good estimate of its evidence with regard to the king-symbol. It presented a figure—no doubt of the person celebrated in the inscription—with a symbol similarly formed and similarly marked to that in the Tarkutimme seal.

The question here presents itself: In what order are the characters outside the staff or spear to be taken? Now in the Hittite inscriptions the *boustrophedon* manner of writing is observed. A line having been written from left to right, in the next the direction is reversed, and the writing goes back from right to left. This fact could not have been known to a forger in 1860, yet it is in accordance with this principle that our inscription is engraved. Having therefore read from top to bottom, we must go back, and read from the bottom towards the top. Accordingly we shall have to take next after the tall cone denoting "king" the smaller double cone. Prof. Sayce (apparently under the influence of Dr. Mordtmann's idea that the "deux petits obélisques réunis" owe their origin to the remarkable conformation of a certain district of Asia Minor) regards the double cone as denoting "country." But Dr. Mordtmann grouped these and the taller cone together, regarding all as of similar import. And, so far as their being of similar import is concerned, the conclusion seems to me inevitable. If, however, the

FIG. E.—"King"-symbol on Aleppo inscription.

taller cone denotes "king," the smaller cones, being of similar import, must denote "men." The tallness of the single cone is in accordance with the well-known ancient practice of denoting the greatness of a king by the greatly increased size of the figure representing him. It is true that, in accordance with Assyrian custom, the cuneiform legend gives "country." But whether a monarch is called king of a country or of the people inhabiting that country depends on local usage. "Queen of Great Britain" and "King of the French" are familiar contiguous examples in recent times. We may regard, then, the double cone as denoting "people," plurality being expressed by doubling the cone, and intensified probably by the numerous transverse marks.[1]

The symbol next above the double cone is, I believe, unique, no other example being found, so far as I am aware, on any of the inscriptions. To me it seems clear that this symbol is an ideograph of the country *Zume*. There are, it will be seen, on the lower side of the lower limb three projections, which may be reasonably regarded as representing mountains. The number *three* probably denotes a good many mountains. We may take it that Zume lay along the banks of a river or estuary with mountains on one side. A remarkable analogy is presented by one of the monuments in the British Museum from Jerablûs. We have here again the oval ideograph of "city,"[2] already mentioned in connection with the

[1] I have no hesitation in referring these cones to a phallic origin. This in early times would be regarded as a very natural way of representing "man"; and, like other designations of men, cones might easily come to denote both sexes, and a people generally.

[2] The ideograph is slightly broken on the monument.

Boghaz-Keui bas-reliefs. Here again, as on the Tarkutimme seal, we have the three mountains, occurring in this case on both sides. The intention is, to indicate a city located in, or at the head of, a valley lying between mountains.[1] The name of the city is in all probability denoted by the other characters, to the reader's left, the doubled curve (the doubling denoting plurality) and what is probably intended for a tree beneath.[2] This twofold indication of the name, for the sake of clearness, is entirely in accordance with the usage of both the Assyrian and Egyptian monuments. And similar evidence might be adduced from more remote sources.

Thus a twofold indication of the name Zume in the Hittite inscription on the seal must be regarded as altogether probable; and it seems to me beyond reasonable doubt that the last characters, the four nearly vertical strokes, with one horizontal, express the name Zume phonetically. Dr. Mordtmann observed, with reference to these strokes, that it would be difficult to give them a phonetic value without regarding them as numerals, but that so to regard them would be fruitless in result. In this last remark he was, I think, in error. They are, in my judgment, numerals, though here used, not with reference to their numerical value, but merely as phonetic signs; and to show that they are to be so taken, the engraver has placed them at an angle, or, so to speak, tilted them up. The last character, the two vertical strokes with one horizontal, gives precisely the Assyrian symbol for 100, but written after the archaic manner, before the wedge-writing was introduced. *Me*, the Assyrian for "a hundred," is, moreover, precisely the value that we require here. *Zu* or *su* will then be the name for 2, the first character.

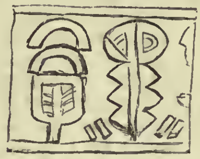

FIG. F.—Symbols from Jerablûs monument in the British Museum.

There is no great difficulty in connecting this with the Assyrian *sanu* 2, or *sunnu* ½, supposing that the *n* was slurred over in pronunciation and eventually dropped. And it must be remembered that, if those who made this seal spoke a Semitic dialect, there is no reason to suppose that this dialect was absolutely identical with any of the Semitic dialects otherwise known to us.[3]

It will be thus, I think, seen that there is a reasonable correspondence between this Hittite inscription and the cuneiform inscription round the circumference of the seal. It should be observed, too, that both with regard to the king and the country the phonetic designation is supplementary—in the first case to the portrait of the king, and in the second to the ideograph of the country. The inscription is mainly ideographic. It is important that this fact should be kept in view in the decipherment of other inscriptions.

With regard to the characters behind the king, or on his right side, it should be observed not only that the engraver had on this side a smaller space at his disposal, but also that he probably thought it necessary or desirable to place close to the figure the tall cone denoting "king."

[1] Dr. E. B. Tylor observes, "Map-making is a branch of picture-writing with which the savage is quite familiar, and he is often more skilful in it than the majority of civilized men" ("Early History of Mankind," p. 89). But of course the authors of these monuments were by no means savages.

[2] Having regard to the position of Jerablûs, where the monument was found, and to some other facts in relation thereto, I read the name conjecturally *Bamoth-elah*—that is, "Bamoth of the Terebinth."

[3] The two strokes similarly tilted up, and repeated occur on the monument in the British Museum mentioned just above (see Fig. F). With the same value as on the seal we should have *Su-su*, or *Zu-zu*, a reading by no means improbable; but I cannot in this place discuss the matter further. Cf. Zuzim, Gen. xiv. 5, and Zamzummim, Deut. ii. 20.

That the two signs for the royal name are not engraved immediately above the cone may have resulted from the space above the king's right arm being too contracted. There is another change in the characters on the king's right side which is noteworthy. It will be seen that both the ideograph of the country and the numerals giving the name are inverted. On the left side of the king the characters were to be read from left to right of the reader, but on the right side they are to be read from right to left. This change is in accordance with the *boustrophedon* manner of writing previously mentioned, but it is a change which seems totally incompatible with the idea of forgery.

(*To be continued.*)

ELEMENTS AND META-ELEMENTS.

THE President of the Chemical Society, in his address at the anniversary meeting, has further developed views which he had already propounded in his address to Section B of the British Association at Birmingham, and in a subsequent Friday evening lecture at the Royal Institution. He would have us believe that the atoms of an element are not all precisely of one absolute pattern; that atomic weights, in fact, are not constants, as generally supposed; but that we must regard each element as a species of which many varieties exist almost infinitely more like unto each other than to the atoms of any other approximating species of element; and that what we term the atomic weight is but a mean value around which the actual weights of the individual atoms of the species range within certain limits. Could we separate atom from atom, we should find them varying in weight within very narrow limits on each side of the mean.

Mr. Crookes supports his arguments by a wealth of illustration culled chiefly from his own unique experience; and, whatever the ultimate intrinsic value to science of his hypothesis, there cannot be a question that the study of the transcendent problem of the nature of the elements will have gained greatly in fascination by its promulgation; that lines on which such study may be carried on will have been indicated; and that he will have lightened the inexpressibly wearisome labours of fractionation by casting around them the poetic play of fancy. The subject is of such importance that it appears desirable to consider the position which chemists may fairly take up, and from which it is permissible to criticize the arguments that have led to the suggestion of the existence of meta-elements.

Apart from the higher interest which Mr. Crookes has now infused into them, his researches on the rare earths will ever excite admiration in all who study them, as models of scientific investigation; and they will afford undying testimony to his determination and patience in search of truth, as well as to the incomparable fertility of resource in experimenting of which he is possessed. Among the individual observations are many of a most suggestive and striking character which, sooner or later, must claim attention; but it cannot be denied that the data are as yet insufficient for their exact interpretation. This is true also of Krüss and Nilson's remarkable observations; indeed, it may be questioned whether their results all admit of the absolute interpretation which they are inclined to put upon them. In the paper in which the omnipresence of samarium is demonstrated, in giving an account of the many anomalies which he encountered in his search for x—the substance characterized by an orange-coloured band in the phosphorescent spectrum, and which subsequently turned out to be samarium—Mr. Crookes tells us how he came to the conclusion that samaria (x), which of itself gave little or no phosphorescent spectrum in the radiant-matter tube, became immediately endowed with this property by admixture with certain other substances—lime, for example—which substances likewise of themselves had no power of phosphorescing with a discontinuous spectrum. Many substances were found effective; and there was a general resemblance between the spectra, but nearly all of them differed from one another in detail. Mixtures of samaria and yttria gave spectra differing to a very marked extent according to the proportions in which the two substances were present. All who take note of these observations must agree that they are of a most remarkable and significant character: they certainly leave no room for doubt as to the necessity of exercising the utmost caution in inferring the absence or presence of particular substances from spectral appearances and changes. Judging from Mr. Crookes's observations, and from our general knowledge of the rare earths, it would almost appear that they have the power to form double oxides akin to double salts, and the effect on the spectrum produced by associating one oxide with another may be compared with the somewhat similar effect of a solvent on the spectrum of a coloured substance. The part that such double oxides perhaps play appears as yet to have been left out of consideration. It is desirable also to take into account the possible presence of double salts, and of their influence on the spectrum, before deciding as to the bearing of Krüss and Nilson's observations.

Reference is made by the President of the Chemical Society in his address to Carl Auer's investigation of didymium. Now the differences between Auer's neo- and praseodymium—the reputed constituents of didymium—are very marked; but as yet unfortunately we have no information respecting their atomic weights. This is true also of the various reputed constituents of the rare earths studied by Mr. Crookes and Krüss and Nilson. Until such information be forthcoming, the suggestion that what is commonly regarded as the atomic weight of an element is but an average value, therefore, can only serve to direct attention anew to the extreme importance of the most exact and exhaustive study of atomic weights.

What is called yttria, according to Mr. Crookes (Proc. R.S., xl. 506) is a highly complex substance capable of being separated into several simpler substances, each of which gives a phosphorescent spectrum of great simplicity, consisting for the most part of only one line. Now, supposing that the several constituent meta-elements of ordinary yttria be found when isolated to differ almost imperceptibly from each other both in chemical properties and in weight, yet the spectral differences will admittedly be very marked—as marked perhaps as are the differences between elements which exhibit very diverse chemical properties and atomic weights; and it will be illogical to deny to these meta-elements the right to rank as elements proper—as distinct species, not mere varieties.

Why, then, does Mr. Crookes think it inadmissible in the elementary examination to open the doors so wide that the number of admissions will be limited only by the number of applicants? It is because he thinks that the periodic system of classifying the elements offers an insuperable barrier to this course. Undoubtedly, if this were granted, there would be little choice left us; but can it be granted? We think not. The scheme at present accepted is after all but a very imperfect and provisional classification. The successional order of the elements in the horizontal series is indeed determined in all cases in which the atomic weight is known with a sufficient approximation to truth; and in certain cases where the properties are clearly marked it is possible to assign the true position in the order of succession to an element even when the atomic weight is very inexactly ascertained; tellurium is an example, having been placed before iodine long ere its atomic weight was ascertained to be lower and not higher than that of

iodine. But in arranging the elements in vertical series we have often great difficulty in determining which are true homologues: we have no difficulty in grouping the alkali metals, the halogens, or sulphur, selenium and tellurium, but how are we to place copper, silver and gold, for example? Are we justified in regarding them as true homologues, and in inserting them as intermediate terms in the group of the alkali metals? Ought we not rather to look upon them as but pseudo-homologues, and ought we not to place them apart from the alkali metals, and apart even from each other in vertical succession? This would lead us, instead of classifying the elements in linear vertical series, to arrange them in pyramidal groups, of which the elements of lowest weight form the summits. In fact, there is no justification whatever for the conclusion that the elements belong to only eight families; the most illiberal treatment leads us to recognize at least twelve, and there is no reason to accept this as the limit. We can thus foresee the possible existence of a far larger number of elements than is at present known, differing probably from each other to a marked extent both in atomic weight and properties. But even then the limit is not reached. Those who have classified the elements according to the periodic system, after all—consciously or unconsciously—have but followed the practice adopted in classifying carbon compounds; and if we consider the results arrived at by the study of hydrocarbons, and apply the conclusions to the elements, there appears to be no difficulty in finding place for a far larger number of meta-elements than even Krüss and Nilson would require to accommodate their host of new claimants for elemental rank. If we arrange homologous hydrocarbons side by side in the order of molecular weight, a scheme corresponding to that devised for the elements will result; but, if molecular weight only be considered, the existence of isomeric hydrocarbons escapes notice: if, however, isomers are included, each simple vertical group at once assumes a pyramidal form. In like manner, if the possible existence of isomeric elements be granted, the periodic scheme would admit without difficulty of the existence of a still larger number of elements even than was above indicated.

Nickel and cobalt have often been supposed to be isomeric elements. According to the most recent determinations of their atomic weights, however, cobalt has a higher weight (58·74) than nickel (58·56); but this result is discredited by the fact that cobalt is usually placed before nickel in the periodic scheme, and should therefore have the lower weight, unless the two elements are isomeric.

Whether among the meta-elements of the rare earths there are not numerous cases of isomerism, remains for the future to determine. Unless, however, some new mode of discriminating other than that involved in determining the atomic weight be introduced, the problem is one which appears beyond our present powers, as experimental error cannot be entirely eliminated. But it is perhaps of all the problems in chemistry the most important to solve, on account of its bearing on the higher problem whether the elements are simple or compound substances. So many converging lines of evidence now render it probable that the elements are compounds that the discovery of isomeric elements would probably suffice to carry conviction to the minds of all who are open to argument on this question. H. E. A.

THE DURATION OF LIFE.[1]

JOHANNES MÜLLER, the celebrated German zoologist, said: "All organic beings are transitory; life passes from individual to individual with the appearance of immortality, but the individuals themselves perish." This proposition is perhaps not so true as it seems to be. Nevertheless, it is certainly true that life has its natural limits, at least in all those animals and plants that ordinarily come under the notice of the layman. But the duration of life is very different in different animals, and it would be interesting to know the reason of this. Differences in length of life have been thought to depend on differences in structure and composition. Obviously the size of an animal will fix a certain minimum of time required for growth: owing to the relation between increase of bulk and increase of absorbent surface, pointed out by Leuckhart and Spencer, a larger animal will require a longer time to secure the surplus of nutriment required for reproduction. The degree of structural complication will also fix a minimum time: the activity of the vital processes, the rate of metabolism,—*because it influences the time at which reproductive power, the goal of individual life, is reached*—will influence the total duration of life. But these inner conditions do not fix the duration of life. Birds, whose vital processes are so rapid, may far surpass in age the sluggish Amphibia. Among ants, the males, females, and workers are practically identical in size, complication of structure, or rate of metabolism; yet the females and workers live several years, the males only a few weeks.

We must seek in the environment for the forces finally determining the duration of life. We find the length of life to be in each case an adaptation arranged by natural selection in the interests of the species. So soon as an individual has produced young enough to fill up the gaps caused by death, it ceases to be of use for the species. Where fostering of the brood obtains—be it uterine or post-uterine—we expect and find a longer duration.

The apparently accidental causes of death remove far more individuals than natural death. The longer an individual lives the more chances of accident does it undergo; *and so selection, acting in the interests of the species, rather than prolonging the life, hurries on the time of reproduction.* At first, it seems impossible that the great age reached by many birds (Raptores may survive their century) is the shortest possible. But the enemies of the eggs and of the young of birds are very numerous. The death-rate is enormously greater than in the case of mammalian embryos developing within the parent. Adaptation to rapid flight precludes great fertility. Bad fliers like the *Phasianidæ* lay many more eggs in a season and live through far fewer seasons.

The adaptation is very clear in the case of the larval life of insects. The larvæ of bees and of many ichneumons placed in the midst of an abundant food supply become pupæ in a few days. The larval stage of predacious larvæ which have to waste time and energy in securing their prey, and of vegetable-feeding larvæ, on account of the less nutritious nature of their food, lasts very much longer. The usually short life of the imago bears no relation to the length or shortness of the larval life, but is directly adapted to its own purposes. In the simplest case, where copulation takes place as soon as the wings are dried, and where the eggs are deposited rapidly and carelessly, the whole adult life lasts but a few hours. Where the mate has to be sought, or the eggs deposited in special conditions, or where active habits preclude simultaneous maturation of eggs, the duration of life is prolonged in correspondence with the special requirements. Adult insects are perhaps the most hunted of animals, and in them is found the extreme case of adaptive shortening.

The inner changes on which natural death depends are not very clear. They can hardly depend on cell destruction; for it is upon that that the processes of life are based. More probably they depend on a failure to produce new generations of cells to replace the cells broken down in the vital processes.

The occurrence of death at all is a provision to secure

[1] "Ueber die Dauer des Lebens." Von Dr. August Weismann. (Jena, 1882.)

the greatest possible number of contemporary individuals of full strength. Contact with the world wastes away individuals with here an accident to-day, there an accident to-morrow. The possession of immortality by the individual, while a doubtful boon to it, would be a harmful luxury to the speies. Death makes room for new, complete individuals. Death is, however, by no means a universal attribute of organisms. In unicellular organisms the single cell is at once somatic and reproductive, and, while liable to accidental destruction, is potentially immortal. The Protozoon divides without a remainder; and the life of each Protozoon alive to-day has descended in direct continuity from the life of the primordial Protozoon.

In the Metazoa a division of labour has separated reproductive cells from somatic, and their complexity, by admitting of mutilations short of destruction, has rendered them mortal. The reproductive cells had to remain capable of an indefinite number of generations lest extinction of the race occurred; but when the somatic cells became specialized, there at once arose the possibility and the necessity of a limit to the number of generations.

It is clear that the size of an individual is an inherited property. Conditions of nutrition can only negatively determine growth. No superfluity of nutrition could build up the framework of a dwarf into a giant. Natural selection acting on variations has fixed the average size of individuals. It has in fact fixed the space limits of cell reproduction, and could have equally well fixed the limits in time—the duration of life—of individuals. There is a continuity of life from organism to organism through the divisions of the immortal germ-cells. The somatic cells arising from the germ-cell in each generation possess a limited reproductive capacity, and the limits are fixed by natural selection for each species so as to maintain the greatest possible number of contemporary individuals of full vigour.

P. CHALMERS MITCHELL.

NOTES.

THE French Association for the Advancement of Science has had a successful meeting at Oran, in Algeria. M. Laussedat, the President, chose as the subject of his address the civilizing influence of the sciences. This was the second meeting of the Association in Algeria, the first having been held in 1881.

THE nineteenth annual Conference of the National Union of Elementary Teachers was opened at Cheltenham on Monday. The President, Mr. Pope, in his inaugural address, spoke bitterly of the existing system of elementary education, which he denounced as a "failure." On Tuesday, the same tone was adopted by the Rev. E. M. M'Carthy, of King Edward's School, Birmingham, who read a paper to show that the system violates two of the fundamental principles of true education. Those principles are: (1) that the course of studies laid down for each stage should be in harmony with, and adapted to, the natural development of the individual child's mind and body; and (2) that all educational processes should develop faculties so as to produce habits of ready and accurate thinking, besides furnishing the mind with knowledge for use and imparting mechanical skill in the use of it.

PROF. KIEPERT, of Berlin, will start immediately on a journey of research in Western Asia Minor. He will be accompanied by Dr. E. Fabricius, the archæologist. The journey will last three months.

ON Easter Monday, 12,374 persons visited the Natural History Museum, South Kensington. The number of visitors on the corresponding day last year was 6570.

THE Report of the Meteorological Council for the year ending March 31, 1887, which has recently been issued, shows that at that date observations were being taken for the Office on 143 ships, exclusive of the vessels of the Royal Navy, all of which are supplied by the Council with instruments, although the keeping of a special meteorological log is optional. The work in hand by the marine branch is: (1) the completion of the synchronous charts of the North Atlantic; (2) a discussion of the meteorology of the Red Sea; (3) current charts for the Atlantic, Pacific, and Indian Oceans; (4) charts of the Aden cyclone of June 1885. In order to discover the cause of this storm and of its unusual course across the Arabian Sea, synchronous charts of the North Indian Ocean for the month of June are being prepared. In the weather branch, forecasts are drawn three times a day. A comparison of the results of the 8 p.m. forecasts gives 81 as the total percentage of success. Hay harvest forecasts were issued to some selected stations, as in previous years. Storm-warning telegrams are issued to 141 stations; the trans-Atlantic messages appear to have been of no practical value for the purpose of these warnings—rather the contrary, as they have occasionally caused the premature issue of warnings to our coasts when no storms followed. The principal changes in the climatological branch have been the erection of self-recording anemometers at Fleetwood and North Shields, and of an electric anemometer at Valentia Island, but unforeseen difficulties have hitherto prevented this from being brought into operation. The Report contains a table showing the distribution of gales round the coasts of the British Islands during each month for the fifteen years 1871–85.

M. L. CRULS, the Director of the Imperial Observatory at Rio de Janeiro, has made an appeal to all meteorological observers for assistance in the compilation of a "Universal Climatological Dictionary," which is intended to comprise, in a methodical form, the principal meteorological elements from as many stations as possible over the whole globe. The data asked for are the mean monthly and yearly temperatures, together with the monthly maxima and minima, and the dates of the yearly absolute extremes; the relative humidity, amount of cloud, rainfall, number of days of rain, thunderstorms, and frost, and the prevalent wind, in each month; the mean annual height of the barometer, and its mean annual oscillation. The work proposed by M. Cruls would be very useful, as, although information already exists for a great number of stations, it is dispersed in many different publications, and is expressed in different measures, so that comparisons are difficult. Details relating to the meteorological elements of his own country especially are much wanted.

IN the *Annales du Bureau central météorologique* of Paris for 1885, vol. i., M. Renou has discussed the rainfall of Paris for the last 200 years. The observations were begun in 1688 by Lahire. At that time the Observatory was outside Paris, some distance to the south, but it is now in the midst of a district surrounded by high buildings. It is a curious fact that soon after Leverrier assumed the directorship he planted some trees near the rain-gauge, which in time affected its readings; these trees were afterwards cut down by Admiral Mouchez. The rainfall seems to have undergone some changes in this long period. At the time of Lahire there was a marked maximum in July; now there are two less marked maxima in June and September. The number of rainy days amounts on an average to 169. Snow occurs very irregularly, but it is never entirely absent in any winter. The heaviest rainfall in a short period was on the 9th of September, 1865, which yielded over 2 inches on the terrace of the Observatory in $2\frac{1}{4}$ hours; the gauge on the ground overflowed.

WHILE studying the laws of dissolution of salts, M. Umoff came to the following correlation, which seems not to have been yet remarked, and which he communicated in a paper in the Memoirs of the Odessa Society of Naturalists (vol. xii. 1). For

potassium chloride, bromide, and iodide, as also for natrium iodide, the weights of salt necessary to saturate a given amount of water at 100° C. are proportionate to the cubes of densities of the respective anhydride salts; while for sodium chloride the same law is true with regard to the saturation weights of water at 0°. The saturation-weights of potassium chloride and natrium iodide at 100° being the double of what they are at zero, they belong simultaneously to both groups.

M. LINDELÖF has contributed to the Proceedings of the Scientific Society of Finland (tome xvi.), a paper on the trajectory of a body moving over the earth's surface under the influence of terrestrial rotation. The author considers that the explanation of the movements of atmospheric currents, for instance, as generally given, is far from sufficient, and leads to inexact ideas. The paper is divided into four parts: the first three deal with the equations of the different movements of a body, and with the forms taken by the trajectory; in the fourth part the theory is applied to the calculation of the passage of the atmospheric wave observed after the Krakatão eruption in August 1883.

PROF. W. BRÖGGER lately submitted to the Swedish Geological Society an account of the work done by the Committee appointed for the purpose of obtaining reports on earthquakes occurring in Sweden. It was decided that trustworthy reporters should be appointed in all parts of the country, and that a number of inexpensive seismographs should be purchased. At the same meeting Baron Nordenskiöld exhibited a new silicate of lead from the Harstigs Mine, in Värmland. Among recent papers of special interest published by the Society is one on the meteors observed in Sweden in 1887, by Dr. Svedmark.

AT a recent meeting of the Seismological Society of Japan, reported in the *Japan Weekly Mail* of February 4, Prof. Milne read a paper on earthquake sounds. These frequently precede the shock, are often heard during its progress, and sometimes have been heard after the earthquake proper has ceased. Their character is very varied, from a low, barely audible rumbling, to a loud rattling, like a cart on a stony street, or a volley of musketry. They are heard better in some districts than in others; better probably where the earth's structure is hard and solid than where it is loose and soft. After discussing some of the explanations that have been given, Prof. Milne suggested that there is a close connection between these sounds and the smaller vibrations which invariably precede the shock proper. He had counted as many as seven per second of these sinuosities, and we are warranted in assuming the existence of still smaller and quicker vibrations preceding even these. With more delicate seismographs we might be able to catch the very early infinitesimal movements that herald the approach of an earthquake. With thirty or forty vibrations per second we should have an audible note of very low pitch. It was suggested in the subsequent discussion that as seismographs show a tail-end of sinuosities very similar to the initial ones, we should expect to hear sounds succeeding as often as preceding an earthquake.

THE Report of Mr. Cautley, the Acting-Consul at Trieste, on the forests of Austria, just issued by the Foreign Office, says that perhaps Austria has a larger proportion of forest in comparison with its area than has any other country. The woods cover about 3,500,000 acres, of which 80 per cent. is timber forest, and the remainder of young growth. The Government and the large land-owners own 69 per cent. of the total forest area, the parish authorities 20 per cent., the clergy 5½ per cent., and peasants about 1½ per cent. The forests are, in fact, the principal source of wealth to Austria, and, calculating the cubic contents of all the timber, and reckoning each cubic foot at nine-tenths of a penny, the wealth of the whole country in this respect may be set down at close on £40,000,000 sterling. The yearly increase in the value of the forests is said to be over half a million sterling.

IN the *Zoologist* for April, Mr. Postlethwaite, of Hallthwaites, Cumberland, states that, last autumn, while netting for salmon in the Duddon Estuary, fishermen brought to the surface some massive horns of the red deer. One pair, with the skull attached, must have had at least fifteen points; the length of one horn is 40 inches; the distance apart at the top of the horns, 42 inches; the circumference of the burr, 11 inches. In another case, a skull was recovered with only a portion of one antler attached; and of a greater size than in the previous example. The horn is broken just above the third tine, the length from the base being 14 inches; the length of one tine, 13½ inches; and the circumference of the burr, 10½ inches. A scapula was dredged up and brought to shore at the same time. The weight of each of these specimens was great, the first-named being as much as a man could comfortably carry. Similar horns were found some years ago, and in the neighbouring estuary of the Esk at various times many such antlers have been discovered, most of which are preserved at Muncaster Castle. Mr. Postlethwaite adds that the channel of the Duddon is shifting and running close into the sides of an old peat moss, from which it seems not unlikely that the horns have been washed. In an editorial note appended to this interesting communication it is suggested that the animals which possessed these fine horns may have been wanderers from the great forest of Bowland, in Lancashire, where red-deer lingered until the early part of the present century; and that they may have roamed over Martindale Fell, in Westmoreland, "where a few of their descendants are still preserved, a pleasing link of association with the past."

THE whale fishery in the Greenland seas and Davis Straits was very unprofitable in 1887. In an article on the subject in the current number of the *Zoologist*, Mr. Southwell says that whales are by no means exterminated. Capt. Gray saw fourteen of them in Greenland, and Capt. Adams is reported to have seen seventeen in Davis Straits; but, from long persecution, they are now "simply unapproachable."

THE French Consul at Bilbao states in a recent report that the pilchard or sardine fishery on the Atlantic shores of the northern portion of Spain proved in 1887 a most disastrous failure. During the three months of June, July, and August, which are generally the most abundant in the year, nothing was caught but sardines far too large for the boxes commonly used in the trade. The amount taken in 1886 was 1650 tons, and during the corresponding months in 1887, it was only 790 tons. This large falling off is supposed to be due to the fact that the fish do not find the food they require on this coast, formerly one of their favourite habitats. Perhaps in a large measure it is owing to their having been driven away by the reckless system of fishing which has been adopted in the past.

THE Report of the Mason Science College, Birmingham, for the year ending February 23, 1888, has just been issued. The Chairman of the Academic Board testifies that, although the year was not marked by any new or striking developments in the educational policy of the College, or by any special additions to the existing curriculum of the subjects taught, the general progress of the College upon the lines laid down in previous years was eminently satisfactory. Not only was the total number of day students larger than in any previous year, but the increase affected, in varying proportions, nearly all the different departments. The year was also characterized by a marked increase in the number of systematic students. By "systematic" students are meant those who enter the College with the object of preparing for the various University or medical examinations, for technical dip-

lomas, or for the Associateship of the College, or who are studying some definite subject with the view of teaching, or original research, or with regard to its practical application to manufacturing industries.

WE have received the Proceedings of the Royal Physical Society, Edinburgh, for the session 1886–87. Among the contents is an interesting Presidential Address, by Mr. John A. Harvie-Brown, on the faunal importance of the Isle of May, purely from an ornithological point of view.

WE have received the first part of what promises to be an admirable work—"An Illustrated Manual of British Birds," by Mr. Howard Saunders. The book will be completed in about twenty monthly parts. It is being issued by Messrs. Gurney and Jackson.

A TWELFTH edition of the late Dr. David Page's "Introductory Text-book of Geology" (Blackwood) has been issued. It has been edited by Prof. Charles Lapworth, who, in order to bring all the departments up to date, has found it necessary to recast or re-write almost the whole of the work, with the exception of the introductory and concluding chapters.

MR. HALY, Director of the Colombo Museum, has published a first Report on the Collection of Birds in that institution. It fills about eighty pages demy octavo.

THE new number (the third) of the American periodical—the *Technology Quarterly*—opens with a valuable account, by Mr. W. O. Crosby, of the methods of instruction in mineralogy and structural geology in the Massachusetts Institute of Technology. Mr. S. W. Hunt continues his discussion of the precision of measurements; and Mr. F. W. Clark contributes notes on the assaying of lead, silver, and gold.

THE Johns Hopkins University, Baltimore, has received from the Maryland Academy of Sciences a considerable portion of its scientific collection. Among the specimens is the skeleton of a young fin-back whale captured in the lower part of Chesapeake Bay. Stumps of cycads, which were presented to the Academy by Mr. P. T. Tyson, are also greatly valued. They were taken from the Upper Jurassic clays of Maryland.

ACCORDING to a communication by M. A. Pavloff to the Moscow Society of Naturalists, the meteorite which fell in August last at Okhansk, in Perm, is one of the largest yet known. Its weight, before it was broken, was about 1100 lbs. It belongs to the group of stony meteorites. As it contains particles of unoxidized nickel iron, it must be classified with the sporado-siderites. Its spherical mineral aggregates bring it under the heading of chondrites.

THE following extract from a private letter by a British officer, dated Sittang, Upper Chindwin, February 4, 1888, may be of interest to anthropologists:—"We have arrived here after eight days of hill-marching with very many ups and downs—the highest point just over 5000 feet. We are now completely out of Burma—the hills were sparsely inhabited by uncivilized Chins and Nagas—and are now in a small State, a plateau in the mountains at a level of nearly 3000 feet. The ruler and his people are Hindus by conversion or adoption some hundred years or less ago—the only example I know of Hindu proselytes. The Burmans are tattooed from waist to knee with a fine pattern in blue, looking as if dressed in short dark tights. They wear the hair long, rolled on the top of the head, and covered with a bright-coloured silk kerchief, put on somewhat as one sees in pictures of Negro women of the Southern States in America. The Shans, who were our neighbours in the hills near the Ruby Mines, wear very baggy trousers, like the Chinese, of coarse blue cotton stuff, have uncut hair, and for a head-covering a hat, either of straw or a coarser kind of wicker, of colossal circumference. This hat is as big as an ordinary silk umbrella, but flat except in the middle, which is conical for the reception of the top-knot, and as this might sometimes prove an insecure hold they often wear a fastening under the jaw. They tattoo more extensively than the Burmans, and sometimes stow away jewels under the skin. I have seen lumps which may have been so caused, from their appearance, but I never had the chance of proving their secretion by enucleation. The Nagas, whom we have used in the last few days as carriers, do not tattoo, and wear a skimpy kilt. The hair is uncut and coiled on the front of the head, the lump or coil of hair secured by a band round the base; the band often made of strings of blue beads or a tape of leather, on which two or three rows of small white shells are sewn. A silver or other metal skewer, about ten inches long, is often stuck through the hair, like the arrows worn by some belles of the West—whether only for adornment, or used as a fork or harpoon, I know not. All these savages have the ears pierced. The Naga carries his snuff in a bit of bamboo thicker than an ordinary lead-pencil; and the Burman, who smokes eternally, sticks his cigar *in* his ear-lobe—and his cigar is about the size of that Mr. Verdant Green was induced to smoke, of such calibre that it would not pass through a Colt's revolver barrel. The Nagas here are not tall, but their calves and thighs would attract attention even at a Highland gathering at Athol or Braemar. Their loads they carry with a neatly made neck-and-shoulder yoke. From the yoke in front is a brow-band, while behind a rope-loop passes under the load."

THE Students' Engineering Society of the University College, Bristol, concluded the winter session, on March 26, with a public disputation on the gas-engine *v.* the steam-engine, and on March 27 gave a *conversazione.* The electrical and engineering exhibits attracted much attention, and a highly appreciated concert was rendered by the students and their friends.

THE additions to the Zoological Society's Gardens during the past week include a Gannet (*Sula bassana*), a Greater Black-backed Gull (*Larus marinus*), British, presented by Mrs. Rickards; a Hawfinch (*Coccothraustes vulgaris*), British, presented by Mr. Chas. Faulkner; a Common Swan (*Cygnus olor*), British, a —— Penguin (*Eudyptes pachyrhynchus*, from New Zealand, deposited.

OUR ASTRONOMICAL COLUMN.

THE PERIOD OF ALGOL.—Mr. S. C. Chandler publishes, in Nos. 165, 166, and 167 of *Gould's Astronomical Journal*, a careful and thorough discussion of the period of this interesting variable. Starting with the observations of Goodricke in 1782, he had at his disposal the times of nearly 700 minima as observed by about fifty astronomers, spread over a little more than a century. His first task was to reduce these observations to a common system—an operation the more necessary, since, in the present low state of our knowledge, differences in the processes of reduction are more important in their effect, if they do not completely overshadow personal differences in observation. Mr. Chandler decided, therefore, to abandon the use of the minimum phase as a reference-point, and re-reduced the entire mass of observations on a method the essential principle of which consisted in taking, as the reference-point, the mean between the times of equal brightness on the descending and ascending branches of the light curve. This involved the abandonment of 199 minima, for which sufficient details could not be procured, but left 496 to be employed in the investigation. Unfortunately these are not by any means evenly distributed as to time, and in the earlier part of the present century satisfactory observations are very scarce.

That the period of Algol was itself subject to change was suspected by Wurm and proved by Argelander, but the formulæ deduced by the latter have not represented later observations. Mr. Chandler has succeeded, however, in reducing its apparently highly complicated anomalies to a comparatively simple law.

This law comprises two inequalities, with the periods respectively of 141·3 years and 37·7, and coefficients of 173·3 and 18·0 minutes of time. A third period of 17 years, with a coefficient of 3·5 minutes, was suspected, but the coefficient is so small as to bring it almost within the limit of errors of observation. The resulting elements are as follow: 1888 January 3, 7h. 21m. 29·23s. (G.M.T.) + 2d. 20h. 48m. 55·425s. E′ + 173·3m. sin. ($\frac{1}{50}$ E′ + 202° 30′) + 18·0m. sin ($\frac{3}{40}$ E′ + 203° 15′) + 3·5m. sin ($\frac{1}{6}$ E′ + 90° 20′); where E′ = E (Schonfeld) − 11210. The interpretation of the theory is as follows:—The period at the time of Goodricke's discovery of the character of the variation was 2d. 20h. 48m. 58·0s., lengthening to 59·8s. in 1798, diminishing again in the next ten years to 57·2s., and then again lengthening irregularly to 59·2s. in 1830. A rapid diminution shortly followed, and the rate was reduced to 54·0s. in 1843. After a halt a further but less rapid diminution set in, and in 1858 the period was 52·8s. The following six years saw an increase of 1·6s., followed by another shortening, until in 1877 the period had fallen to 51·1s., from which time it has remained nearly constant; but should the theory be correct, a period of increase must shortly set in, which, with halts and retrogressions, will attain a maximum somewhat late in the coming century.

The paper concludes with a table of heliocentric times of minima up to August 1898.

M. Oudemans, Director of the Utrecht Observatory, is likewise preparing a work on this variable, and requests observers to transmit to him copies of their notes on all observed minima since 1883.

OBSERVATIONS OF VARIABLE STARS.—Mr. Edwin Sawyer has given, in Nos. 164 and 165 of *Gould's Journal*, his observations of several variable stars made during the year 1886. The following table will show how some of these compare with the ephemerides given week by week in NATURE.

Star.	Phase.	Observed.	Calculated.
V Cancri	*M*	1886 March 29	April 12
R Ursæ Majoris	*M*	1886 April 29	May 12
R Virginis	*M*	1886 April 8	April 10
S Coronæ	*M*	1886 May 10	April 10
R Scuti	*m*	1886 July 21	June 27
	M	1886 Sept. 12	Aug. 1
	m	1886 Dec. 2	Nov. 17

Mira Ceti was observed at maximum 1886 January 9; *g* (30) Herculis at minimum June 14, and at maximum September 20; and W Cygni at three epochs, viz. *m* July 8, *M* September 10, and *m* November 5.

Gore's new variable near χ_1 Orionis, to which Mr. Sawyer gives the lettering U Orionis, but which other astronomers have generally designated T, attained a maximum about 1887 December 14. The maximum was only a feeble one, − 7·5 mag. The light remained almost stationary from 1887 November 29 to 1888 January 2, a period of thirty-four days. The period of the star must be almost exactly a year.

The variable Lal. 40083, discovered by Mr. S. C. Chandler (see NATURE, vol. xxxv. p. 282), and to which he has given the name X Cygni, has shown from further observation that its light-curve is not constant in different periods, the minimum brightness being especially variable, but since the bright and faint minima do not alternate regularly the star does not belong to the β Lyræ class. Mr. Chandler's revised elements for the star are as follow: 1886 October 13, 14h. 20m. G.M.T. + 15d. 14h. 24m. E. Approximate duration of increase 5·6 days, of decrease 10·0 days. The maximum brilliancy is generally about 6·4m.; the minimum ranges from 7·2m. to 7·7m.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 APRIL 8–14.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 8

Sun rises, 5h. 20m.; souths, 12h. 1m. 43·3s.; sets, 18h. 43m.: right asc. on meridian, 1h. 10·4m.; decl. 7° 29′ N. Sidereal Time at Sunset, 7h. 53m.

Moon (New on April 11, 9h.) rises, 4h. 46m.; souths, 10h. 6m.; sets, 15h. 35m.: right asc. on meridian, 23h. 14·6m.; decl. 8° 21′ S.

GEOGRAPHICAL NOTES.

A SHORT excursion into the almost unknown interior of San Domingo was made last summer by Baron H. Eggers, in the course of which he explored the mountainous district, and made a complete study of the vegetation of this elevated region; he further discovered a route along which the exploration of this little-known mountain region may be carried out with facility. The following details are taken from the traveller's own account of his journey, published in *Petermann's Mitteilungen* (Part 2, 1888). He left Puerto Plata, on the north coast, on May 2 last, and about the middle of the same month found himself at Jarabacoa on the Rio Yagin, having passed through Santiago on his way. While at Jarabacoa he ascended Monte Barrero (4100 feet) in the vicinity of the town. The steep slopes of this peak are covered with lofty pine woods. In the small ravines and between rocks the traveller observed many interesting plants, *e.g.* the dark red *Fuchsia triphylla*, a bright red *Siphocampylos*, a large *Pentarhaphia*, and a beautiful *Cyathea*; he also found a large number of hitherto unnoticed plants, including an ilex, several Compositæ, Labiatæ, &c. The animal life in these pine forests appears to be very poor: there are scarcely any insects, and a species of crow is the only bird seen. At the end of May the traveller with a small party of blacks set out in a due southerly direction for the Valle de Constanza. The valley is well watered, and its height above the sea is 3840 feet. Its inhabitants, numbering 100, are engaged in cattle-rearing, and the cultivation of beans, maize, cassava, tobacco, &c. The climate is cool, and from November to March dry; during the rest of the year it rains. The thermometer at 6 o'clock in the morning of May 28 stood at 59° F. The higher part of the surrounding mountains, which almost everywhere contain gold, though in small quantities, are quite unexplored. From the Valle de Constanza the traveller made a

further excursion to the south-east to a savanna region, situated in a depression among the mountains, and called by the natives "Valle Nuevo." The path led over forest-clad mountains with intervening gorges, and formed a continual ascent till the Valle Nuevo was reached, which is 7450 feet above the sea. One of the forest tracts which the traveller traversed was especially dense and almost impassable; beautiful mosses, ferns, orchids, lycopods, and other epiphytes were growing on the trees. The Valle Nuevo is surrounded by low hills, which form the culminating points of the range; the highest of these, viz. Pico del Valle Nuevo (8630 feet above the sea-level) was ascended by the traveller.

DR. RINK contributes to the current number of *Petermann's Mitteilungen* an account of the results of the recent journeys made by Lieuts. Ryder and Block along the coast of Greenland to the north of Upernivik in 1887. By accurate measurements made in the ice-fiords of Angpadlar Fok, &c., both in April and August, some interesting and important results have been secured as regards the physical geography of this region. Some of the ice-fiords are very prolific in ice-bergs, notably that of Giesecke, where the edge of the permanent ice has retreated considerably within recent years. The results show not only the extraordinary rapidity, but the great variableness in the movements of the ice, apart apparently from the temperature of the time of year. The average temperature of the air during the measurements from April 20 to 24, was from $-9°$ F. to $-15°$. On January 28 the water temperature, at a point where the ice-fiord was 512 fathoms in depth, was as follows: at the surface 27°·7 F., at 50 fathoms 28°·9, at 200 fathoms 32°, and at 287 fathoms 32°·2. The question of the limit and movements of the inland ice of Greenland, to which the attention of recent Danish explorations has been directed, and towards the solution of which the results obtained by Lieuts. Ryder and Block have materially contributed, is discussed by Herr Rink in his paper, which also gives some interesting notes on the botany, geology, and ethnography of the country.

IN the April number of the Proceedings of the Royal Geographical Society there is an excellent new map of Siam, based on the surveys of Mr. James McCarthy. There also will be found the second and third of General Strachey's Cambridge geographical lectures.

AT the last meeting of the Royal Geographical Society a paper of unusual interest and originality, on the Solomon Islands, was read by Mr. C. M. Woodford, who spent several months in the group in 1886–87. Mr. Woodford's attention was mainly directed to Treasury Island, his head-quarters for some months being at Alu, on that island. He made many journeys into the interior, and was so successful that he obtained nearly 17,000 specimens in natural history, which, so far as they have been examined, have been found to comprise three new genera, and eight new species of mammals, fifteen new species of birds, six new species of reptiles, and over a hundred new species of Lepidoptera. Mr. Woodford visited, besides Treasury Island, the islands of Fauro, New Georgia, Guadalcanar, and others, exploring their interiors as far as possible, and in the case of Guadalcanar attempting to ascend Mount Lammas (8000 feet), without, however, succeeding. He followed the Bokokembo River as far as possible, finding the vegetation most luxuriant, and composed of large Ficus and other forest trees, with occasional clumps of sago and areca palms, but few coco-nuts. The coast natives are greatly afraid to venture into the interior, partly through fear of the bush-folk who live in the mountains, and partly through superstition. Mr. Woodford's observations on the natives are of great value; he had unusual opportunities of observing their modes of life. They are mostly inveterate head-hunters and cannibals. Natives of different parts of the group differ considerably from one another, but they belong to the Melanesian or Papuan type. Mr. Woodford believes, however, that on the island of Ysabel there is a strong infusion of Polynesian blood from Ongtong Java, or Lord Howe's Group, as canoes are known to have been driven in bad weather from that group, and to have arrived on the coast of Ysabel. The natives of Bouka and Bougainville, and of the islands of Bougainville Straits and of Choiseul, are intensely black in colour, but as one journeys eastward the colour changes to a dark brown. They have woolly hair, but occasionally natives are met with wavy, and in some cases straight hair. Mr. Woodford attributes this fact to an infusion of Polynesian blood, and has noticed it in natives from Ysabel, also at Fauro.

THE Royal Geographical Society of Sweden has awarded the *Vega* Gold Medal—instituted in honour of Nordenskiöld's voyage—to Dr. Wilhelm Junker, the celebrated African traveller. The medal, which has not been awarded since 1884, has hitherto had only four recipients, viz. Nordenskiöld, Palander, Prejevalsky, and Stanley.

THE ATOLL OF DIEGO GARCIA AND THE CORAL FORMATIONS OF THE INDIAN OCEAN.[1]

DIEGO GARCIA is a typical atoll; a narrow strip of land varying in width from a mile to 30 yards, nearly completely encircles a lagoon of irregular shape. The lagoon is open to the ocean towards the north-west, its mouth being divided by three small islets into four channels, of which three are sufficiently deep to allow ships to enter the lagoon. The whole of the land composing the atoll is very low; the highest point in the island is not more than 30 feet above the level of high tide, and this height, which is quite exceptional, is due to the accumulation of great heaps of sand through the action of the south-east trade winds which blow with considerable strength for more than one-half of the year. Diego Garcia is the southernmost atoll of the Chagos Group; it lies in S. lat. 7° 26′, E. long. 72° 23′, and forms the last of the great chain of coral formations reaching from the Laccadive Islands, through the Maldives to the Chagos Group. To its south-west lie the submerged atoll-shaped reefs known as Pitt's Bank and Centurion's Bank, to its north lies the huge submerged atoll known as the Great Chagos Bank. It is an interesting fact that throughout the Laccadive, Maldive, and Chagos Groups there is no instance of a fringing or of a barrier reef; nothing but coral structure rises above the waves; all the islands are atolls; none of these are upraised, but there are several submerged banks. The existence of this long line of atolls seemed to be one of the strongest arguments in favour of Darwin's theory of the formation of coral reefs.

In Diego Garcia the nature of the soil varies considerably from place to place. In some localities it consists of nothing else than bare coral rock upon the surface of which coral boulders are scattered about; in other places it is composed wholly of calcareous sand, and one may dig down for 6 or 8 feet without finding coral rock. It is obvious after a short examination that some parts of the land are older than others, and that the great strip of land was formerly a series of disconnected islets which have since been joined together by the accumulation of sand and coral *débris* between them. In the older parts of the island, which have apparently been covered with vegetation for a considerable period, a thick peaty mould has been formed by the decay of fallen leaves and stems of trees and shrubs.

Throughout the island the outer or seaward shore is higher than the inner or lagoonward shore, owing to the pile of coral boulders thrown up in the form of a low rampart along the former by the action of the waves. In most places a flat reef extends fully 60 yards seaward of the rampart; and this reef is just uncovered at low spring tides. As a rule the inner shore slopes gently down into the lagoon for some distance, and then pitches down rather suddenly to a depth of 10 or 12 fathoms, but in some places there is a depth of 6 or 8 fathoms close up to the inner shores. Marshy pools of fresh or brackish water are found in the centre of the strip of land on the south-east and west sides of the island; into these the sea enters in many cases during the highest spring tides, and at the south-east and south ends of the island it has established permanent breaches into some of these pools, through which the tide runs in and out regularly from the lagoon. Thus there are formed sheets of water like secondary lagoons within the strip of land; these are known on the island by the name of *barachois*, and they are of some importance when one comes to consider the amount of change which is continually going on in the island.

Externally the shores slope away very rapidly to considerable depths, the sounding-line giving depths of 250 fathoms and upwards at a distance of a few hundred yards from the edge of the reef, excepting at Horsburgh Point at the south-east side, where a depth of 45 fathoms is found at a distance of 1 mile from the shore. After a stay of two or three months on the island one cannot fail to be impressed with the immense amount of

[1] By G. C. Bourne, B.A., F.L.S., Fellow of New College and Assistant to the Linacre Professor in the University of Oxford. Communicated to the Royal Society by Prof. E. Ray Lankester, F.R.S.

change which is continually in progress. Large masses of sand are in the space of a month deposited in one spot to be swept away during the next month and deposited in another. Everywhere there is evidence that the sea has encroached upon the land, or that the land has in its turn gained upon the sea. In one place numerous dead and fallen cocoa-nut palms show where old-established land has been carried away; in an adjoining spot tracts of sand, either bare or covered with a scanty growth of young shrubs, show where the combined action of wind and waves has added a new piece to the island. Within the lagoon the currents are constantly changing in force and direction, and their every change affects the growth of coral in their track. In estimating the structure of the atoll these changes should be kept in mind, although their complexity makes it far more difficult to arrive at a correct conclusion.

In the course of my investigations I learnt to distinguish the following kinds of coral rock formed by the action of the waves or wind, or both combined.

Firstly, *reef rock*, a tolerably homogeneous mass of compacted coral *débris*, the component parts of which are so thoroughly infiltrated with carbonate of lime held in solution in the sea-water that the masses of fragments of coral composing the rock are rarely distinguished from one another. This form of rock exhibits a fine horizontal stratification; it is invariably formed under the sea or between tide marks.

Secondly, *boulder rock*, formed just above high-tide mark by means of the masses of coral which are transported across the reefs by the waves and are piled up to form the low rampart already alluded to. The interstices of the boulders are soon filled up with coral *débris* and sand, and are cemented together by the spray. Such rock is only formed on the seaward shores, and invariably shows a stratification dipping downwards towards the sea.

Thirdly, *shingle rock*, which may be of two kinds. The first kind is horizontally stratified, and is scarcely distinguishable from reef rock, except in its finer texture; it is formed below water or between tide marks by the agglomeration of small pieces of broken coral, among which are included numerous shells of mollusks, remains of Crustacea, Echinoderms, &c., and in the more sheltered parts of the lagoon it may include considerable masses of dead Madrepores embedded in their natural position in the rock. This rock is of a looser texture than the reef rock. The second kind of shingle rock is formed above high-water mark by the action of the waves. It is entirely composed of small fragments, and exhibits a fine stratification dipping seawards at an angle.

Lastly, there is the *sand rock*, formed above water by the action of the wind. Wherever masses of fine sand are piled up within reach of the spray they are gradually compacted, and form a friable rock, the stratification of which dips seaward.

In many parts of the island I observed that the land was composed of stratified reef or shingle rock, the strata of which were perfectly horizontal, and did not dip down towards either shore. Having observed the manner in which the different kinds of coral rock were formed, I was at a loss to understand how such horizontally stratified masses could have been formed in their present position above high-water mark, and could only believe that they were originally formed as reef or shingle rock below high-water mark, and had been subsequently raised to their present position. I was thus led to believe that a slight elevation had taken place, and this belief was strengthened by a study of the formation of East Islet. This islet is about 800 yards long, and nearly 100 yards broad; its westermost extremity is composed of masses of sand piled up on the underlying reef rock, and in this place there is a clump of high trees (*Hernandia peltata*). The eastern and by far the larger part of the islet is of different formation. The even surface of the soil is covered with a low scrub, but bears no trees nor cocoa-nut palms. It forms a low plateau, the surface of which does not slope down towards the lagoon, but is perfectly horizontal, and stands 4 feet above the very highest spring tides. The shore on the lagoonward side shows an abrupt fall of 6 feet to the reef, which in this place extends for a distance of 50 yards towards the lagoon, and is only left uncovered at the lowest spring tides. At the eastern extremity of the island there is no reef, but from 1½ to 2 fathoms of water are found within a few yards of the shore. This point is exposed to the ocean, and a strong and constant current sets against it, so that it is undergoing a considerable amount of erosion. On the north or seaward side the reef again extends outwards from the shore, the latter differing from the inner shore in the presence of a talus of large boulders which have been thrown up against it by the waves. Wells have been sunk in numerous parts of the island, though, for some reason which I cannot explain, water is only found in one of them. Numerous pits, some of which are 9 feet deep, have also been dug for the purpose of planting cocoa-nuts. These pits and wells expose the interesting structure of the superficial part of the island. Beneath a thin surface layer of sand and mould lies a horizontal layer of stratified shingle rock, in which large embedded coral masses may occasionally be distinguished; this layer is about 2½ feet thick. Beneath is a layer of loose coral sand about 18 inches thick, and beneath that is another layer of coral rock of the same character as the first, and about 3 feet thick. Beneath this is another layer of friable sand lying on the solid reef rock into which the excavations did not penetrate. These layers lie perfectly horizontally, and do not dip in any direction. They crop out above the reef on the steep eastern and southern shores, and as the loose sand is washed out by the waves the overhanging layer of rock breaks off and falls down in large masses. The central parts of this area are absolutely beyond the reach of any waves at the present time, and as the strata of rock and sand run evenly through it there is no evidence of its having been formed by successive additions of material through the action of the waves. Nor can it possibly have been formed under the surface of the water unless it has since been raised to its present position, for, as I have said, its upper surface is 4 feet above the level of high spring tides. On one occasion when the tide rose to an abnormal height and invaded several parts of the main island, I saw that the water reached to within 3 feet of the top of the shore, but even then the whole of the upper stratum of coral rock was well above the waves. It is scarcely credible that an even layer of shingle rock could have been formed above the highest high-water mark.

My belief in elevation is further strengthened by the following facts, communicated to me by M. Spurs, a resident for twenty-five years at Diego, an ardent naturalist, and much interested in coral formations.

A small shore crab of the genus *Ocypus* is always to be found on the sandy flats between high and low water marks. These crabs, as is well known, form numerous galleries in the fine muddy sand, which they line with seaweed, &c., to prevent their falling in. These galleries open to the surface by short passages placed perpendicularly, the mouths of which open only a few inches above the level of low tide. This crab is only found on the shore between tide marks; on the dry land its place is taken by *Gearcinus*, another genus of crab, which forms different burrows. In the west part of East Islet there is an aggregate of friable, scarcely compacted sand, which has somewhat the appearance of half-dried clay. It lies 5 feet above high-water mark, and was found by M. Spurs, during some excavations which he had to make for the purpose of constructing a slip for boats, to be riddled with the sea-weed-lined galleries of *Ocypus*, evidently long since disused and empty.

Having made this observation on East Island, M. Spurs made a search in similar formations on the main island, and found, he tells me, precisely the same facts in several instances, aggregates of sand lying at some distance above high-water mark, riddled with the abandoned burrows of *Ocypus*. Now, since the burrows of *Ocypus* are quite characteristic, and could not have been mistaken by so good an observer as M. Spurs for those of another species, and since they are in the present day only found between tide marks, these observations afford a further presumption in favour of a slight elevation having recently taken place. In any case they preclude the idea of any subsidence being in progress, as Mr. Darwin fancied to be the case in the Keeling atoll. M. Spurs further informs me that, during the time that he was superintendent of the oil company's estate, he caused more than 30,000 pits to be dug on the main island for the purpose of planting cocoa-nut palms, and that he frequently observed in different localities the same alternate layers of sand and rock that I have described as existing on East Island. These alternations of sand and rock would suggest alternations of very slight subsidence with very slight elevation, rather than a single movement of upheaval, yet on the supposition that all the layers were formed beneath the water, as their horizontal stratification leads me to believe, I can venture on the following explanation. The mass of rock which forms the base upon which the islets and other dry land rests is solid reef rock, and the whole floor of the lagoon is similarly formed.

The latter is covered at depths of 3 or 4 fathoms and upwards by a layer of fine sand, which may attain a thickness of 2 or 3 feet. In protected parts of the lagoon and in spots where the changeable currents have ceased to deposit any quantity of sand, corals will grow in considerable quantities, chiefly those wide-spreading species of Madrepora which cannot find a lodging on the exterior of the reef, where they would be dashed to pieces by the waves. By the continual growth of new colonies on the top of the old ones which have died, a layer of solid rock of considerable thickness may be formed. Whilst diving for corals at the lower part of the lagoon, I often noticed such layers of half-formed rock on which living coral was growing or not, according as the constantly changing currents were at that time throwing up sand in the locality or not. Thus on the west side of the lagoon, off Point Marianne, there are large tracts of recently formed coral rock, on which no living corals are to be seen, whilst on the east side of the lagoon, exactly opposite to Point Marianne, a similar basis of rock is luxuriantly covered with growing coral.

Now, as the currents are constantly changing, and as the changes may, as I saw, affect an area some miles in extent, one may suppose that an area was first covered with corals growing on the sand, which everywhere covers the reef rock, when the latter lies more than a fathom below the surface. A change in the currents brought abundant sand to the spot, killed the corals, and deposited an even layer of sand of some little thickness over the rock formed by the skeletons of the dead corals. A further change in the currents would again render the spot suitable for coral growth, and a new layer of rock would be formed over the last layer of sand. I have seen quite analogous formations in progress in a fathom of water a little way above Point Marianne. Raise the formation to the surface, and you get that stratification which occurs in so many parts of the island, a stratification which cannot be explained on any theory of subsidence, and is scarcely less difficult to explain on the supposition of rest. At first I had some hesitation in extending to an island on the borders of the lagoon, as is East Island, a view of the formation of layers of sand and rock derived from an inspection of the interior of the lagoon, but afterwards I saw that similar layers were being formed just within the large reef known as Spur's Reef, west of Middle Island, so that no objection can be raised on that score. The whole character of the Chagos Group is very much opposed to the theory that atolls and barrier reefs are formed during subsidence. There are several atolls rising above the waves, that of Peros Banhos being 55 miles in circuit, and composed of numerous small islets placed upon a ring-shaped reef through which there are several large and deep channels. Egmont or Six Islands is an instance of an atoll in which the encircling reef is perfect and unbroken by any channels, the land consisting of six islets placed for the most part on the southern and western sides of the reef. There are several submerged banks, nearly all of which have an atoll form. Of these the best known is the Great Chagos Bank, a huge submerged atoll 95 miles long and 65 miles broad, having a depth of 4 to 10 fathoms over a narrow rim around its periphery, and a central lagoon of a depth varying up to 45 fathoms. South-west of the Great Chagos Bank, distant less than 15 miles, lies the atoll of Six Islands, and on the other side of these, scarcely 12 miles distant, lies another submerged atoll, known as Pitt's Bank. South-west of Pitt's Bank are two smaller banks, Ganges and Centurion's Banks. Darwin considered that the Great Chagos Bank afforded particularly good evidence of the truth of the subsidence theory. He regarded it as an atoll carried down by a too rapid subsidence below the depth at which reef-building corals flourish. The same would be the case for Pitt's Bank and the two others just mentioned. A more intimate knowledge of the Great Chagos Bank, and of the relations of it and other submerged banks of existing land, shows this view to be untenable. In the first place, the rim of the Great Chagos Bank is on an average not more than 6 fathoms below the surface, and therefore situated in a depth eminently favourable for coral growth, and there are actually six islets on the northern and western edges rising above the water, and some of them inhabited. Secondly, any such rapid subsidence could not have affected areas only 30 miles apart without involving the Six Islands atoll lying directly between them. A similar argument might be extended to the more northern islands of the Chagos Group, and even to Diego Garcia itself, although it lies somewhat apart from the rest of the group. Again, if atolls and barrier reefs are formed around subsiding peaks, it is at least curious that throughout the Laccadive, Maldive, and Chagos Groups there are no instances of high islands surrounded by barrier reefs, marking the last remnants of pre-existing land. In the more western parts of the Indian Ocean, between Madagascar and the Seychelles, there are numerous atoll islands, and in long. 60° E. there lie the submerged Saya de Malha Bank and the reef known as Cargados Carajos. Between these two lies the extensive Nazareth Bank, having over it depths of from 14 to 45 fathoms. The Saya de Malha Bank appears to have the characters of a submerged atoll, having a central depression of 65 fathoms, surrounded by a rim which has only 8 to 16 fathoms on its eastern side, but 22 fathoms on the western. Some of the groups north of Madagascar afford very good evidence of upheaval. Aldabra Island, situated in lat. 9° 22′ S., long. 46° 14′ E., is a perfect instance of an upraised atoll. Captain Wharton describes the external shores as consisting of low coral cliffs, about 20 feet high, the surface of the land being composed of jagged coral rock. The lagoon is entered by a passage varying from 11 to 5 fathoms in depth, but its internal portions are either very shallow or partly dry at low water. Not far distant is the Cosmo Ledo Group, a perfect atoll, with a lagoon some 4 fathoms deep, or less. There are ten islets of various sizes on the reef, and all of them appear to have been elevated some 10 feet. There are some hills 40 and 50 feet high on the two largest islands, but these appear, according to Captain Wharton, to be formed of blown sand. The Farquhar Group and Assumption Island, situated within the same area, have been raised, according to the same authority, some 10 feet. Providence Island, in lat. 9° 14′ S., long. 51° 2′ E., appears to be a low island situated upon the edge of the atoll-shaped Providence Reef. At a distance of 19 miles from Providence Island is the island of St. Pierre, which has no fringing reef. It is particularly interesting, for although it is in close proximity to the low Providence atoll, it has been raised about 40 feet above high water, and in the absence of a fringing reef the sea breaks with great violence against a low cliffy coast, hollowing out a number of caverns which, from the description given in the sailing directions for Mauritus and its islands, appear to open inshore by "blow-holes." [1]

Near and among these raised coral formations are several submerged banks, the most important of which is the McLeod Bank, situated in lat. 9° 57′ S., long. 50° 20′ E., between Providence Island and the Cosmo Ledo Group. The details show that there is a group of coral formations, situated in lat. 10° S., north of Madagascar, in which are found raised atolls—atolls whose dry land just rises above the waves and submerged banks. There can be no clearer proof that atolls are formed in areas of elevation, and, if the facts which I have already stated concerning Diego Garcia are of any weight, it would seem that most of the coral formations of the Indian Ocean mark areas of elevation rather than of rest, certainly they are not evidence of subsidence.

Those who have felt that the evidence brought against Darwin's subsidence theory is too strong to be resisted, must often have felt that no satisfactory explanation of the lagoons of atolls or the lagoon channels of barrier reefs has been given in its place. Semper was the first to suggest that the lagoon was formed by a solution of the interior parts of the reef, and more recently this view has been urged with great force by Murray, who points out, in addition, that corals on the periphery of a reef must, from their position, get the advantage over those more interiorly situated, being more directly in the track of food-bearing currents. Neither of these explanations has completely satisfied me. That sea-water exercises a solvent action upon carbonate of lime does not admit of doubt, and that the scour of tides, combined with this solvent action of the water, does affect the extent and depth of a lagoon is obvious. But I challenge the statement that the destructive agencies within an atoll or a submerged bank are in excess of the construction. It would be nearer the mark to say that they nearly balance one another. In the first place, the carbonate of lime held in solution by sea-water is deposited as crystalline limestone in the interstices of dead corals or coral *débris*. Anyone who is acquainted with the structure of coralline rock knows how such a porous mass as a Mæandrina head becomes perfectly solid by the deposition of lime within its mass. This deposition can only be effected by the infiltration of sea-water. In reckoning the solvent action of sea-water, therefore, account must be taken of the fact that a not inconsiderable proportion of the carbonate of lime held in solution is redeposited in the form of crystalline limestone. Of

[1] For the information on the islands north of Madgascar I am indebted to the courtesy of Captain W. J. L. Wharton, R.N., F.R.S.

this, it seems, Mr. Murray has not taken sufficient account, and has, therefore, overstated the destructive agency of the sea. Secondly, the growth of corals, and the consequent formation of coral rock within the lagoon, is generally overlooked.

Whilst diving for corals at Diego Garcia, I had abundant opportunities of studying the formation of coral rock within the lagoon, in depths under 2 fathoms. The layers of tolerably compact rock thus formed are of no mean extent or thickness; they soon become covered with sand, and are thus protected from the solvent action of the water. I have found it impossible to reconcile Mr. Murray's views with what I saw of coral growth within a lagoon. Not only do the more delicate branching species of the Madreporaria flourish in considerable numbers, but true reef-building species—Porites, Mæandrina, Pocillopora, and various stout species of Madrepora—are found there. It is a mistake to suppose that certain species of corals are restricted to the external shores, others to the lagoon. My collections proved that many of the species growing in the lagoon at distances of 5 miles and upwards from its outlet are identical with those growing on the outer reef. In addition to them are numerous species, such as *Seriatopora stricta*, *Mussa corymbosa*, *Favia lobata*, *Fungia dentata*, and many others that are not found on the outside. The reason is that the last-named are either free forms, such as Fungia, or are attached by such slender and fragile stems to their supports that they could not possibly obtain a foothold and maintain themselves among the powerful currents and waves of the open ocean.

These various species, numbers of which grow close together, form knolls and patches within the lagoon, and it cannot be doubted that their tendency is to fill it up.

These considerations have led me to discredit the solution theory as an explanation of lagoons and lagoon channels, and other objections have been lately urged with great force by Captain Wharton. The conclusion which I reached, after carefully considering the conditions of submerged lakes of atoll form, is that the ring-shape of the outer reef is to be explained by the peculiarly favourable conditions for coral growth found on the external slopes. Although corals may, and do, flourish in lagoons, they are only found in knolls and patches, and are always liable to be smothered, when, by a change in the tidal currents, sand is thrown down upon the place where they are growing. On the external slopes, however, corals grow in extraordinary abundance, and chiefly those massive forms whose skeletons take so conspicuous a share in the formation of coral rock. If once it is admitted that the periphery of the reef offers peculiarly favourable conditions to the growth of reef-forming corals, it follows that, as the reef rises to the surface, its external parts will outstrip the more internal, and will reach the surface first, forming a rim around a central depression or lagoon. This elevated ring will be as marked a feature in submerged as in complete atolls.

Corals are always thickest along the slopes around a coral reef, and the reef tends to increase at its periphery, growing upwards there, whilst it tends at the same time to spread outwards. These principles hold good in the case of a submerged bank as well as in the case of a reef that is awash, and a submerged bank must tend in the course of time to reach the surface in its circumferential portions, and form an atoll-shaped reef, on the rim of which detritus may be heaped from place to place, forming shingle cays or islets which may temporarily form dry land. In atolls where storms are of frequent occurrence, regular storm-beaches may be formed, till the fragments piled high upon one another may form low islets standing some 6 or 10 feet above high-water mark, upon which vegetation may subsequently find a footing. Atolls are often formed in this way, without any elevation taking place, and such has undoubtedly been the case in the Florida reefs, where atolls (the Tortugas) and barrier reefs and islands have been formed in an area of complete rest. No one who has read the admirable work of Alex. Agassiz on the Florida reefs can fail to agree with the author's conclusion that the islets there have been formed by the action of the wind and waves alone, without any assistance from the upheaval of the bed of the sea. But I am not satisfied that this has been the case in the Chagos Group. Storms are of very infrequent occurrence there, and the horizontal masses of reef rock standing above high-water mark cannot be attributed to the normal action of the prevailing winds and currents.

In the Florida reefs the nature of the soil betrays its origin—its strata slope towards the sea on every side, and the lamination of the rocks attests the long-continued action of waves and spray. But the alternate horizontal layers of sand and rock occurring so abundantly at Diego Garcia are quite different; they do not dip seawards, their composition differs from the rocks of the Florida reefs, and their edges, instead of showing signs of accumulation of fresh material, are often bluff, and show that the sea is gradually eating them away. It is difficult to explain these appearances except on the hypothesis of slight elevation. It might be objected that if any upheaval had taken place, the banks lying at various depths below the surface would have been raised to different heights, and that it would be in the highest degree unlikely that so many would be raised some 4 or 5 feet above high-water mark and no more, throughout so large areas as the Laccadive, Maldive, and Chagos Islands, and the various low groups in the Pacific. The force of the objection must be admitted, but it may be observed that atolls raised from 10 to 40 feet above the waves are not so uncommon as has been hitherto supposed, and that the numerous submerged banks lying at very various depths show that all the reefs have not been raised to one height in a single area of elevation. The uniform level of many atolls and barrier reefs admits of a further explanation. A reef raised some few feet above the sea-level is at once attacked by the waves, and as the rim is very narrow, it must soon be worn away till the whole of the land is eaten away, and its surface is brought awash once more. Thus every slight movement of elevation would soon be compensated by the denuding action of the waves. The island of St. Pierre, already described, is a good instance of this process of erosion. It cannot be doubted that this island, which has recently been raised 40 feet, is undergoing rapid waste, and must soon be reduced to the level of the sea. At Diego Garcia I was astonished at the rapid destruction of dry land which is in progress, on the outside as well as the inside of the lagoon. The destruction is not so great on the outside as on the inside as a rule, for in the former case the rampart of coral boulders thrown up by the waves compensates in many places for their erosive action. But in the bay above Horsburgh Point, exposed to the full strength of the south-east trades, the destruction is very great. M. Spurs, an old resident of the island, writes to me on this subject: "Cette destruction est très rapide; Diego perd en moyenne un pied de terrain par an, tant intérieurement qu'extérieurement, excepté aux pointes nord-est et nord-ouest, où une partie des sables, entrainés du fond de la baie par les vents de sud-est, conservent à ces deux pointes leur largeur première."

M. Spurs has over-estimated the rate of destruction, but there can be no doubt that it is very considerable. It is most conspicuous along the shores bordering the lagoon. The stumps of cocoa-nut palms, the newly-made breaches into the land, forming shallow inland lagoons, the vertical faces of old banks of half-consolidated sand, all attest it. Just above Point Marianne is a road running along the lagoonward shore, which when I left the island had been narrowed by the action of the sea to a mere path, and was in some places almost impassable, as the sea had made clean breaches across it, and found its way into some shallow fresh-water lagoons lying on the other side of the road. I was assured that this road had been over 12 feet wide some years previously, and that it was formerly separated from the lagoon by a narrow strip of land of an equal width. Perhaps the best evidence of the destruction of land is afforded by the "barachois" at the southern extremity of the island. These barachois are inland lagoons connected with the main lagoon by a narrow outlet some 2 fathoms deep or more. They are filled and emptied every tide, and their floor is intersected by numerous small channels running in every direction. No corals grow within the barachois, and a slight study convinces the observer that the daily scour of the tides is denuding their shores and floors very considerably.

Barachois are formed in the following way:—During unusually high tides, when the waters of the lagoon are dammed back by a north-westerly wind of unusual violence, the water rises to great heights and invades the land in several places. In some instances it actually makes a breach in the lagoonward shore, and fills up the shallow depressions which are often found in the middle of the strip of land. A pool of salt water is thus formed, which kills the cocoa palms and other vegetation growing in its bed, and, as this process is repeated again and again, in the course of a few years a channel is cut out between the pool and the lagoon, which finally becomes so deep that spring tides, and finally even neap tides, run in and out of the pool regularly. As soon as these conditions are established, the channel is scoured out and deepened, and the daily tides scour out the bed of the pool, forming a complete barachois.

It is not easy for one who has not seen it to understand how

much of the loose soil of a coral islet can be moved by a single tidal encroachment. It happened that I was riding past the very thin strip of land between Minni Minny and Barton Point the day after an abnormally high tide. The strip of land here is not more than 30 yards across, and the sea had washed right over it on the previous day, clearing away an amount of soil which was almost incredible. My companion, M. Casimir Leconte, told me that the sea had not been known to wash over this place before. It was apparent that, after a few more of such high tides as I had witnessed, a permanent breach would be made at this spot, and another lagoon outlet would be formed, which would be continually deepened as the tide set through it. At the south-eastern side of the island I noticed that the land was being rapidly destroyed on the outer shores just opposite to a half-formed barachois, whose margins are situated not 60 yards from the outer shore. If the same process of external destruction continues, whilst the barachois is deepened and scooped out from within, it will not be many years before the ocean makes a new channel into the lagoon at this point. Thus the continuous strip of land which now nearly encircles the lagoon of Diego Garcia is tending to be split up again into a series of islets. At the points where the breaches are made the tides and ocean currents will rush with great force into the lagoon, and will scour out deep channels similar to that now existing between Middle and East Islets.

These facts taken together show how the normal action of tides, winds, and waves is constantly tending to lower to the sea-level any dry land that may have been formed by elevation or otherwise. It does not seem to me to be surprising that the majority of atolls and barrier reefs are, under such circumstances, only just able to maintain their surfaces above the sea-level.

No explanation of atoll formation would be complete if it did not include an explanation of the Maldive atolls. This has been felt by Darwin, who has explained the formation according to his theory. Without attempting to enter into a lengthy discussion, I will give my own explanation of the atoll. Tilla-dou-Matte atoll is, as is well known, a huge atoll composed of atolls. The islets forming the rim of the main atoll are themselves atolls with their own lagoons; the main lagoon contains a few secondary atolls corresponding to the coral patches in an ordinary atoll. It will be generally admitted that coral reefs are constantly increasing to seaward because of the excessive growth of coral on their external slopes.[1] As the inward shores of an atoll are constantly being removed, and an atoll if completely formed tends to be broken up again into small islets when it has reached a certain size, and as the channels between the islets must be continually deepened by the scour of the tides until deep passages are formed, an atoll like Diego Garcia may be expected to reach in time a condition like that of Peros Banhos. It is probable that a large bank like the Great Chagos Bank, when it reaches the surface, can never give rise to a continuous strip of land, but must consist of a chain of islets separated by channels of some depth and by tracts of submerged reefs. The islets and tracts of reef in either case would be bounded by deeper channels, and these channels, swept by strong currents, would become wider and deeper, for corals could not thrive in them. After a time the islets would become so far isolated, and the entries into the lagoon would become so large and numerous, that oceanic conditions would prevail in the lagoon, and then there would be around each separate islet or piece of reef all the necessary conditions for the formation of a new atoll. The currents would impinge upon one side of the islet or reef, sweep round it, and give a backwash at the further side; the corals would flourish in the circumferential parts of the reef surrounding the islet, and new atolls with shallow lagoons would be formed.

In Tilla-dou-Matte the lagoons of the secondary atolls are tolerably deep. In this case they must have been formed before any land reached the surface. Applying the same reasoning as in the former case, it can readily be understood how in the case of the Great Chagos Bank, which has wide and deep breaches in many places, the isolated reefs as they grow to the surface must tend to assume an atoll form. An examination of the chart shows that this is the case. The Great Chagos Bank in the course of time will rise to the surface as an atoll composed of secondary atolls or atollons, similar to, but on a smaller scale than, the Tilla-dou-Matte atoll. The explanation of atollons in the centre of a large lagoon in which oceanic conditions have been established, is quite obvious.

[1] This statement may at first sight seem at variance with what I have just said about the rapid destruction of land on the outer and inner shores of an atoll; but in the latter case it is *land above water* that is destroyed. Coincidently with this process the reef rock below water is constantly tending to raise itself and to spread in all directions, owing to the perpetual growth of corals and the accumulation of their skeletons.

THE ROYAL HORTICULTURAL SOCIETY.

On Tuesday, March 27, the Scientific Committee of the Royal Horticultural Society met in the Committee-room of the Drill Hall. Among the numerous subjects brought forward were the following:—

Dispersal of the Seed in Pinus insignis.—Dr. Masters, alluding to the great differences that exist in the species of *Pinus*, as to the time at which the constituent scales of the cone separate in order to liberate the seed, showed a series of cones of *Pinus insignis*, the oldest of which bore the date 1864. In this all the scales were widely separate. The most recent cones dated from 1877, and in them the scales were not at all separated. Between these two extremes, cones were shown exhibiting almost every intermediate stage of separation. It is to be remarked that the separation begins generally just above the centre of the pendulous cone on the side furthest away from the branch, at the place where the excentricity of the cone, due to the free exposure to light and air, and the absence of obstacles afforded by the branch was greatest, and that it follows a spiral course towards the base of the cone. The scales separate in successive spiral coils, till, at length, all except a few at the base and apex respectively, and which are probably sterile, are separated one from the other.

Semi-double and other Orchids.—Dr. Masters explained the construction of numerous malformed orchids which were interesting as throwing light on the morphology of the order. Some extraordinary malformations of Fuchsias were shown, and a drawing was exhibited of a magnificent new Anthurium, which had appeared accidentally with an importation of *Cattleya Gaskelliana*, in the garden of the Right Hon. J. Chamberlain. The heart-shaped leaves are of gigantic size, and the large boat-shaped spathe is of the richest crimson colour.

Eucalyptus urnigera.—Dr. Masters showed specimens of this Tasmanian species in flower and fruit. They had been received from Whittinghame Gardens, Prestonkirk, near Edinburgh, not far from the sea, and where the tree is perfectly hardy.

Daffodil with Crested Corona.—Rev. E. C. Gabbett sent through Dr. Masters two flowers of a curious Daffodil from plants growing on his lawn in Co. Limerick. The "frill," or outgrowth, is produced from the outer surface of the corona, which has thus a very peculiar appearance.

Douglasia lævigata.—Mr. G. F. Wilson alluded to this plant as having been shown for the first time. It is a low-growing Primulaceous plant, with tufted leaves and lilac flowers, like those of an Androsace, but larger, and with the tube of the corolla longer than the calyx, and with only two seeds to the capsule. The species are the natives of North-Western America, the first known species having been collected by Douglas not far from the sources of the Columbia River, and named in his honour by Dr. Lindley.

Araucaria imbricata Timber.—Mr. Ford, gr., Leonardslee, exhibited slabs of wood cut from a tree of this species, and which at 6 feet from the ground girthed 26 inches, the tree being 35 feet in height. The wood was yellow, soft, evenly grained, and, judging by the distance between the rings, quickly grown.

Numerous other plants and objects of interest were exhibited and commented on.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 15.—"A Class of Functional Invariants." By Mr. A. R. Forsyth, F.R.S.

The memoir is occupied with the investigation of a class of functional invariants, constituted by combinations of the partial differential coefficients of a dependent variable, z, with regard to two independent variables, x and y. The definition of the invariant is given by the property that, when the independent variables are transformed to X and Y, and the same combina-

tion as before is formed with regard to these new variables, the equation

$$\Phi = \left\{ \frac{\delta(x, y)}{\delta(X, Y)} \right\}^m \phi$$

is satisfied.

The transformations for which any detailed results are given are of the general homographic type. The characteristic properties of such invariants are :—

(i.) Every invariant is explicitly free from the variables, but necessarily contains both the differential coefficients p and q of the first order.

(ii.) It is homogeneous in the differential coefficients, and is of uniform and the same grade in differentiations with regard to each of the independent variables.

(iii.) It is symmetric or skew symmetric with regard to these differentiations.

(iv.) It satisfies four differential form-equations and two index-equations, all linear and partial of the first order.

An invariant is said to be proper to the rank n, when the highest differential coefficient of z which occurs in it is of order n. By means of the solutions of the form-equations, the following propositions relating to irreducible invariants in a single dependent variable, z, are established :—

Invariants can be ranged in sets, each set being proper to a particular rank.

There is no invariant proper to the rank 1; there is one proper to the rank 2; there are three invariants proper to the rank 3.

For every value of n greater than 3 there are $n + 1$ invariants proper to the rank n, which can be chosen so as to be linear in the partial differential coefficients of order n.

Every invariant can be expressed in terms of this aggregate of irreducible invariants; and the expression involves invariants proper to rank no higher than the order of the highest differential coefficient which occurs in that invariant.

Some of the properties of the irreducible invariants involving differential coefficients of two dependent variables are obtained, and, in particular, it is shown that there is a single irreducible simultaneous invariant proper to the rank 1, and that there are four such invariants proper to the rank 2.

The theory of eduction is next considered, with some examples. Finally, it is shown that the theory of binary forms can be partly connected with functional invariants.

March 22.—"Second Preliminary Note on the Development of *Apteryx*." By T. Jeffery Parker, B.Sc., C.M.Z.S., Professor of Biology in the University of Otago. Communicated by W. K. Parker, F.R.S.

Chemical Society, March 15.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read :—The nature of solutions as elucidated by the heat evolved on their dilution; Part 1, calcium chloride, by Mr. S. U. Pickering. To determine the nature of the action which takes place on diluting aqueous solutions, the author has examined calcium chloride, and, in a series of elaborate experiments, has obtained results which form a curve of great regularity. This regularity, however, is only apparent, since on differentiation a number of independent curves are obtained, each of which on further differentiation gives a straight line. The points at which these lines meet, when produced, indicate percentages of water corresponding to distinct hydrates of the salt, and moreover coincide in every case, within the limits of experimental error, with the points obtained by treating in a similar manner the curve expressing the densities of the various solutions. The author contends that these results, taken in conjunction with the fact that the variation in the electrical conductivity and the density of sulphuric acid on diluting with water also point to the existence of certain hydrates in solution, make it no longer reasonable to doubt that solutions do in reality consist of such hydrates, and is of opinion that any theory of the nature of solutions which ignores their existence must be rejected absolutely and for ever. A new form of mixing calorimeter, devised for these experiments, was exhibited.—The action of thiocyanates on aldehyde-ammonias, by Dr. A. E. Dixon.—Carboxy-derivatives of quinone, by Dr. J. U. Nef. Ethylic paradiketohexamethylenecarboxylate, obtained by the reduction of ethylic quinonetetracarboxylate with zinc dust, exists apparently in three distinct modifications, only two of which, however, have been studied—the one modification is green and crystallizes in needles, the other is yellow and crystallizes in plates; after fusion, the former appears dark yellow and the latter bright yellow. If either modification be separately dissolved in carbon bisulphide, a solution is obtained from which the two substances crystallize out together; the solution also has the same colour and the same absorption spectrum whichever modification be dissolved. The author calls attention in the paper to a number of similar cases of dimorphism.—The action of acetone on ammonium salts of fatty acids in the presence of dehydrating agents, by Dr. S. Ruhemann and Mr. D. J. Carnegie.—A method of estimating nitrites either alone or in presence of nitrates and chlorides, by Mr. T. C. Day.

PARIS.

Academy of Sciences, March 26.—M. Janssen in the chair.—New theory of the equatorial *coudé* and of equatorials in general (continued), by MM. Lœwy and P. Puiseux. Here are given the general formulas promised in the previous communication, together with the terms depending on the position of the outer glass.—On the relations of atmospheric nitrogen with vegetable humus, by M. Th. Schlœsing. A detailed account is given of the experiments carried out according to the already described method for the purpose of ascertaining whether gaseous nitrogen is fixed by vegetable soil. The disappearance of the oxygen shows in six different cases that the combustion of the organic substances takes place in various degrees depending on the quantity and nature of such substances. During this combustion nitric acid is formed with disappearance of the ammonia. The volume of gaseous nitrogen contained in the soil does not perceptibly vary.—On the absorption of saline substances by plants (continued), by MM. Berthelot and G. André. The experiments here described deal with the acetate of potassa, an organic salt analogous to those present or produced in the plants; also with the nitrate of potassa, the formation or accumulation of which is characteristic of certain species, especially of the Amaranthus group. This accumulation is shown to depend rather on the period of vegetation than on the proportion of the salt in the ground.—New nebulæ of a remarkable character discovered in the Pleiades, by means of photography, by MM. Henry, and described by M. Mouchez. Besides a new nebula round Maia in the Pleiades, the more recent researches of MM. Henry have revealed a great mass of cosmic matter covering a large part of this constellation. But the most remarkable discovery, and one of an absolutely unique character, is a rectilinear thread of nebular matter projected from the central mass nearly in the direction from east to west for a distance of 35′ to 40′ of arc, but with a thickness of no more than 3″ to 4″. This thread crosses on its path seven stars, which it seems to string together like the beads on a rosary, and slightly changes its direction at the point where it meets the largest of these stars. A second streak, somewhat similar, but shorter, is perceptible in the middle of the nebular mass.—Preliminary work for the execution of the photographic chart of the firmament, by M. Mouchez. Reference is made to the publication of a *Bulletin* specially devoted to this object. Two more Observatories, those of Potsdam and Oxford, are announced as intending to take part in this great work, making thirteen stations altogether. These, it is stated, are already sufficient to secure the completion of the undertaking in the course of four or five years.—Treatment of auriferous sands by amalgamation, in ancient times, by M. Berthelot. The second part, just published, of the already noticed "Collection des Alchimistes grecs," contains the works of Zosimus, a writer of the third century of the new era, dealing with the extraction of gold by means of its natural ores treated with mercury. This process appears to have been substituted for a still more ancient method, in which the ore was fused with lead, salt, a little tin, and barley bran, and submitted to a genuine process of refining.—Observations of the Comet 1888*a*, made at the Paris Observatory with the equatorial of the West Tower, by M. G. Bigourdan. The observation here recorded was taken on March 25, when the comet, discovered at the Cape, on February 18, by M. Sawerthal, was approaching the northern hemisphere.—On a new mercury-bath for the observation of the nadir, by M. Périgaud. This valuable appliance at last gives the long-sought solution of the problem, how to employ the mercury-bath for determining the vertical, and for taking observations by reflection in all states of the weather, and on ground subject to the constant vibrations produced by carriage traffic, as in large towns.

Berlin.

Meteorological Society, March 6.—Dr. Vettin, President, in the chair.—Dr. Zenker gave an account of his work, which has been awarded a prize by the Paris Academy, on the distribution of heat over the surface of the earth. When considering the total heat which reaches the earth's surface, it is of course dependent upon the distance of the sun, and is greater at perihelion than at aphelion in the ratio of the inverse square of the sun's distance. The varying ellipticity in outline of the earth in its various positions has no influence on the heat received owing to the extremely slight difference thus produced. If any one point of the earth's surface is alone considered, then the heat received is determined by the sine of the sun's altitude or the cosine of its zenith distance, for which the speaker gave an equation expressed in terms of amplitude and declination. From the above relationships it follows, leaving the air out of account, as has usually been the case, that the heat received by the Pole on a summer day is greater than that which falls on a point at the equator. Thus taking as unit the heat received during twenty-four hours by a place at which the sun is in the zenith, the North Pole receives an amount of heat represented by 0·397, and a point on the equator an amount represented by 0·292. But the air absorbs a large part of the sun's heat. The speaker considered it unreliable to estimate the height of the atmosphere from the amount of heat-absorption, as is frequently done, inasmuch as the chief absorption takes place in the deeper layers of the air. For the determination of the coefficient of absorption Dr. Zenker accepts the values obtained by Langley from his bolometric experiments, with a reservation, however, as regards the absorption which takes place in its highest layers, which he did not admit. One factor of great importance is the diffusion of heat, already described by Clausius, from the small particles of water, dust, and air in the atmosphere, which are calculated under other definite assumptions. Another factor which must not be lost sight of is the reflection of heat at the earth's surface; this is calculated for the three cases of a surface of water, land, and snow. Special tables are given of the heat reflected from these three kinds of earth-surface for separate places per day and per year. The application of this theoretical part of the research to the climatology of the earth's surface, the speaker intends to lay before the Society at some future time.—Dr. Less drew attention to the meteorological conditions of the past few days. A minimum temperature on March 1 was succeeded by a thaw on the evening of the 2nd, which was followed by a second very low temperature which again gave way to a thaw on the 6th. The rise and fall of the barometer corresponded to the above: the very considerable double variation in atmospheric pressure was caused by a minimum passing through South-West Sweden across the East Sea to Russia, which was succeeded by a partial minimum following the same course. Exactly similar meteorological conditions were in existence from February 4, and were caused by a minimum with its succeeding partial minimum following the same course as above. Such an exact similarity of path and action of two minima is of very rare occurrence, and deserves to be carefully studied; on both occasions, in February and March, very wintry weather was observed.—Dr. Hellman drew attention to the unusually heavy snow-fall of the past winter. As yet the maximum number of days on which snow falls in Berlin has been fifty, but this year up to the present time it has already fallen on fifty-eight days; in the same way, until this year never more than eight consecutive days of snow-fall have been observed, but this winter there has been one period of sixteen consecutive days on which snow has fallen.

Stockholm.

Royal Academy of Sciences, March 14.—Studies on the Characeæ and Violæ of the Isles of Gotland and Oeland, by Dr. Wahlstedt.—Studies on the geographical distribution of the plants in the province of Wermland, by Dr. Ringius.—On the currents of disjunction, by Dr. Mebius.—On the institution of pendulum observations in Sweden, by Prof. Rosén.—A review of the Orthoptera of Scandinavia, with descriptions, by Dr. Haij.—Analyses of gadolinite and hornilite, by Dr. W. Pettersson.—On the production of nitro-cymol and its products of oxidation, by Prof. Widman and Dr. Söderbaum.—On the occurrences of *Limnadia lenticularis* on the Isle of Nordkoster in the province of Bohus, by Hr. Hanson.—A thunderstorm combined with water-spouts near Upsala, by Hr. Th. Wigertz.—On fossil wood from Egypt and Eastern Asia, by Prof. Schenk, of Leipzig.—Volcanoes in the interior of the north-eastern parts of Iceland, by Hr. Thoroddsen, of Reykjavik.—On the determination of the constants in the diurnal rotation, by Dr. Bohlin.

Amsterdam.

Royal Academy of Sciences, February 25.—M. Martin exhibited a geological chart of the course of the River Surinam, appending the communication that, during his stay in the West Indies, he succeeded in discovering the geological formation in which the gold occurring in those parts, and long since known as wash-gold, was originally deposited. This formation is the crystalline schist, a stratum in which, in Brazil also, most of the gold is met with. The speaker urged that Brazil and Surinam offer striking points of resemblance both in the order and nature of their stratifications.—M. de Vries made a communication on his determination of the molecular weight of raffinose. His results, based upon physiological methods, tended to support the formula of Loiseau and Scheibler,

$$C_{18}H_{32}O_{16} + 5H_2O.$$

—M. Hubrecht described the early stages in the development of the blastodermic vesicle of the hedgehog. He claimed that the stages observed and described by him go a long way towards explaining the questionable points in the early stages of the human blastodermic vesicles that have yet been noticed.

THURSDAY, APRIL 12, 1888.

SOUTH KENSINGTON SCIENCE TEACHING.

WE are glad to notice that the attention of the House of Commons has at last been called to the deplorable condition of the accommodation allotted to the teaching of science at South Kensington. Our readers are aware that this subject is by no means a new one, as attention has frequently been called, not only in our columns, but in those of the leading daily political journals, to what Sir Henry Roscoe, not too strongly, termed "the disgraceful state of things." We believe, however, that Friday evening was the first occasion upon which the subject has been brought before the House of Commons.

When the House went into Committee on the Civil Service Estimates, the vote being for £9900 to complete the Science and Art Department buildings, Sir Henry Roscoe pointed out, in the first place, that the accommodation for the teaching of physics in this our only Government College for the training of science teachers, would in Germany be thought a disgrace in a third-rate town. The site of the makeshift laboratory, which, owing to the increase in the number of the students in this department, was arranged in a temporary building belonging to the French annexe, is now required for the Imperial Institute; and no substitute has yet been found, nor any suggestion offered, beyond that made by Mr. Plunket, that two of the official residences should be devoted to this purpose —a scheme which, we are not surprised to learn, did not meet with the approbation of those who know what is wanted, viz. the authorities of the Department. Mr. Mundella, as a former Vice-President, strongly indorsed the statement respecting the absolute necessity of steps being taken to place the Royal Normal School in a decent position, as far at least as its physical department is concerned. He pointed out the undesirability, to say the least, of removing the residences of the officials of the Museum from the ground, not so much on account of the immediate aid which the resident departmental heads would give in case of fire (though this we consider is important), as because their presence would insure the removal and proper care of the most valuable of the exhibits should such an accident happen. But, apart from these considerations, the idea of the Treasury suggesting that the only Government Science School in England should resort to such means for accommodating perhaps the most important of the experimental sciences is one which could only occur to the English official mind. After all, as Sir George Campbell said, "we are not a nation of paupers," and we may well demand decent accommodation for our National Science School.

The debate was not confined to this relatively small though not unimportant point. Sir H. Roscoe proceeded to explain that this opened the door to a much wider question, viz. that of the permanent housing and protection of the collection of scientific instruments and apparatus, of which he remarked that few persons were aware that we are possessed of one of the finest collections in Europe, containing not only a large number of the most delicate instruments used in physical research, but also apparatus of unique historic value. Such a collection as ours, if it existed in France or in Germany, would be appropriately housed in buildings worthy of its interest and importance; witness the industrial and scientific museums of Berlin and Vienna, or the still more palatial accommodation existing for similar collections in Paris. But in our metropolis these collections are housed in a temporary shed used by the various International Exhibitions, for which miserable accommodation the Government are actually paying a yearly rent of £2000. Reference was made during the debate to the existence of the inter-departmental Report on this subject moved for by Sir Henry Roscoe in June 1886. From this important document it is clear that the proposal to consolidate certain Government scientific institutions, to build a series of galleries on the land west of Exhibition Road, for the purpose of accommodating not only the science collections, but also the National Portrait Gallery and some other collections, met with the approval of all the members of the Committee, consisting of such men as Lord Lingen and Sir F. Bramwell, with the exception of Mr. Milford, at that time the Permanent Secretary of the Office of Works, whose opinion was apparently adverse to the possession of any national science collections at all As might be expected, no steps have, since the publication of this Report, been taken, beyond the removal of the National Portrait Gallery to Bethnal Green. Surely it is time that a state of things which would not be permitted to exist in any decently-sized town on the Continent should be amended. The buildings of the Imperial Institute are now raising their head on the site of the late International Exhibitions, and a road is being driven through from Queen's Gate on the west to Exhibition Road on the east. Plots of land, one directly south of the Imperial Institute buildings, and one north of the Natural History Museum, are now available, and can be purchased from the Commissioners of the 1851 Exhibition by the Government for a comparatively small sum. If this is not soon done, the Commissioners intend to sell their land to private individuals, to build a row of dwelling-houses fronting the road and looking on to the Imperial Institute. Will such a course of things be permitted? Is it possible that the Government, after the report from the ablest men of science and statesmen of the time, should allow this opportunity to pass? We must not; and we have good hopes that the promise of the First Lord of the Treasury, that this question will receive the attention of the Government, will not turn out to be an empty form, and that a statement will be made by the Government on this matter without unreasonable delay.

The debate was enlivened by a passage of arms between Lord Randolph Churchill and Mr. Mundella. The former, in his character of an economic reformer, repudiating what he called the excessive expenditure on buildings, told the House that it had not the remotest idea of the hundreds of thousands of pounds spent by the country in the payment of Professors' salaries, and other forms of encouraging science and art. It is a pity, for the sake of the "Professors," that the return for which Lord Randolph asked is confined to expenditure on bricks and mortar, otherwise he might have learnt how

far his statement of the existence of these luxurious professorships is borne out by fact. Still, we do not wish to quarrel with Lord Randolph's economic mood. We are not concerned to defend every expenditure on buildings or art collections in South Kensington or elsewhere ; and it is quite possible that, if these matters are looked into, an extravagance in this direction may be proved. In that case, in Lord Randolph's words, "the hon. member for South Manchester may have more to spend than he has at present," or, to express this in non-Parliamentary phraseology, a larger proportion of the present grant may be devoted to the pressing and important requirements of science.

EXPERIMENTAL RESEARCHES ON HYDRAULIC CEMENTS.

Recherches Expérimentales sur la Constitution des Mortiers Hydrauliques. Par M. H. Le Chatelier, Ingénieur des Mines. (Paris: Vve. Chas. Dunod, 1887.)

THE large employment of concrete for the construction of harbour-works, for building houses, paving streets, and other purposes, has created a considerable demand of late years for hydraulic cements. Cement manufacture is one of the comparatively new industries which have taken root in Ireland. This treatise of M. Le Chatelier is so valuable an addition to our knowledge of the chemistry of a great and important manufacture, that a short abstract of its contents will be welcome to many of the readers of NATURE, especially as the work is of unusual scientific interest.

The chemical reactions which result in the baking and hardening of plaster of Paris, mortars, and hydraulic cements are treated under the following heads: (1) plaster of Paris; (2) barium silicates; (3) hydraulic mortars and cements.

The first scientific investigation of the baking and setting of plaster of Paris was made by Lavoisier, and the process is thus explained by him. There are two stages at which the water is removed from gypsum; three-fourths of the water of hydration are much more easily expelled by heat than the last fourth. When gypsum is dehydrated by heat it absorbs water again with avidity, and suddenly becomes a confused and hardened mass of crystals.

Berthier's observation that plaster of Paris ordinarily contains from 4 to 8 per cent. of water has been confirmed by Landrin. The baking and dehydrating of gypsum was investigated by M. Le Chatelier by observing the periods measured by a chronograph, during which a thermometer marked successive increments of 5° of temperature when plunged into powdered gypsum heated progressively and regularly in a test-tube standing in a bath of paraffin. The longest periods correspond with the greatest heat absorption and dehydrating effect. From 130° to 140° C. the period was 20 minutes 40 seconds, between 165° and 180° C. it was 5 minutes. Dehydration is partial at 155°, but complete at 194° C. There are two distinct phases of dehydration of the compound $CaSO_4 \cdot 2H_2O$: the first corresponds to the formation of $(CaSO_4)_2 \cdot 3H_2O$, the second with $(CaSO_4)_2 \cdot H_2O$; this is plaster of Paris. The hydration which causes the quick setting of plaster can be represented by the equation: $(CaSO_4)_2 \cdot H_2O + 3H_2O = 2(CaSO_4 \cdot 2H_2O)$.

Cause of the Hardening.—It has been shown that a solution of hydrated calcium sulphate dissolves dehydrated plaster, and this after a short interval separates out as crystals of gypsum. This action explains the setting of plaster; water hydrates the compound partially, and dissolves the hydrate to saturation; this dissolves anhydrous sulphate to supersaturation, and deposits it as a hydrate, after which more of the anhydrous salt becomes dissolved. These two opposite actions take place simultaneously at contiguous points. The more rapid the hydration, the greater is the degree of supersaturation, and the quicker the setting of the plaster. Many anhydrous salts harden when in contact with water, as for instance sodium sulphate, but in every case there is a previous formation of a supersaturated solution.

It is established that crystallization which accompanies the setting of plaster of various kinds results from the difference in solubility of the compounds which set, and those which are formed during the setting: the first occur in a state of unstable equilibrium in presence of water, and can have only a transitory existence.

The crystals which form during setting are frequently, if not always, extremely delicate prisms united by one of their ends round central nuclei so as to form little spherical groups.

The mechanics of setting and hardening can be referred to crystallization. Starting with the idea that the hardening of mortars is not an isolated phenomenon without analogy, and that it is certainly similar to, if not identical with, one or other of the known methods, M. Le Chatelier describes these as follows:—Hardening by *compression*, of powders; by *desiccation*, as with clay or gelatine; by fusion and *solidification*, metals; by *crystallization*, soluble salts.

These can be referred to two simpler and more general phenomena:—

Mutual adherence of solid particles, produced at a minute distance from each other.

Mobility of the particles, which admits of their coming together. The momentary solution of a salt which sets affords the necessary mobility of the particles. The setting of mortar evidently enters into the category of phenomena of hardening by solution and crystallization. When the solid particles have once come together the specific hardness will depend upon the internal *cohesion* of the crystals and their mutual *adhesion*.

The *cohesion* of substances varies within very wide limits, of which the extreme terms amongst substances which enter into the composition of cements are: *plaster*, which is soft enough to be scratched by the nail, and *quartz*, hard enough to scratch steel. All we know about cohesion is that it is a primordial property of matter.

Adhesion, unlike cohesion, is a very complex and consequently a very variable phenomenon. Its variations can almost exclusively serve to explain the considerable differences in resistance which are often a distinguishing property in analogous cements. It varies with the chemical nature of the bodies in contact. The adhesion of a crystal of calcium sulphate to a glass plate is *nil*; on the contrary, it is so great with barium silicate that the

crystals break rather than become detached. It also varies with physical conditions, as, for instance, the more or less polished condition of surfaces in contact. The total adhesion is evidently proportional to the extent of surfaces in contact: it will be so much the greater as (1) the volume of empty spaces due to excess of water employed in mixing is less; (2) as each crystal for a given weight of matter presents a great extent of surface (the form of elongated prisms recognized in the crystallization of plaster and of all similar products is eminently favourable to the development of adhesion); (3) as the crystals are grouped so as to increase the volume of empty spaces and so as to diminish their number and isolate them one from the other. A structure like that of pumice is particularly favourable to strength. The nature of the solvent, temperature, and nuclei of crystallization, all serve to modify considerably the growth of crystals, and consequently to influence in a like degree the strength of the mortar. A study of barium silicate has led to the conclusion that its hydration may take place in a manner denoted by the following equations:—

$$BaSiO_3 + 6H_2O = BaSiO_3 \cdot 6H_2O$$
$$Ba_2SiO_4 + 15H_2O = Ba_2SiO_4 \cdot 6H_2O + BaO \cdot 9H_2O$$
$$SiO_2 + BaO \cdot 9H_2O = BaSiO_3 \cdot 6H_2O + 3H_2O.$$

The setting of siliceous baryta cements is due to the production of the same hydrated silicate, $BaSiO_3 \cdot 6H_2O$, in whatever manner it may be formed.

Mortars and Hydraulic Cements.—Calcareous mortars are divided into two classes: air-dried mortars; hydraulic mortars and cements.

Air-dried mortar is made from quick-lime slaked with water and mixed with sand. As Vicat has shown, the first stage of its setting is caused by the desiccation of extremely fine particles of lime, and is identical with the hardening of clay. The sand acts as in the making of bricks—it prevents too much shrinkage by forming an incompressible base or body. A further degree of hardening is caused by the conversion of the lime into carbonate.

The burning of limestone, unlike the dehydration of gypsum, is the result of the phenomenon of dissociation, as was proved by Debray. Various kinds of lime all become burnt at 850° C.

Hydraulic Cements.—These are obtained by baking natural or artificial mixtures of lime and clay, containing from 21 to 27 per cent. of clay.

They are divided into *slow-setting* and *quick-setting* cements. The former are baked at a much higher temperature than the latter. The setting of the former proceeds for some hours, and much facilitates their use.

There appear to be three different anhydrous calcium silicates, of which one only, the tricalcic silicate, $SiO_2 \cdot 3CaO$, is attacked by water, and is capable of setting; there are three calcium aluminates, which all set very quickly after mixing with water; there are ferrites of lime, which slake and swell out like quick-lime, and numerous other compound silicates which are more or less unalterable by water.

The only hydrated salts which can exist in presence of an excess of lime, and which are formed from the above, are:—

Silicate, $SiO_2 \cdot CaO \cdot 5H_2O$.
Aluminate, $Al_2O_3 \cdot 4CaO \cdot 12H_2O$.
Ferrite, $Fe_2O_3 \cdot 4CaO \cdot Aq$.

A microchemical study of anhydrous cements has shown that there are colourless crystals of a pseudo-cubic or hexagonal appearance. The intervals between these crystals are filled with coloured matter without crystalline character, which has been in a state of fusion. The crystals are formed by chemical precipitation in the midst of the brown fusible matter which afterwards solidified on cooling. The composition of the crystals is that of a calcium silicate, and of the amorphous portion of silicates of alumina, iron, and lime; the first compound alone is alterable by the action of water, and is that which plays so important a part in the setting and hardening of cements.

Analyses of four different varieties of cement support the view that this substance is essentially a tricalcic silicate.

There is no free lime in Portland cements of good quality, though there may be aluminates and ferrites.

Drawings taken from microscopic thin sections serve to illustrate the appearance of hydraulic cement when anhydrous and when undergoing hydration.

Lastly, the author deals with the causes of the destruction of hydraulic mortars in the air, in fresh and in salt water.

W. N. HARTLEY.

ELEMENTARY MICROSCOPICAL EXAMINATION.

Elementary Microscopical Examination. By T. Charters White, M.R.C.S., late President of the Quekett Microscopical Club. 104 pp. (London: Roper and Drowley.)

THE author of this work tells us that he has aimed at leading "the possessor of his first microscope into the smooth path of progress, by pointing out the simplest and most elementary methods of observation, and, after so far clearing the way, leading him gradually to the higher branches of microscopical manipulation." It must be admitted that he has succeeded in doing this. His modest little volume is both sound and original, and confirms the conviction that popular treatises, to be of good effect, must be produced by those who have themselves endured the drudgery of routine work and who have acquired their experience first hand. One sees throughout this work traces of a generation which is past, but as the book is not written for the schoolmen of to-day, criticism is, from their stand-point, disarmed.

The little volume is, notwithstanding, one of considerable merit. There may be cited, as bearing testimony to the care with which the author has selected his recipes, the incorporation of the glycerine-alcohol method of preparing delicate tissues, originally introduced by Strasburger. As evidence of originality, we may cite the following: "It (glycerine) needs discrimination in its use, as it cannot be employed for calcareous tissues as bone or shell, as they would become decalcified after being exposed to its influence for some time." Hints such as these, which are the very salvation of the *dilettante*, can only be the outcome of prolonged practical experience, and they testify most powerfully to the intrinsic merit of the work in which they appear. In dealing with photo-micrography the author describes an apparatus designed by himself. He is evidently an expert in this field, and in his device he has aimed at producing a machine which may be constructed by the worker at a minimum cost. A very worthy motive this, but experi-

ence can alone show how far he has succeeded. We should doubt the efficacy of his instrument ourselves, and we certainly cannot indorse his belief that, "however scrupulous the draughtsman may be, however unbiassed he intends to be, errors may creep in, and therefore photo-micrography . . . . comes in to insure complete veracity with a saving of labour."

Woodcuts are given of some few of the accessories enumerated. Chief among them is a very monotonous array of scalpels and probes, which form the frontispiece. Strange to say, the author makes not the least mention of most of those in his text, despite a reference in the index. It is clear, however, from the context, that they are to be regarded as aids to the study of insect anatomy: we have here a superfluity, for choice among the knives represented would be so embarrassing that, by the time the operator made up his mind, the subject itself would be far advanced towards decomposition. The introduction of curved scissors is no less to be deprecated. Apparatus and accessories have a fascination for most people, but the best work has always been done with the simplest tools. It must never be forgotten that it is the head at the one end, and not the mechanical aid at the other, which does the real work.

We would take exception to the introduction of the words "mountant," "semi-hard," and one or two others which might be named. The statement that the mites are "almost the smallest class of created beings" falls very unhappily from a pure microscopist, while the definition given of the Foraminifera needs modification.

We are pleased to note that the author has been mindful of the charms of the tow-net—perhaps the most important instrument in the future of marine zoology. If Mr. White's work be divested of its bugs' heads, and other similar objects which are the mainstay of those for whom he writes, there remains a solid substratum which far excels in merit that of many more pretentious works on the subject.

OUR BOOK SHELF.

A Manual of the Geology of India. Part IV. Mineralogy. By F. R. Mallet. Published by order of the Indian Government. (London: Trübner and Co., 1887.)

WHILE the third volume of this work possessed a certain interest for the statesman and the capitalist, including as it did descriptions of the minerals of economic value, the present one will only claim the attention of scientific readers. It may be a matter of surprise that nearly all that is certainly known about the minerals of India should be capable of compression into less than two hundred pages. But, as the author points out, excavations for mining or other purposes have not, as a rule, been superintended by men possessing the knowledge requisite to enable them to record facts of scientific importance; further, there is no demand for non-economic minerals, and consequently no mercenary incentive to collect specimens.

In looking over the book we are at once struck with the meagre character of much of the information given. Numbers of questions occur which we should like to see settled, but which are unanswerable in the present state of our knowledge, or rather ignorance, of Indian mineralogy. But our author is certainly not to blame for this. He has made the most of the scanty materials at his command, and the result is a valuable contribution to mineralogical science, which will serve as a basis for a future work on the subject worthy of our Indian Empire. The classification adopted is that of Dana, as given in his "System of Mineralogy."

In the collection of materials for the book which we hope will grow out of this, English residents and educated natives might do science much service. The study of mineralogy was extensively pursued in England until displaced by the more attractive subject of stratigraphy, but as India presents such a vast field there is no reason why the subject should not become popular again. Workers in this department will find Mr. Mallet's book of the greatest service.

Through the Yang-tse Gorges. By A. J. Little, F.R.G.S. (London: Sampson Low, 1888.)

MR. LITTLE recently undertook a two months' journey from Shanghai, the metropolis of the Chinese coast, to Chung-King, the commercial metropolis of Western China. The present volume consists of the journal kept during his travels, and an admirable journal it is, full of the results of careful and minute observation, and written in a fresh, lively, and entertaining style. Few travellers, with the exception of "the ubiquitous missionary," have ascended to the highest navigable point of the Yang-tse, the only road of intercommunication between the eastern and western districts of the Chinese Empire. Most readers, therefore, will find in this book much that is new to them about the Chinese people and their country. There are many vivid descriptions of the varied scenery through which Mr. Little passed, and his notes on industries, social customs, and popular religious ideas are invariably interesting and suggestive. Upon the whole, he has no very exalted opinion of the intellectual and moral qualities of the Chinese, and he is not disposed to believe that the empire, under the influence of Western ideas, is about to enter upon a new and momentous stage of political and social development. Everywhere he found the bureaucracy intensely conservative, and bitterly prejudiced against foreigners. They are willing enough to adopt superior mechanical appliances, so far as implements of war are concerned; but in all other matters they prefer to move along the old lines, which, having been good enough for their forefathers, must, they think, be good enough for themselves.

Home Experiments in Science. By T. O'Conor Sloane, Ph.D. (London: Sampson Low, Marston, Searle, and Rivington, 1888.)

THE author of this work has produced a very readable and useful book for those who wish to employ their leisure hours in gaining knowledge and information about the elementary parts of the various branches of science. The volume consists of a collection of experiments that can be easily performed with home-made apparatus; good detailed instruction as to the necessary mechanical operations is given, together with ninety-seven woodcuts of the experiments and the apparatus employed. The branches of science included in these experiments are mechanics, general and molecular physics; the chapter on soap-bubbles contains some very interesting experiments about them; and the concluding chapter consists of hints to those who are about to begin scientific lecturing.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prof. Rosenbusch's Work on Petrology.

OF the great value of Prof. Rosenbusch's work on petrology, so excellently reviewed by Dr. Hatch, to which your corre-

spondent "A. B." draws attention, there can be no doubt, so far as it is regarded as a storehouse of information; but whether the system of classification proposed therein will not tend to retard rather than to further progress is a question on which I am at present more than doubtful. The two points to which Dr. Hatch and your correspondent draw attention as inherent weaknesses—viz. the "dyke rocks," and the subdivision of the "effusive rocks" into palæo-volcanic and neo-volcanic—appear to me such serious defects, that to praise a system which largely rests on them is like complimenting a viaduct by saying that it is an excellent viaduct but two of its piers unfortunately have a bad foundation.

But dismissing this as a question too large for discussion in your columns, I will confine my remarks to some defects in detail, rather serious as they appear to me, which are exhibited by the classification as tabulated by your correspondent.

(1) A mere "linear" classification fails, I believe, to represent satisfactorily the relation of the igneous rocks, because it separates too widely rocks very closely related—such, for instance, as the Dacites and Rhyolites (Liparites), and their corresponding holocrystalline representatives. Hence I believe that the branching system such as I indicated in my Presidential Address to the Geological Society in 1885 is more logical and more in accordance with the facts of Nature.

(2) In regard to the above example, I fail to understand why Dacites should be included with Andesites and Liparites separated from Trachytes, or, if we speak of their holocrystalline representatives, why we should separate Granite from Syenite, while we include Tonalite with Diorite. It is true that Granites are common and Tonalites are rare, and possibly the latter always contain some hornblende; but until it is shown that a quartz-plagioclase-biotite rock does not exist, or that the substitution of hornblende for biotite is of primary importance, there does not seem any valid reason for suppressing the group.

(3) As the term Diabase has long had a recognized meaning, I fail to see any good reason for substituting it for Dolerite, to which, as generally understood, it stands in much the same relation as do many Serpentines to Peridotites. Neither can I admit the propriety of separating Gabbro from it.

(4) The wide separation of the Leucite and Nepheline rocks from the Basalts seems also to me to be of doubtful advantage.

(5) If the term Peridotite be used in the sense in which it has generally been employed (*e.g.* by Dr. Wadsworth in his excellent "Lithological Studies")—namely, to denote a rock in which silicates of magnesia and iron abound, with some also containing lime but with little alumina—it is surely not possible to regard Limburgite as its "effusive" equivalent. That rock seems to me to be more properly associated with the Picrites, not as defined by Dr. Wadsworth (*i.e.* olivine-augite rocks), but as equivalent to the Palæopicrites of some authors—viz. pyroxenic rocks, containing a fair amount of olivine, and some feldspar, which last, however, has a very variable proportion. The true position of these rocks appears to me to be as a connecting-link between the Peridotites and the Dolerites.

There are other points in the work to which I should like to call attention, but I am writing away from books, and should have refrained for a season had not "A. B.'s" letter seemed to me to call for a word of friendly protest. No one can be more deeply sensible than I am of the value in many respects of Prof. Rosenbusch's work, but until his classification rests on a firmer foundation it will not, I fear, be really helpful to students in leading them to clearer ideas on a complicated and difficult subject.

T. G. BONNEY.

The Delicacy of the Sense of Taste.

AT the Philadelphia meeting of the American Association, in 1884, we presented a paper upon the general subject of the "Sensitiveness of the Special Senses." We have since continued our investigations,[1] and have the honour to present at this time the results of some experiments upon the sense of taste.

The object of the experiments herein described was to find out what substances, or classes of substances, are most readily detected by the sense of taste, and the relative delicacy of this sense towards these substances. For the production of familiar typical effects upon the organs of sense the following substances were selected:—

I. (bitter) . . .	Quinine.
II. (sweet) . . .	Cane sugar.
III. (acid) . . .	Sulphuric acid.
IV. (alkaline) . . .	Sodium bicarbonate.
V. (saline) . . .	Common salt.

The attempt was made to include other substances in this list, but it was difficult to find any, not embraced in the five classes above mentioned, which would not betray their presence either by colour or odour. Indeed it is surprising, to one who has not given the subject attention, to what an extent we are accustomed to depend upon the aid of the sense of smell in the classification of tastes. The fact has been noticed by several authors that, if the nostrils are closed, the range of our taste becomes very much limited.

Our method of testing the delicacy of the sense of taste was to make solutions, of known strength, of the different substances; then, by successive dilutions, to make from these several series of weaker solutions; each one being of one-half the strength of that preceding it. All the bottles containing these substances, and several bottles of water, being placed side by side without regard to order, the person to be tested was requested to taste of each solution and place it in its proper class. In each series the lowest solution was so very dilute that it was deemed impossible to distinguish it from water. Unknown solutions were to be classed with water. As the tasters were found to be liable to mistake occasionally even the stronger solutions, an opportunity was given, at the close of the test, to correct such accidental errors. In carrying out these tests we found that the most trustworthy results were to be obtained by instructing each operator to pick out the stronger solutions, temporarily classifying with water all which were not immediately recognized; and then to go over the latter solutions a second time, properly classifying such as could further be detected.

These tests were made by 128 persons, between the ages of twelve and fifty—eighty-two men and forty-six women. The average results are given in the following table:—

Table of Averages.

I. *Quinine.*

Male observers detected 1 part in 390,000 parts of water.
Female ,, ,, 1 ,, 456,000 ,, ,,

II. *Cane sugar.*

Male observers detected 1 part in 199 parts of water.
Female ,, ,, 1 ,, 204 ,, ,,

III. *Sulphuric acid.*

Male observers detected 1 part in 2080 parts of water.
Female ,, ,, 1 ,, 3280 ,, ,,

IV. *Bicarbonate of soda.*

Male observers detected 1 part in 98 parts of water.
Female ,, ,, 1 ,, 126 ,, ,,

V. *Common salt.*

Male observers detected 1 part in 2240 parts of water.
Female ,, ,, 1 ,, 1980 ,, ,,

This table indicates only the *average* delicacy of taste for each substance included in our experiments. The tests brought to light many astonishing individual peculiarities. For instance, there were persons who could detect with certainty 1 part of quinine in 5,120,000, while others failed to notice 1 part in 160,000. How far this difference is due to education it is not possible to say. Among the tasters were quite a large number who had been accustomed for several years to the handling and recognition of drugs and chemicals. Their record was considerably above the general average, but they were, on the other hand, surpassed by a few individuals who had had no previous training.

The results of our experiments may be briefly summed up as follows:—

1. The sense of taste is much more delicate for bitter substances than for the others included in our list. (The relative delicacy for quinine and sugar is very nearly 2000 : 1.)

2. Taken in the order of their effect upon the organs of taste,

[1] See the following papers:—"On the Relative Bitterness of different Bitter Substances" (Proceedings of the Kansas Academy of Sciences, 1885); "On the Relative Sweetness of different Sugars" (Reports of the Kansas Board of Agriculture. 1885); "On the Sensitiveness of the Eye for Colours of a Low Degree of Saturation" (*American Journal of Science*, III. vol. xxx. p. 27); "The Sense of Smell" (NATURE, vol. xxxv. p. 74).

the classes of substances used stand as follows: (1) bitters; (2) acids; (3) saline substances; (4) sweets; (5) alkalies.

3. The sense of taste is as a rule more delicate in women than in men (in the case of all substances tried excepting salt). The number of persons experimented upon was hardly sufficient, considering the very striking individual peculiarities met with in the course of our investigation, to permit us to lay great stress upon the relative averages obtained for the two sexes. We are not inclined, however, to regard the higher degree of sensitiveness shown in the averages for female observers as accidental, and our confidence in the approximate value of the results is strengthened by the fact that in the two portions into which our data naturally divided themselves, about half the tests having been made at a different time and under different circumstances from the remainder, the averages for each set agreed very well, not only as to the relative sensitiveness to the various substances employed, but also to the relatively higher degree of delicacy exhibited by women.

4. The ability to detect a dilute bitter is very generally accompanied by inability to detect a dilute sweet, and *vice versâ*.

5. The long-continued habitual use of a substance does not seem to influence in any marked way the delicacy of the sense of taste for that substance. Our tests with quinine afforded an excellent opportunity for the investigation of this point, as some of the persons experimented upon had made long continued use of that drug as a medicine. The results obtained were entirely of a negative character. We could discover neither increase nor decrease in the ability to taste the drug on the part of those habituated to its use.

Several other questions have been raised but not answered by our experiments. How many, for instance, of these substances, each being diluted in proportion to its effect upon the organs of taste, can be detected if mixed together? If so mixed, in what order will they be recognized, and will it always be in the same order by different persons? Again, what is the influence of the temperature of the solution upon our ability to taste its ingredients?

We deplore the fact that the above tests have not been extended to a much larger number of persons, but a careful study of the results of the limited number of experiments made leads us to believe that they do not differ widely from the probable averages of a much more extended series.

The Salt Industry in the United States.

HAVING occasion not long since to look up the statistics of the salt industry, I naturally turned to the latest edition of the "Encyclopædia Brittanica" (vol. xxi.), where the following statement met my eye:—"The deposits of salt in the United States are unimportant. The country possesses no really considerable salt industry, but is supplied so far as interior consumption is concerned to a small extent by brine springs."

As this did not at all correspond with the knowledge I had gained by a somewhat casual glance over the field, I took pains to look up the subject more thoroughly, and find the above statement so radically wrong that I venture to call your attention to it; though this I should scarcely have troubled myself to do had it appeared in any publication of less acknowledged authority. To be sure, we have no means of knowing just how great an industry must be to be classed as "really considerable," but by comparing the annual product of the United States with that of other countries we may claim, at least, an attempt at an approximation.

But first as to the character of the beds in the United States. It is true there are as yet known no beds comparable in depth and extent with those of Barcelona or Galicia, but nevertheless they are amply sufficient to supply all demands for ages. As long ago as 1869, Dr. Sterry Hunt published, in the Reports of the Geological Survey of Canada, results of borings at Goderich, Canada, in which, in a total depth of 1382 feet, six successive beds of salt were passed through, varying in thickness from 6 to 34 feet, and aggregating a total thickness of 126 feet. What area is covered by these deposits is yet to be ascertained; but they are known to extend over Central and Western New York, Northern Pennsylvania, North-Western Ohio, and Southern Ontario. At Warsaw, in New York State, one of the beds has a thickness of 80 feet. The extent of the deposit at Petite Ainse, Louisiana, has also yet to be determined, but a vertical shaft 165 feet in depth lies all the way in solid salt, and does not penetrate it. The above, although but two out of many, I mention since they have been known for years, and it would seem Mr. Lyte could have informed himself regarding them had he so attempted. Concerning the many extensive beds in the region of the Great Basin, ignorance is more excusable. Statistics showing the annual output of both rock and sea salt will best show the extent of the industry. I give below statistics for 1883, 1884, and 1885, taken from "Mineral Resources of the United States," p. 474. One barrel equals 280 lbs.

	1883. Barrels.	1884. Barrels.	1885. Barrels.
Michigan	2,894,672	3,161,806	3,297,403
New York	1,619,486	1,788,434	3,304,787
Ohio	350,000	320,000	306,847
West Virginia	320,000	310,000	223,184
Louisiana	265,215	223,964	229,271
California	214,286	178,571	221,428
Utah	107,143	114,285	107,140
Nevada	21,429	17,857	28,593
All other States and Territories	400,000	400,000	250,000
Totals	6,192,231	6,514,937	7,038,653

Complete statistics for all countries are not available, and I have to rely to a considerable extent on Encyclopædias, whose accuracy I now have reason to question. They are as follow:—

England (1881)	1,854,000 tons.
France	300,000 ,,
Spain	300,000 ,,
Portugal	250,000 ,,
Italy	165,000 ,,
Austria	400,000 ,,

	1881.	1882.
United States	834,548 tons.	897,732 tons.

In regard to the above figures, I confess to feeling sceptical save with reference to those of the United States and England. Nevertheless, granting that they do not give the full amounts by one-half, even then the United States stands second in the list of salt-producing countries.

What, then, constitutes a really considerable industry?

GEORGE P. MERRILL.

U. S. National Museum, Washington, D.C., December 3, 1887.

Force, and Newton's Third Law.

THE point mentioned by "Nemo" in your issue of March 29 (p. 511) is undoubtedly one that troubles most students at some stage or other; but there is no room for discussion about it; the matter lies in a nutshell: *a body does not exert force upon itself*. Think, for instance, of a horse and cart. The horse pulls the cart, and the cart pulls back the horse equally; how, then, can the cart move? The only puzzle lies in the false implication that the cart's pull-back is exerted upon the *cart*. Directly it is perceived that there is only one force acting on the cart, viz. the pull of the horse, no difficulty is felt as to why it moves. The "action" of A is not exerted upon A, but upon B. The "reaction" of B is not exerted upon B, but upon A. The time-rate of change of momentum of each and every body is equal to the total force acting upon it.

OLIVER J. LODGE.

Grasmere, March 31.

The New Photographic Objective.

THE letter of Sir Howard Grubb in your issue of March 8 (p. 439) appears to make some further explanation desirable on my part. The invention of the new form of photographic objective seems to have been made about the same time in America and in England. An experimental lens of this kind was constructed by the Messrs. Clark, after consultation with me, in May 1887. The 13-inch lens which they subsequently made upon the same plan was completed on July 8 of that year. My absence during the summer in Colorado, with the intention of selecting a place for the new instrument upon some mountain of considerable height, caused me to overlook the account of the English invention in the *Observatory*. Since my return, the telescope has been mounted in Cambridge, on the grounds of

this institution, where it is found to give highly satisfactory results. Photographs of η Orionis which have been made with it exhibit the elongation of the star, although the distance between its components is only about 1″. The newspaper report to which Sir Howard Grubb refers, that a patent was granted for the invention, is without foundation. The Messrs. Clark have never patented any of the improvements made by them in optics, and have had no intention of deviating from their usual practice in this instance.

Life of Fleeming Jenkin.

I HAVE read with singular pain a paragraph in your notice (signed with the initials of one whom I admire and respect) of my Life of Fleeming Jenkin. To accuse a man of falsehood in private life is a strong step. But I must explain to your reviewer, I might lie to him all day long and not be so disgraced as if I put one single falsehood in a book. For the making of books is my trade by which I live; I supply them on honour, and the public gives me bread for them in confidence. Your reviewer will perhaps more readily understand what he has done (I am sure in ignorance) if I supply him with a parallel. To say that a man of science was a liar would be highly disagreeable; but if I were to say he had falsified an experiment, and to say so publicly in print, I should be curious to see the expression of his face.

I dwell upon this because it is plain your reviewer scarcely understands what literature is, and I fear others may be equally at sea. On the merely personal matter, that I am supposed to tell a deliberate falsehood on my own authority and about my dead friend, I will make but one remark. Hasty reading is the fit precursor of hasty writing; in no word have I indicated that the certificate in question was "worthy the name"; and the terms of the document are at the reviewer's service to-morrow, if he be curious.

ROBERT LOUIS STEVENSON.

March 28.

THE HITTITES, WITH SPECIAL REFERENCE TO VERY RECENT DISCOVERIES.[1]

III.

THE conclusion has been already expressed that the Hittite inscription of the Tarkutimme seal is, in the main, ideographic, and that the phonetic element is supplementary; that, in fact, regarding the figure of the king as part of the inscription, the sense is fully given without taking into account the phonetic element. Some scholars and investigators have, however, taken a different view. This fact, together with the alleged resemblance of some of the Hittite hieroglyphs to characters of the Cypriote syllabary, has had much influence on certain recent attempts at deciphering the Hittite inscriptions. With regard to the alleged analogy of the Hittite and Cypriote characters, it may be allowed that the derivation of the latter from the former is in itself by no means impossible. As yet, however, the evidence of such derivation which has been presented is certainly inadequate: to a great extent it is little better than visionary. Moreover, if, from closeness of resemblance or otherwise, satisfactory proof of the derivation had been given, it would by no means necessarily follow that, when all or any of the Hittite inscriptions which we possess were sculptured, the Hittite writing had become already so far developed that the hieroglyphs generally, or in great proportion, had acquired distinct syllabic values. As to how far resemblances between the Hittite and Cypriote characters give evidence of essential connection or derivation, the reader may perhaps satisfy himself by inspecting the list given by Dr. Isaac Taylor ("The Alphabet," 1883) and reproduced by Prof. Sayce in Wright's "Empire of the Hittites," 1886, chap. xi. More extended lists have been given by Captain Conder (who follows to a considerable extent in the track of Prof. Sayce) in the plates of his "Altaic Hieroglyphs." But, as it seems to me, in neither case have the Hittite characters been always given with such essential accuracy as is desirable. This remark applies more especially to some of Captain Conder's figures, notwithstanding his observation in "Altaic Hieroglyphs," p. 35: "A careless reading and confusion of distinct emblems must lead us wrong; and for this reason exact copies are indispensable." But, even if this objection be waived, the evidence must still be regarded as inadequate. As to "the subject of the inscriptions," Captain Conder remarks that it "is exactly what we should have expected. They occur on statues of the gods, and they are invocations only" (*op. cit.* p. 149). Now that the inscriptions "occur on statues of the gods" is certainly not true with regard to most of those which are known to us, and as we have them. The "doorway inscription" in the British Museum and the inscriptions from Hamath are connected with no statue whatever. In other cases, where there is a statue, or large figure in relief, it is by no means to be assumed that the figure is always that of a deity. But, as a specimen of what Captain Conder finds in the Hittite inscriptions, I may give his "free rendering" of the first two lines of that very ancient inscription in the British Museum of which I have just spoken as the "doorway inscription." I give Captain Conder's "free rendering" rather than his "verbatim translation," as likely to convey a less unfavourable impression:—

"1. Prayers of the Monument of Set. Powerful words for the living fire, the Most High . . . the divine. . . .

"2. . . . to . . . (pour?) Tammuz, Āa, living fire, Most High descending (propitious?) Thee strong Set . . ." ("Altaic Hieroglyphs," p. 194).

With respect to utterances of this kind it is not necessary to say much more than that they certainly have not the claim to consideration which would result from a connected and congrous rendering. Such a rendering might have been adduced as giving some answer to the position that evidence is wanting as to the Hittite hieroglyphs representing, in the main, syllables either in the Accadian or Altaic language, or in any other language whatever. Then, as to the inscriptions being concerned mainly or exclusively with theological prayers and invocations, the analogy of the Assyrian inscriptions—which the Tarkutimme seal with its cuneiform legend itself suggests—would rather lead us to expect that the subject-matter of the inscriptions is usually success in war, with allusions to the gods, and prayers and thanksgivings, chiefly in relation to such success. And this more realistic view is in accordance with the heads of oxen and of asses, with the clubs and the swords, and other symbols of equally materialistic character which appear on the inscriptions. Moreover, somewhat more than a year ago, the British Museum fortunately obtained an engraved stone of unquestionable antiquity, giving evidence in accordance with that of the seal of Tarkutimme, and tending to show that the Hittite inscriptions are in the main ideographic or pictorial.

The allusion just made has reference to a circular hæmatite seal from Yuzgât, in Asia Minor, which was added to the antiquarian treasures of the Museum in October 1886. Yuzgât is not very far from both Boghaz-Keui and Eyuk; therefore the discovery in this locality of an important Hittite antiquity cán scarcely excite surprise. For the present, the seal is named, most conveniently, from the place where it was found, "the Yuzgât seal." This seal resembles the seal of Tarkutimme in being circular; and the two seals agree also with reference to there being an inner circle which divides the figures or characters round the circumference from those in the central space. The seals differ, however, in size, the Yuzgât seal being much the smaller. The latter seal, moreover, is not bilin-

[1] Based on Lectures delivered by Mr. Thomas Tyler at the British Museum in January 1888. Continued from p. 540.

gual, and it has not a convexity of surface, like the seal of Tarkutimme. The Yuzgât seal, in fact, is flat, with the exception of the central space, which is concave, and which consequently causes a central convexity in the impression. On careful observation it may be perceived that the figures on the circumference divide themselves into three groups. In the centre of the first group is the winged solar disk supported on a cone. It seems not unlikely that this cone is essentially identical with the "king"-symbol already discussed in connection with the Tarkutimme seal. Here it may point to the prominence and pre-eminence of the sun-god as ruler of the world, all things animate and inanimate being subjected to his sway. The solar king in the centre, with the two figures, one half-kneeling and one standing, on each side, constitute the first group. These two figures on each side present features of very great interest. Nearest to the solar emblem are two horned ox-headed figures, apparently masculine, with the palms of the hands uplifted, in the act of adoration. The ox's head is not here presented in profile, as is usually the case on the Hittite monuments, but the horns and ears and the tapering muzzle are depicted with sufficient clearness. These figures may be taken as representing the moon-god, and recalling in

Fig. G.—The Yuzgât seal in the British Museum (enlarged).

their masculinity the Babylonian moon-god Sin. This seeming masculinity should be remembered if a comparison is made with other ox- or cow-headed figures of deities, as, for example, those found by Dr. Schliemann, and about which there was not very long ago some discussion. More distant from the solar emblem are two draped figures which we may regard as types of the female deity Ashtoreth, viewed as a moon-goddess. There is tolerably clear evidence that one of these draped figures is horned, and probably also ox-headed. In the case of the other, on account of a flaw in the seal, this is not equally manifest. Though the attitude is different, these female lunar deities appear also to be worshipping the sun-god. The lunar deities, like other figures on the seal, appear all to have turned-up toes, indicating probably the so-called "Hittite boots."[1] With these figures of lunar deities may be compared a symbol of Ashtoreth as a moon-goddess on the longest Hamath inscription, giving a crescent moon with the head of an ox above and within it, while beneath is an equilateral triangle or else a cone.[1]

If we strike a diameter across the seal from the solar disk, it will come, towards its extremity, to what is apparently a king seated on his throne and wearing a cap with a horn in front. Between the king and the group of sacred figures already described, there is on each side a distinct group, making up altogether the three groups which I have mentioned. Of the two groups not yet described the more interesting, on account of its resemblance to what may be seen on the inscriptions, is the group behind the king. There appears strong reason to believe that in this group we have a genuine example of picture-writing, in which the successful chase of a stag is represented. There is first (most remote from the king) a tree, indicating the forest, where the hunt occurred. Then come two javelins, used no doubt by the hunters of the stag, and next after these there is a sort of trident, employed, I should suppose, to give the *coup de grâce*, and of this trident I shall have an additional word to say directly. Next to the trident we find a bundle, or basket with a handle, which naturally suggests the idea of carrying. Then there is a stag's head with large antlers, and beneath it two arms with hands pointing towards the king. As the king is sitting with his face towards the group of figures in front of him, the engraver, in order to denote the king's acceptance of the stag's head (which may represent the whole

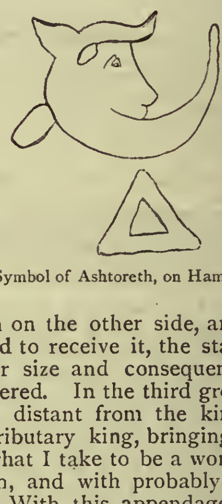

Fig. H.—Symbol of Ashtoreth, on Hamath inscription.

stag), has given on the other side, and above the king's arm outstretched to receive it, the stag's head a second time, of smaller size and consequently somewhat less artistically rendered. In the third group, beginning with the figure most distant from the king, we have what is very likely a tributary king, bringing a gift or tribute. Before him is what I take to be a woman veiled after the Oriental fashion, and with probably a baby suspended from her arm. With this appendage she may possibly have been regarded as likely to prove more acceptable to the king. Between the woman and the king is what I have regarded as a conventional symbol of a castle, indicating that the presents were received by the king in his castle. The symbol is difficult to determine; but I cannot find any more probable explanation. What it is particularly important to observe is, that the other two groups on the circumference of the seal being pictorial or ideographic, it is scarcely possible to escape the conclusion that the third group—that which I have regarded as representing the successful chase of a stag—is of the like character.

Of the objects in the central space I am unable to speak with any confidence. They may be so placed as objects of interest merely, or, taken phonetically, they may denote a name. There is a crescent, beneath it a nearly semicircular knife with a handle (if it is not possibly a ladle seen in profile), a mace or club, a sort of grating, and a trident smaller than that in the outer

[1] It is worthy of note here that about a third of the circumference is occupied by these sacred figures. From this fact may be derived a probable explanation of the vacant space over the king's head in the seal of Tarkutimme (*supra*, p. 537). The engraver, we may suppose, when he commenced engraving the king's name, intended to devote a third of the circumference to sacred objects, or at least to leave it vacant as usually so devoted. He, however, miscalculated the space at his disposal. Resolved, however, to leave some vacant space at the top, and especially over the king's head, he was compelled to leave a space in the middle of a word. Prof. Sayce has given a different explanation (*Zeitschr. für Assyriologie*, November 1886.)

[1] Mr. Rylands's drawing of the inscription gives the former, and this may possibly be right, though the cast of the inscription in the British Museum does not make this altogether clear. The original is unfortunately at Constantinople.

circle. Besides these objects, there is an equilateral triangle, like eleven others among the symbols in the outer circle. I was inclined to think that these triangles might perhaps in some way modify the meaning of the other symbols, till I noticed that not only does their size differ, but also that the vertex of the triangle, usually directed upwards, may be directed downwards to suit better the shape of the surrounding area. This is clearly seen in the space between the larger stag's head and the king. We cannot, however, come to the conclusion that these triangles are employed merely for artistic effect, and to fill up vacant spaces, even if these objects were not wholly disregarded. The recently-discovered Tarsus seal gives important evidence in favour of the sacredness of the equilateral triangle. We must conclude that the triangle is employed on the Yuzgât seal as a sacred symbol, and that as such its vertex is usually directed upward, but that this position is sometimes varied in accordance with the exigencies of space.

With regard to the group on the seal, concerned with the chase of a stag, I have spoken of its resemblance to what may be seen on the Hittite inscriptions. This is especially noteworthy with regard to the group represented in Fig. I, from the so-called doorway inscription in the British Museum. Progress in decipherment is not as yet sufficiently advanced to enable us to determine the precise significance of all the symbols, but of the general meaning there seems no room to doubt. Beginning from the end of the figure to the reader's right, the meaning

Fig. I.—Group of symbols from Jerablûs monument in the British Museum.

intended to be conveyed appears to be that booty in the shape of many oxen, asses, and other treasure, which had been obtained by the powerful assistance of the gods, was presented to the king. The parallelogram with a square on each side I regard as indicating "many." That this was the sign of plurality was the opinion of my distinguished friend, the late Dr. Birch. The head of the ox and of the ass do not seem to require remark; but above the latter is a massive and powerful right hand, with fingers clenched, and with part of the fore-arm. This would be a very appropriate symbol of strength or power.[1] Close above the right hand, and at the top, are a straight stroke, or parallelogram, with a crescent beside it. These symbols combine to form the usual symbol of deity on the Jerablûs monuments. I can only assert this now; but the evidence is abundant, and I hope to prove it fully in the sequel. Next after the closed fist with the symbol of deity comes part of an arm with the hand open and pointing towards the king. The analogy between this hand and those beneath the stag's head on the Yuzgât seal is almost too obvious to require remark. Of the value of the two crescents, which are, so to speak, back to back—a symbol not uncommon on other inscriptions—I cannot speak with any confidence.[2] At the bottom is a foot, which would very appropriately denote the act of going to the king. Next to the open hand at top is a symbol

[1] Cf. "The saving strength of his right hand" (Psalm xx. 6), and "his right hand, and his holy arm, hath gotten him the victory" (Psalm xcviii. 1). But the figurative use of the right hand as a symbol of strength presents no difficulty.

[2] It seems not unlikely, however, having regard to the symbols which the two crescents accompany here and elsewhere, that they distinguish a particular kind or class of persons.

the origin of which Mr. Rylands, to the best of my recollection, formerly referred to a bag grasped and pressed together a little below its mouth, by a hand. If this view is correct, this symbol has become, like many others, somewhat conventionalized. The bag is depicted so as to enable us to see within it at the bottom. Here are three objects, probably pieces of gold or silver used as uncoined money; and the number three may, as elsewhere, denote a great many. Beneath the bag is what has been regarded as a yoke; and, having regard to the bundle or basket on the Yuzgât seal, this may very well denote the carrying to the king. Last comes the head of the king himself, with conical cap and "pig-tail," and above him is a symbol which is perhaps best regarded as derived from the idea of a canopy above the king. As on the Yuzgât seal, the king's face is turned away, but this is because the inscription is intended to be read *with the faces*—that is, in the direction towards which the faces point—and not, as some have asserted, *against the faces.* The former arrangement is the more natural, and would have *a priori* the greater probability, but the latter is commonly, though, as Dr. Birch once said with reference to this point, not invariably, observed on the Egyptian monuments. In support of the latter view it is alleged that there is usually, at one end of the first line of the inscriptions, part of a figure with the face turned away from the other characters in the line, but with the fingers pointing towards the face or mouth, as though indicating "I have something to say." This figure, it is

Fig. K.—Figure from Jerablûs monument in the British Museum.

urged, must mark the beginning of the inscription, and, as the face is turned away, the characters must be read against the faces. But, in the first place, the figure referred to occurs elsewhere, and not solely and invariably at one end (to the reader's right) of the first line. The significance of the figure is, in all probability, as stated, but, as the figure is evidently that of a servant or minister, and not that of the king or other great personage with whose doings the inscription may be supposed to be concerned, we should expect in the first place, and before the particular message, or the subject-matter of the inscription, is entered upon, a statement of the name and titles of the person from whom the message proceeds. At the commencement of the Assyrian inscriptions there is often a very copious statement of this kind. And in fact on three of the Hamath inscriptions there is what appears to be a name immediately before the figure with the hand towards the mouth. The group of symbols discussed just above gives pretty strong evidence as to the direction in which the inscription in which they occur is to be read; and I hope to give some further evidence on this point in the sequel.

A word must be here added with respect to the trident on the Yuzgât seal. The trident is more usually associated with the sea and the sea-god than with warfare on land, or the chase. It was employed, indeed, in the Roman arena; but, as the gladiator using it was furnished also with a net, there may seem to be still some reminiscence of the sea. With regard to the trident being employed in the chase, I may adduce the evidence of a curious seal-impression which I obtained some time ago from Mr. Ready, of the British Museum. The objects

depicted are apparently the head of an animal, probably some kind of goat or ibex, parts of the animal's carcass, and a trident essentially similar to those on the Yuzgât seal. Mr. Ready is unable to tell me in what

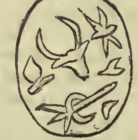

Fig. L—Seal with figures (enlarged).

collection this curious seal, which is very small, is to be found. So far as I am aware, it is not in the British Museum.

PRACTICAL EDUCATION.

PLAINLY speaking, it must be admitted that to an impartial observer the great problem of anthropology is this: Is the mind, or soul, a mysterious and supernatural, yet at the same time a definite limited *quantity*, with certain set "spiritual" functions, or is it, being of material growth, capable of infinite development? The former is the metaphysical view of the subject, the latter that of the evolutionary physiologist. Without deciding which is the true school, it may be remarked that the metaphysicians have long ceased to teach anything new, while physiology gives us, almost daily, facts of an astonishing nature. Here and there in the works of Darwin, Carpenter, Haeckel, Huxley, Bain, Maudsley, Spencer, and David Kay, we find what would have been "conclusions most forbidden," even to a Rosicrucian or Cabalist, in days of yore. And these are that man may develop his memory and other faculties in the simplest and most practical manner, as a bee builds its combs, grain by grain, until he shall far surpass what he has ever been. These discoveries as to man are in exact step with the stupendous revelations of the spectrum analysis, and the scientific reduction of the elements.

I recently published a work, the result of many years' labour, entitled "Practical Education," in which I endeavoured to give the results of experiments with nearly two thousand pupils, combined with the suggestions in the works of the writers above alluded to.[1] Having long been occupied with investigating the problem of technical education, I offered to the School Board of Philadelphia, in 1880, to devote myself entirely to the experiment of ascertaining *exactly what children could do*. That boys and girls from eight to fourteen years of age could *not* set type, make shoes, execute heavy carpenters' work, &c., had already been ascertained in Pennsylvania at a cost of about £200,000. I had, however, learned in Egypt, South Germany, and other places, that the very young can execute the decorative work which is known as that of the minor arts, and that so well that it had a market value.

Walter Smith, now of Bradford, had published a system by which design was taught at the same time with drawing. I had, two years before I met with Smith's system, which is now much employed in America, set forth the same idea in a work entitled "The Minor Arts." It soon became apparent that, by beginning with design, the youngest child developed—with invention—interest, attention, and intelligence. The results went far beyond my anticipation. It was found by the most careful inquiry that the pupils who attended the art classes had the highest "averages" in other studies, such as arithmetic, geography, and composition. This fact is the more striking from this—that the School Board, having made inquiries unknown to me, found that among 110,000 pupils the 200 who attended the Industrial Art School were among the first in *everything*.

An immediate inference from this fact is that visual perception or eye-memory (as set forth by Francis Galton) and attention or interest (as explained by Dr. Maudsley) are also factors which enter into the training of the constructive faculty. These, as is clearly explained and very fully illustrated by David Kay in his admirable work on "Memory," lead us to the conclusion that memory, by a simple process of accretion and repetition, may be developed to an incredible extent even in children. Practically, this was nothing new. Before the invention of printing, men by millions, among Druids and Brahmins and Northmen, Red Indians and mediæval scholars, Chinese and Japanese, had shown that an individual could remember perfectly what is now represented by a library. Max Müller has proved this. I myself have known a graduate of Pekin who fully illustrated it.

Memory is not "mind" or intelligence. Yet the works of Homer, the "Mahabharata," and the great scientific grammar of Pānini, were taken down and preserved for centuries by memory alone. The great history of Japan, by Hirata Atsune, was composed without the author's taking a note, and written from recollection, without reference to an original work. What man has done man may do. The deduction from all this is as follows:—

Firstly, that memory may be trained in mere children, by an easy process of committing by heart and constant reviewing, to such an extent that, guided by attention or determination, anything once read or seen may be accurately recalled. A great collection of illustrations of this may be found in Kay's "Memory," and in my own work on "Practical Education."

Secondly, that to counterbalance mere memory the mind must be trained by exercises in quickness of perception. These, in the beginning, may be merely mechanical. There are steps from inducing an infant to notice an orange on the floor up to simple games, from games to mental arithmetic or mental geography and grammar, to problems requiring the highest intelligence. The process is like that in developing memory—*little by little with constant reviewing*. And, as is the case with memory, all this has been established by innumerable practical examples. But with the one, as with the other, there should be no endeavour to cultivate thought or intellect or imagination until *both* are fairly mastered.

Thirdly, memory and quickness of perception blend and are developed in the awakening of the constructive faculty or in design, and its application to modelling, embroidery, wood-carving, and similar easy arts. And to those who object that all this does not awaken the higher faculty of intelligence or thought, it may be replied that experience or experiment have demonstrated the contrary. It is true beyond denial that a boy or girl who remembers readily and perceives quickly, and who has been trained to invention by designing, *does* think. Call them, if we will, only the tools of the great trade of thought, and a training to their use, is there no difference between two children of equal capacity, brought into a shop, when one knows what everything around is meant for, and how to handle it, when the other is yet to be taught? But the fact is beyond all dispute that children, even if trained to design alone, begin to think in every way. The experience of the Philadelphia school, and more or less that of every well-conducted Kindergarten, prove it. The trouble is, according to the requirements of a late review, that people ask for genius at once from an infant. "Teaching children to remember is not training them to think." But it is the foundation-stone.

[1] "Practical Education" (London: Whittaker and Co., Paternoster Square).

It is the giving them the faculty to collect material to employ thought. Quickness of perception is the next stage of the building. It awakens a sense of the relations which things remembered bear to one another. But the most illiterate man would not deny that a boy with a good memory, who is "sharp to notice everything," is not far off from being clever. Does not this, indeed, constitute about all the cleverness which practical life requires? But it is most unfair that any man, who has not examined the evidence, or read the facts which have been accumulated to show that extraordinary quickness of perception of every kind can be induced by proper training, should at once declare it to be impossible. It is a question not for metaphysical *a priori* assumption, but for scientific research, experiment, and test.

To render what I have said clearer, I would add that, if we begin by memorizing *mere words*, and nothing else, without any special effort to attach meaning to them, or only just so much as will aid in the work, the pupil will, in a short time, acquire a mechanical faculty for remembering. As soon as this becomes habitual, easy lessons which, so to speak, explain themselves, are introduced, and so, step by step, with great care the learner is led to acquire that which involves intelligence. Now, the whole system lies in this: that what a boy or girl perfectly remembers is easier to understand than when it is only half grasped. As it is, we begin in teaching a language by requiring a child to learn all at once to remember words, to pronounce them, and to master their grammatical structure and relations. I never knew of but one instance in my life in which anybody over twenty-five years of age ever learned to speak French like a native. This was a lady, who, before learning the meaning of a word, passed several months in mastering the pronunciation. Schliemann, the excavator of Hissarlik, who for many years learned a language every six months, advocates this system. By learning one thing at a time, at first, we are far better able to acquire several things at once in a more advanced stage. In acquiring quickness of perception, as in memorizing, the processes are identical—they begin by the simplest mechanical methods, and advance to the most refined.

The same development in a commensurate manner is observed in teaching industrial art. To give a child, or even a dull adult, some idea of design, I would allow him or her to group cardboard leaves into a pattern, and trace round them with a pencil till the fingers became familiar with the implement. There are not many cases in which this is advisable, but, having tried it many times, I can assure those who have not that it does not in the least degree prevent beginners from acquiring the boldest freehand practice. The more pains we take with the rudiments of every kind of culture, the easier is the acquisition of advanced branches.

The age is now being called on to face a great problem. It is that of over-pressure. From every side we hear in every newspaper of a thousand things which everybody is assumed to know. A certain great thinker—or writer—was said to have tested in vain "the American mind," by asking everyone he met in the United States, "Have you read Obermann?" It was not true, but it was truthful because it might have been, and because it truly represents the current pedantry of requiring, as a proof of culture, a knowledge of every German, Swiss, or French introversial- transcendental- or sentimental-ist. It is as true of society as of the school. "Shall the meeting-house be moved away from the growing dung-hill, or the dung-hill from the meeting-house?" Such was the great problem which was discussed by a Yankee town council. Shall we go on increasing the branches of popular education, or reduce them? Why not try the experiment of ascertaining whether the pupil will not learn more by first acquiring the art of learning? That is the problem which we are all bound to discuss sooner or later. It cannot be evaded. It is forcing itself upon us from every side. A perusal of all the London reviews or magazines for a month is enough to make any polyhistor—if such a man exists—feel like an ignoramus. It is becoming a clear case of *non possumus*, as the Chicago Professor declared when he recognized the impossibility of shooting two 'possums with only one ball. Either the capacities must be increased, or the contents diminished. And that the powers of memory, perceptiveness, and construction can, by a very easy system of rudimentary culture, be developed to what would seem to be miraculous, is in accordance with the teachings of the most advanced men of science, and is established by innumerable facts. All that is needed now is to combine into a single system the truths which have hitherto been scattered, and to make that a subject of general education which has been illustrated only by separate examples.

It was seriously objected, when I for the first time undertook to make industrial art a regular branch of instruction in public schools, that the number of children who had any capacity or *gift* for such a study, or enough to make it advantageous, was so limited that it would not be worth while to try the experiment. The result of several years' teaching was that while among nearly two thousand pupils only one or two were found who had this "gift," there was not one single child who was not abundantly capable of learning decorative design, and mastering the minor arts. Precisely the same thing is being said as regards teaching memory and perception. "It will succeed with *geniuses*, but not with all." Now, it is an extraordinary thing, and one to be specially noted, that the antecedent proofs and probabilities that every child can become a clever artistic artisan were very few and far between compared to those which illustrate the truth that the other faculties in question may be as generally acquired. Secondly, it was urged against the one, as it is now being urged against the other, "Where will you find teachers?" They were speedily found in the art school, for we soon developed them from among our pupils, while I had in addition a class of grown-up ladies who were specially educated as instructors. But the great objection, and the one which to this day perplexes the majority of people, is, "What profit is there in teaching pattern drawing, modelling shoes or leaves, carving patterns or hammering brass? *Will it pay?* Can a boy make a living by it?" This is precisely the problem proposed by Sam Weller's school-boy, who had indeed learned the alphabet, but doubted whether it was worth while going through so much to learn so little. "Is it not better to teach *boys* a *trade?*" is heard on every side in answer to the assertion that boys and girls of tender age should be prepared to begin to study one. In exactly the same spirit a reviewer declares that "we shall do well to ask ourselves whether it is not more important to teach our children to *think* than to remember, and whether a great deal of the matter with which children are expected to load their memories is not lumber." This is quite equivalent to declaring that it is much more sensible to teach boys algebra than have them waste time in learning the numerals or simple arithmetic. If the writer in question had ever read even a little in physiology, he might have learned that it is estimated that there are from 600,000,000 to 1,200,000,000 of nerve-cells in the brain for the generation of nerve force, and the moulding and storing up of our ideas, each having a separate existence, while Prof. Bain gives the number of fibres which transmit impressions at about 5,000,000,000. Now, if any of the objectors to "overloading" the memory do so because they find they are themselves already perilously near to possessing one thousand two hundred million ideas, and really cannot hold any more, nothing remains to be said. Truly, it has been carefully calculated that for the most retentive and richly endowed minds there are only about 200,000

acquisitions of the assumed types, but the amount of genius which a reviewer must possess must far transcend this if he can prove that people should learn to think before they can remember anything.

Ten years ago the training of children to work while studying was deemed chimerical. "It had been tried," we were told, "and it had failed." But it had not been tried properly or sensibly. Ten years hence memory and quickness of perception will also be taught to classes of pupils as a preparation for thought. What man has been we all know, but what man may be no one can tell. This only is certain, that Science now holds in her hand, at last, the key to Nature, and that ere a decade shall pass there will be such revolutions as no supernaturalist ever dreamed of.

CHARLES G. LELAND.

TELEGRAPHS IN CHINA.

THE progress of China is by no means so rapid as some interested persons would have us believe, but beyond doubt the empire is at last moving in a direction favourable to the adoption of Western arts and sciences. The simple fact that telegraphs are being provided there is in itself evidence of the wonderful change which has taken place in the past few years in the attitude of the ruling body, and which not even the most sanguine among us could reasonably have anticipated, to go no farther back than the period of the Chefoo Convention in 1877.

When, however, we find it announced that a complete network, as it were, of telegraphic connections is in course of formation there, it may be worth our while to ascertain whether the foundation of this statement is sound and trustworthy; and in making an examination we shall find it convenient to refer to the substantial progress made and the elaborate system which exists, not merely upon paper, but in absolute perfection, no farther away from China than thirty-six hours' journey by steamer.

Japan may indeed lay claim to the possession of a network of telegraphs; and to obtain an idea of the work to be done in China before a similar claim can be established there, we need only reflect that taking mileage and population into consideration the whole of the Japanese Empire could conveniently be deposited within the boundaries of even one of the eighteen provinces of the Flowery Land. To arrive at a basis of calculation, therefore, we should have to multiply the total length of the existing Japanese telegraph lines at least ten times before any comparison could be instituted. If we were to contrast the East and West, which, however, would be scarcely fair, we should find that a telegraphic system as the term is understood in Europe means something yet immeasurably more extensive and intricate.

Casting aside, then, the extravagant impressions which are often conveyed by the brief telegraphic intelligence which reaches us periodically from the Far East, it is matter for congratulation that the outlying provinces of China are gradually being brought into communication with the capital by the aid of electricity. Yunnan, on the extreme south-western border, has recently been connected, and other equally remote provinces will doubtless be reached without loss of time. With millions of labourers ready to work, the guiding and controlling forces, if present in sufficient numbers, might carry on operations simultaneously, if necessary, in all the eighteen provinces. And undoubtedly there will be a decided advantage in throwing up the lines in almost any fashion so long as they can be made to convey a message, if even, as is most probable, the entire system has to be reconstructed at no distant date. The main object is to so familiarize the natives of the interior with the aspect of these intrusive posts and wires, that they will combine to protect rather than destroy them. And here we are reminded of one point in which the Chinaman differs essentially from his near neighbour the Japanese. When first telegraphs were introduced in Japan, in 1871, the most violent opposition was encountered in the more remote regions at the hands of the agriculturists, who were by no means disposed to acquiesce in all the regenerative projects of the Government of "Benevolence and Light." In China the opposition emanated from the Government itself, inasmuch as considerable diplomatic pressure had to be brought to bear ere the introduction of a telegraph of any kind could be sanctioned, and it is tolerably safe to assume that in the peaceful interior of that vast empire nothing like strenuous objection will be raised to the formation of the line if only it be the aim of the engineers to wound the susceptibilities of the farmers as little as possible in selecting sites for the poles. In Japan the Government was very willing, but the people in many instances were not: in China it has been difficult to convince the Government, whilst the people are eminently docile.

The attitude of ready submission to law and order which characterizes the Chinese farming class affords reasonable ground for the belief that, unless there be a false step on the part of local officials, the telegraphs of China will enjoy an immunity from half the evils which have attended the introduction of the system into other lands. But something will certainly depend upon the policy pursued by the mandarins: it must be one of conciliation. Cultivated land is so exceedingly precious to the Chinese farmer that he can ill afford to have his property disturbed and partly occupied, even if it be to the extent of a square foot or two only, in order that posts may be planted to carry the wires. The system of farming adopted tends to the cultivation of a few acres merely by any one individual, but by diligence and attention a small plot is made to yield practically two and even three crops where one only would be raised in an equal space with us. This is the reason why the good will of the local residents, officials or farmers, will have to be secured.

When these initial difficulties have been overcome, a glorious field will await the development of the telegraphic system. Instead of following in the track of the railway, or journeying side by side therewith, the telegraph will be the forerunner and instigator of improved means of locomotion throughout this immense, almost unknown, region. Even if its effects were limited to the comparatively handy centres of the tea and silk trade there would, in a twelvemonth, be ample justification for its establishment.

It is one thing, however, to have erected a line of telegraph and another thing to provide adequately for its maintenance in efficient working order, without which it would be better not to construct it at all. When communications are interrupted for days together, as must inevitably occur in the absence of a thoroughly complete maintenance organization, the public confidence must be shaken anywhere, and certainly this will apply in full force to China. It is to this most important consideration that early attention should be directed, for the trouble begins the moment the lines are thrown open to the public. When once the merchant has experienced the sensation of being able to complete a bargain on the instant, he is apt to resent fiercely any curtailment of his privileges. It may not be out of place, therefore, to allude to the experience of the pioneers of telegraphy in Japan as evidence of the paramount necessity for establishing this branch of the service on the soundest basis possible. To begin with, testing stations ought never to be farther apart than a day's march on ordinary roads, and trained men are needed at these stations to be held in readiness to set out, on a word from head-quarters, with the necessary tools. Herein is

contained the one essential principle of systematic maintenance. Moreover, it is not enough that breakages of wire be promptly repaired, but the efficient performance of a lineman's duty demands that he should at stated periods patrol his district and remove the possible causes of interruption in the shape of branches of trees and other obstacles to perfect communication before they have time to bring about disaster. His must be the duty of making minute examination of the supports, lest rapid decay at the ground line render even a single post too weak to withstand a sudden shock, and the chain of communication be abruptly severed. He must paint and otherwise preserve these posts, and secure them by the attachment of ample stays against normal or exceptional strains. In a word, a man will find abundant work to fill up his allotted time in a district no more extensive than a day's walking will suffice for him to cover.

Now all this is not mere theorizing, but the relation of what has been done and is being daily carried into effect in Japan, and it is for these reasons that we assert that the Government of that country may claim to possess a telegraphic system worthy the name. At the present time the telegraphic organization extends to every town of any importance within the Mikado's dominions. In the majority of cases these stations are distinguished as being the head-quarters of the local government or prefecture, and all are thus brought into instantaneous communication with the departmental offices at the capital. The four islands are connected by submarine cables, and the Great Northern Telegraph Company's lines form a medium of communication between Nagasaki and the Western world. The Japanese engineer their own service, educate their operators and travelling linemen, manufacture their own apparatus, even of the most complex character, their own batteries, and the galvanized iron fittings for their poles. The insulators in use are of Japanese porcelain, the finest in quality ever produced, capable of withstanding the most severe tests that it is possible to subject them to. Iron poles are not used, because the pine and cedar flourish everywhere, and are obtainable on short notice; moreover, it is often cheaper to replace them, if decay sets in, than to invest in iron, which is costly at the outset, and heavy to transport inland. The rates for telegrams are sufficiently low to bring the convenience within the reach of all classes. Messages are transmitted in either Japanese or foreign languages with equal facility. Finally, the finances of the department are administered in such a way as to show a substantial balance at the end of the fiscal year.

When may we look for this in China?

With the advantages the pioneers of the service there possess we trust we shall not now have to wait long. But it will inevitably be discovered, if the maintenance of the lines be not provided for efficiently from the outset, that a mighty engine of Western civilization is being hampered and thwarted in its progress, and that among the mercantile classes, who ought to be its principal supporters, there will spring up a feeling of distrust which years of success will not entirely counterbalance. There is no reason why China should not manufacture for herself almost everything she requires in the way of apparatus and material, as Japan is now doing; for men of more deft and skilful touch, combined with high intelligence, than the Chinese do not exist. But all their perfection of workmanship will avail the State little if it be not supported by strict perseverance in those duties which appertain to efficient maintenance. Long lines hastily set up across country, with stations few and far between, and without competent workmen to look after them, under substantial control, will soon cease to convey an electrical current. As suggested before, it is one thing to build a line, but quite another matter to preserve it in working order, and it is to be hoped the example of the Japanese will not be lost upon their near neighbours.

J. M.

FLORA OF THE BAHAMAS.

At the Manchester meeting of the British Association a Committee was appointed, with a grant of £100, for the purpose of exploring the flora of the Bahamas. The vegetation of this group has long been known to present some very peculiar features, but it is poorly represented in European herbaria. The Committee were fortunate in securing the assistance of Baron Eggers (sometime Commandant at the Danish colony of St. Thomas), who had lately returned from an important botanical exploration in St. Domingo.

Baron Eggers started at the end of last year, and the following letter gives an interesting account of the progress which he had made up to the time of writing.

W. T. Thiselton Dyer.

Royal Gardens, Kew, February 25.

"*Fortune Island, Bahamas, February* 6, 1888.

"I finally succeeded in reaching here, and as this part of the Bahama Archipelago most likely is less known still than the islands nearer Nassau, I propose to explore this group (Fortune, Crooked, and Acklins Islands), which are not far from the centre of the whole, and which, especially the two latter, are of a good size and fairly wooded. From the day of my arrival I have been exploring this island, which is of a longitudinal form, 9 miles long by 1 to 2 miles broad, highest elevation 110 feet, entirely covered with a low forest or scrub about 10 to 16 feet high. The largest trees do not exceed 25 feet, and that height is rare.

"Partly on account of the season of the year, partly from the protracted dry weather, some of the shrubs and trees have neither flower nor fruit, whilst at the same time the herbaceous vegetation is almost absent. Yet I have succeeded in finding a good number of most interesting plants in flower or seed, and have made, besides, collections of woods and seeds. Cycads I have seen none of here in this island. *Guaiacum sanctum* seems to be common here. Some very curious composite shrubs I have met with. On the shore *Ambrosia crithmifolia* seems very common, as also *Passiflora pectinata.*

"Of palms are found *Sabal umbraculifera*, and another, probably *Sabal Palmetto*, called palmetto here by the inhabitants, which is common and used for making hats. A shrubby *Phyllanthus* is very common, as also a very small-leaved *Erythroxylon. Croton Ujalmarsonii* is frequent. Several species of *Cassia* are found, as also some acacias. One *Psychotria*, a *Phoradendron*, growing on *Byrsonima lucida, Swietenia Mahagoni*, two species of *Coccoloba*, a large-leaved *Euphorbia*, a *Cordia*, and a number of other shrubs and small trees. Of Epiphytes I have seen two Tillandsias and an *Epidendrum*, which latter grows among rocks. No mosses, but some lichens.

"Among common trees is to be noted chiefly *Hippomane Mancinella*, as also *Conocarpus erecta* in two forms, the glabrous and the silvery-haired ones, both growing indiscriminately together in small woods.

"Almost the whole surface of the island is covered with a layer of limestone, coarse, mixed with sand, about 6 inches thick, which appears to have formed a smooth cover over the whole whilst under water. It is now generally broken to pieces, but the pieces are still close together, and only separated by fissures, in which trees and shrubs grow, sending their roots down into the sandy, and sometimes marly, soil beneath. In many places there are hollows, in which a light red soil has been accumulated, and where a few attempts at cultivation are made.

"As a rule, the only cultivation here is on the sandbank that forms the western shore, and on which also the little town is situated. Here is raised some Guinea corn (*Sorghum*) and sweet potatoes, as well as cocoa-nut trees, which seem to thrive remarkably well. This whole north-

western shore, for at least 6 or 7 miles, might be one vast forest of cocoa-nut trees. The small plantations of fifty or sixty near the dwellings present a very healthy appearance, and are in full bearing.

"Otherwise the population of the place, amounting to about 500 I should suppose, support themselves by trading, sailing, collecting sponges, and going abroad as labourers for steamers in the West Indian trade. Some salt is made from an extensive salt-pond that stretches for 4 to 5 miles just inside the north-western shore. Another smaller pond is found on the south-eastern shore.

"The town is a decent little village, with a good church, school, post-office, jail, and very creditable dwellings. The people are very well behaved and decent on the whole. Among cultivated plants around dwellings I can mention *Poinciana regia*, *Casuarina equisetifolia*, *Terminalia Catappa*.

"It is very gratifying to see the spirit of neatness and order that pervades everything in the English islands, and which forms such a contrast to the squalor and utter wretchedness that marks much richer islands, like Hayti, Porto Rico, and Cuba. As the coloured population is of the same race in all these places, it can only be ascribed to the example set by the governing race in this case.

"As you may imagine, the vegetation of this, as of most of these islands, possesses a strong uniformity and sameness, as there are no elevations of any extent to produce variety, and partakes in fact of the character of the vegetation of the sea-shore. I therefore can hardly expect to add much to my collections in this place now, and therefore intend to pass to Crooked or Acklins Island as soon as an opportunity offers.

"In a certain sense, of course, locomotion is easy enough from one island to another, yet you must always wait for an opportunity if you do not want to hire a vessel or a boat for your own use.

"After I have finished this group I propose to go to Nassau, and from there to pass over to Andros, which, from what I have been able to gather, is somewhat different from the other islands, especially on account of its being full of swamps and fresh-water lakes, which ought to give the vegetation a somewhat different character. Andros, too, is heavily wooded, both with pine forests as also with other trees, of which many are cut and exported for timber.

"As the season advances I also expect to find a greater proportion of plants in blossom than at present, so as to make my collections from these islands as complete as possible. Still a number of trees will most likely be represented by their leaves only or at best in fruit, which of course cannot be avoided, unless the exploration were continued through the year, and this, as you may imagine, cannot be done for the amount at my disposal, of which necessarily a part has already been consumed by the voyage hither.

"From what I have collected already, I think, however, I am able to say that I shall get together a considerable herbarium, which I hope will contain no few novelties, and give a fair representation of the flora of this archipelago. I need hardly add that I make copious general notes on the vegetation, as well as on the natural history and physical conditions of the islands in general.

"Yours very faithfully,

"EGGERS."

NOTES.

WE understand that, in accordance with the arrangement made on March 24, an important deputation, consisting of Sir Henry Roscoe, Sir Lyon Playfair, Sir John Lubbock, and Mr. Howorth, met Mr. Stanhope and Lord Harris on Monday last, to discuss the regulations for the selection of Woolwich cadets, so far as they relate to natural science. We believe that the proposals submitted by the deputation will receive favourable consideration.

THE late Mr. Thos B. Curling, F.R.S., has bequeathed £200 free of legacy duty to the Scientific Relief Fund of the Royal Society.

A FRESH case of specimens from the borings in the Delta of the Nile has just been received at the Royal Society.

PROF. HOFMANN, the chemist, celebrated his seventieth birthday on Monday. The Emperor Frederick sent him a patent of nobility, and among many other birthday gifts were portraits of Queen Victoria and the German Empress. From the Prince Regent of Bavaria Prof. Hofmann received a high decoration.

DR. EMIL HOLUB, the African traveller, intends to open a South African Exhibition in the old Exhibition building known as the Rotunde, in Vienna, in May 1889. The industries, exports, and dwellings of the natives will be exhibited, as well as the collections made by Dr. Holub.

A YEARLY pension of 800 roubles has been granted by the Russian Government to M. Potanin in recognition of his work as an explorer in China and Mongolia.

THE question as to the best means of promoting technical education is being earnestly discussed in Russia. A Congress, summoned by the Permanent Committee for Technical Education, is about to meet at St. Petersburg for the consideration of the subject. The sum of £500 has been granted by the Government for the expenses of the Congress.

A RUSSIAN zoological station has been established at Villafranca, a few miles from Nice. The Bay of Villafranca is well known for the work that has been done there by some of the most prominent Continental biologists, and it certainly offers great advantages for the study of marine fauna. An old Italian prison, which was formerly sold to the Russian Government, and used as a kind of naval station for repairs of ships of the Russian Navy, has now been transformed into a zoological station, supported by the Russian Naval Ministry. It has two spacious and well-lighted halls for microscopical work, five smaller rooms, and accommodation for men of science who may wish to carry on biological investigations. It is under the direction of Dr. Korotneff.

WE regret to learn that Captain Temple has been compelled to discontinue the issue of his most interesting and valuable periodical, *Indian Notes and Queries*. His duties at Mandalay, where he is playing an important part in the work of reorganization in Upper Burmah, so occupies his time that he is quite unable to put together periodically the notes sent to him by many contributors. His other periodical, the *Indian Antiquary*, is to be maintained, and contributions to the now defunct serial will be diverted to it.

A DEPUTATION from the "Australian Natives' Association" waited recently on the Minister of Education of Victoria to urge that an Australian series of school-books should be published, so that fuller information on purely Australian subjects should be made available to the children in State schools. It was argued that there was virtually no special information about Australian geography in the books used. The Minister was asked to bear in mind that 650,000 of the total population of Victoria were native born, and that the vast majority were growing up in ignorance of the geography of their native land. Australian literature, like Australian geography, was neglected by the Education Department. The deputation laid particular stress on the argument that the Government would stimulate the Federal sentiment by giving Australian subjects prominence in the State schools.

THE death is announced at Yokohama, on February 17, of Mr. Henry Pryer, an old resident there, who had devoted much attention to the study of Japanese entomology and ornithology. The writer of an obituary notice in the *Japan Weekly Mail* states that, except for a short time, when engaged in arranging natural history collections in the Tokio Museum, Mr. Pryer was occupied in business pursuits, his spare time being given to the study of Japanese fauna; "and it is no exaggeration to state that he had become the authority *facile princeps* on all questions connected with the birds, butterflies, and moths, whilst at the same time he had acquired a most extensive knowledge and store of facts in connection with all the other branches of the zoology of Japan." Mr. Pryer was the author of papers in various English scientific journals, and the Transactions of the Asiatic Society of Japan. In November 1886 he published Part I. of a description of the butterflies of Japan, under the title "Rhopalocera Nihonica," and Part II. is said to be in the printers' hands, and almost ready for publication. It is to be hoped that the third and concluding part may be found in such a state of preparation as will insure the completion of the work. Mr. Pryer, who was the brother of Mr. Pryer of the North Borneo Company's service, like himself an enthusiastic student of Nature, was only thirty-nine years of age at the time of his death.

RUSSIAN zoology has sustained a heavy loss by the death of Prof. M. N. Bogdanoff. He died at St. Petersburg on March 16. His first work, published in 1867, was on the life and the geographical distribution of the *Tetrao urogallus*. Four years later he published a most elaborate and suggestive work, "The Mammals and Birds of the Black-earth Region of the Volga," in which he treated in detail the present geographical distribution of animals in connection with the climate and soil of Russia during the Post-Pliocene period. In 1873 he took part in the expedition to Khiva, and returned with a rich geological collection, now at the St. Petersburg University. The results of this journey were embodied in a capital work on the Khiva Oasis and the Sands of Kyzyl-kum. His next work was on the fauna of the Aral-Caspian basin, which he described in the *Mémoires* of the Society of Naturalists at the St. Petersburg University. In 1875 he began the exploration of the Caucasus, and published the results of his labours in a work, "The Birds of the Caucasus," which has become the foundation-stone of the ornithology of the region. In 1880 he visited a part of the coast of the Arctic Ocean, and the results of his journey were published in the *Mémoires* of the Society at St. Petersburg University. In 1881 he published another excellent work, "The Russian Magpies." Finally, in 1885, he began the publication of his life-work, "The Ornithology of Russia," of which only the first part has been issued. Prof. M. N. Bogdanoff's popular zoological sketches, published in a Russian review, were widely read. All the above-mentioned works, as also many smaller monographs, have been published in Russian.

THE Russian Geographical Society has lost one of its most active ethnographers, V. N. Mainoff, whose works on the Erzya-Mordvinians—their anthropological features and customs—are well known. His knowledge of the Finnish language gave a special value to his works on the remnants of paganism among the Mordvinians, and to his descriptive work on Karelia and the Onega region. He had already published a Finnish grammar in Russian, and was engaged in the compilation of a Finnish and Russian dictionary. The latter task was intrusted to him by the Senate of Finland. He had brought the dictionary up to the letter K.

ANOTHER masterly contribution to the fundamental principles of chemistry, leading us still further into the intensely interesting region of the hitherto unknown, will be found in the current number of the *Berichte*, from Profs. Victor Meyer and Riecke. We have from time to time in these columns noticed the progress of the development of the now famous "position-in-space" theory first formulated by Van t' Hoff, and it will perhaps be remembered that a short account was recently given of the remarkable results obtained by Prof. Meyer from the study of certain complex organic compounds. The main result consisted in the discovery of two new properties possessed by carbon atoms: first, that the four valencies may be deviated from their positions at the corners of a regular tetrahedron; and second, that two carbon atoms united by single bonds may be attached to each other in two ways—one in which they are free to rotate, and another in which rotation is prevented. Recognizing that the chemist must not tread this unbroken ground alone, but that he must go hand in hand with his co-worker the physicist, Profs. Meyer and Riecke have brought together evidence afforded by both physics and chemistry, and have thereupon formulated a theory which appears likely to be the germ of a grand generalization. They suppose the carbon atom to be a sphere surrounded by an ether shell, that the atom itself is the carrier of the specific affinity, while the surface of the ethereal envelope is the seat of the valencies. Each valency is conditioned by the existence of two oppositely electrified poles, situate at the ends of an imaginary straight line, short in comparison with the diameter of the envelope. Such a system of two poles is termed a di-pole. The four valencies of the carbon atom would thus consist of four such di-poles. The middle point of the line joining each pair of poles is further supposed to remain always in the surface of the envelope, but freely movable in that surface, and the di-pole itself would be able to rotate freely round this central point. It is then supposed that the carbon atom possesses a greater attraction for the positive than for the negative ends of the di-poles, so that, owing to the possibility of free rotation, the positive ends would turn towards the centre of the atom. At the same time the valencies of the same atom would repel each other, and take up their positions at the four corners of the regular tetrahedron, from which, however, they could be, as experiment shows they occasionally are, deflected. Thus the molecules of marsh gas, CH_4, or any carbon compound of the type Cx_4, would naturally be symmetrical, but when the four valencies are attached to groups of different weights their positions would probably be altered. A strikingly natural explanation is then given of the nature of single, double, and triple linking of carbon atoms, showing how the first can occur in the two ways previously indicated. It is a matter for sincere congratulation to those who have been labouring so long in building up the now immense fabric of organic chemistry, that it is by reason of the large accumulation of data concerning the carbon compounds that these important principles have been arrived at; and it is to be hoped that before long the data may be sufficient to permit of like investigations of the atoms of other elements.

So many interesting reports relative to waterspouts, sighted during January and February in the western portion of the North Atlantic, have been received by the Hydrographer of the United States Navy, that he has plotted them in a supplement to the Pilot Chart of the North Atlantic Ocean for March, together with the tracks of storms coincident with some of them. The positions of the spouts are given for fourteen days between January 12 and February 29. To specify a few cases:—On January 12 four spouts were seen in lat. 36° 41′ N., and long. 72° 27′ W., and on the 19th several were seen a little farther to the eastward. And again, on January 22, several large spouts were seen in lat. 31° 47′ N., long. 74° 33′ W. The most interesting of all are those seen on January 26–28, for the reason that they were clearly associated with a low barometer area

which moved across the great lakes on the 25th. One of these, seen on January 28, in lat. 39° 30′ N., long. 57° 20′ W., is estimated to have been a mile in diameter. On February 11 the ship *Reindeer* was completely dismasted by a spout in lat. 32° 4′ N., long. 76° 6′ W. The weather was clear at the time, and the whole affair was over in a few minutes. Generally speaking, the rotation was, as in the case of tornadoes, in the opposite direction to that of the hands of a watch, but, in some cases, in the same direction. It is suggested that if instantaneous photographs were taken of some of these remarkable phenomena they would be of great value to the science of meteorology.

AT the meeting of the French Meteorological Society, on March 6, M. Renou stated that the observations at Parc St. Maur showed that the month of February last was colder than it had been since 1855. The temperature of 5° F., observed on February 2, was the lowest on record in that month. On March 1 the minimum, 16°·2, was the lowest recorded in March since 1847. The Society is encouraging the registration of regular observations at the seminary at Port-au-Prince (Hayti). The thermometers, which are now better exposed, show that the temperatures are lower than formerly reported. Very few observations from this district have been published, so that a regular bulletin such as is hinted at by M. Renou would be very welcome. M. Hauvel read a communication on the "Tides of the Photosphere," due to planetary action. In classifying the planets according to their influence on the photosphere, he places Mercury first and Jupiter second, and he argues that at certain positions Mercury causes storms in the photosphere, giving rise to abnormal variations of temperature in our atmosphere, according to the relative position of the earth.

THE German Meteorological Office has published the results of its meteorological observations for the year 1886 (Berlin, 1888, lvi. + 223 pp.). The stations of the second and third orders now number 256, several new ones having been recently established. A regular system of thunderstorm observations has been commenced, and much attention is paid to rainfall; it is proposed eventually to increase these stations to 2000. In addition to the usual data, the maximum falls in twenty-four hours are given for all stations. The system includes several mountain stations, the highest being the Schneekoppe (nearly 5250 feet). The difficulties experienced in mountain meteorology may be judged of from the fact that in the winter the anemometer on the Schneekoppe has to be abandoned, owing to the accumulation of snow, and in the summer the earth thermometer has to be removed, owing to repeated interference by tourists. The history and outfit of the stations are given in many instances, and will be continued in subsequent reports.

THE Bureau of Ethnology, Smithsonian Institution, lately issued a full and useful bibliography of the Eskimo language, by Mr. J. Constantine Pilling. Now it has published an equally good bibliography of the Siouan languages, by the same scholar. The material for both of these catalogues has been gathered during personal visits to the more prominent public and private libraries of the United States, Canada, and France, and by correspondence with missionaries, Indian agents, publishers, and printers of Indian books, and owners of Americana.

AN interesting paper on the use of gold and other metals among the ancient inhabitants of Chiriqui, Isthmus of Darien, by Mr. William H. Holmes, has just been issued by the Bureau of Ethnology, Smithsonian Institution. The objects described by Mr. Holmes were obtained from ancient graves, of which no record or trustworthy tradition is preserved. They are all ornaments, no coin, weapon, tool, or utensil having come to Mr. Holmes's notice. The great majority of the objects were formed by casting in moulds. The work exhibits close analogies with that of the mainland of South America, but these analogies are found in material, treatment, and scope of employment rather than in the subject-matter of the conceptions. The sum of the art achievements of these peoples seems to Mr. Holmes to indicate a lower degree of culture than that attained by the Mexicans and the Peruvians, the ceramic art alone "challenging the world in respect to refinement of form and simplicity and delicacy of treatment."

THE Report, for the year 1886–87, of the Colonial Museum and Laboratory of New Zealand has been issued. It is the twenty-second annual report of these institutions. The attendance of visitors at the Museum was very large, being considerably above the average of former years, especially on Sunday afternoons, when the very limited passage-room often caused inconvenient crowding. The total number of additions to the collections during the year was 10,708. Among these additions were eleven photographs of the wonderful stone carvings and inscriptions found on Easter Island. In the Colonial Laboratory 345 analyses were performed during the year. These are classified as follows: coals and oils, 22; rocks and minerals, 117; metals and ores, 43; examinations for gold and silver, 81; waters, 36; miscellaneous, 46. In the report all the results of these analyses which have a general or special interest are rendered in full.

A SERIES of papers, entitled "Studies in Biology for New Zealand Students," is being issued by the Colonial Museum and Geological Survey Department of New Zealand. We have received the third paper of the series. It is by Mr. Alexander Purdie, Science Master at the Wellington Training College, who has chosen as his subject the anatomy of the common mussels (*Mytilus latus*, *edulis*, and *magellanicus*). Mr. Purdie points out that, as a subject for study, the mussel has the advantages of being readily procurable at most points of the New Zealand coast, and also of not being so small as to embarrass the tyro in the art of dissection.

WE have received the Report of the Marlborough College Natural History Society for the year ending Christmas 1887. During the year the numbers of the Society largely increased; its meetings were well supported; and the work of the Sections was in most cases considerable. Among the contents of the volume are interesting papers on Aristotle on birds, by Mr. W. Warde Fowler; the migration of birds, by Mr. A. H. Macpherson; and spiders and their allies, by the Rev. O. Pickard-Cambridge, F.R.S.

THE second number of the *Internationales Archiv für Ethnographie* contains the first instalment of a paper, in German, by J. Büttikofer, on the natives of Liberia. This contribution is accompanied by two finely coloured plates representing implements and weapons. Dr. B. Langkavel has an interesting article on the uses to which horses are put by races at an early stage of development.

A LITTLE controversy is going on in the *Internationales Archiv* about the northern limit of the regions within which the boomerang is used in Australia. Prof. Gerland, of Strasburg, in his map of the races of Oceania, has drawn the line about 15° 30′ S. lat. In the first number of the *Archiv*, Prof. Ratzel expressed his belief that the line ought not to be drawn so far north, and that it really extends only to about 18° 30′. In the second number, Prof. Gerland maintains his position, pointing out that Leichardt found the boomerang near the Macarthur River, while Edward Palmer, one of the highest authorities on all subjects relating to the North Australians, found it to the north of Mitchell River. The tribes of these northern districts have independent names for the weapon, which they use more frequently in the chase than in war.

A BOOK entitled "Mœurs et Monuments des Peuples préhistoriques," by M. de Nadaillac, is about to be published in Paris. The text will be fully illustrated.

THE *Selborne Magazine* will in future be published by Mr. Elliot Stock.

THE new number of *Mind* opens with an article on the conditions of a true philosophy, by Mr. S. H. Hodgson. There are also articles on the nature and functions of a complete symbolic language, by Mr. S. Bryant; on Dr. Martineau and the theory of vocation, by the Rev. H. Rashdale; and on the unity of consciousness, by Mr. A. F. Shand.

WE have received a little pamphlet by Dr. G. Y. Cadogan-Masterman, Medical Officer of Health, Stourport, entitled "Dermepenthesis: Animal Skin-Grafting," in which the author gives several interesting cases of successful grafting of the skin of rabbits on wounds on the human body.

AN International Exhibition of farmyard poultry, rabbits, game raised for reserved shooting, machinery and engines for bird-culture, hunting-dogs, and sporting apparatus allowed by law, will be held in Rome, at the Botanical Garden, from April 25 to May 10. The Exhibition is being organized by a Committee of the Agricultural Society of Rome.

ACCORDING to the *Naturforscher*, Herr von dem Borne-Berneuchen has succeeded in breeding, in his piscicultural establishment, specimens of the fish known in America as the black boss.

THE additions to the Zoological Society's Gardens during the past week include two Striped Hyænas (*Hyæna striata*) from Algeria, presented by Capt. E. B. Pusey, R.N.; an Ortolan Bunting (*Emberiza hortulana*), British, presented by Mr. W. H. St. Quintin; a Moorish Gecko (*Tarentola mauritanica*) from Cannes, South France, presented by Mr. J. C. Warbury; two Poiret's Newts (*Molge poireti*) from Algeria, presented by Mr. G. A. Boulenger; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited; a Central American Agouti (*Dasyprocta isthmica*) from Central America, purchased.

OUR ASTRONOMICAL COLUMN.

THE PARIS CATALOGUE.—The first two volumes of the great work undertaken by Leverrier a third of a century ago,—the re-observation of the stars of Lalande's catalogue,—have recently been published. The first volume contains the first instalment of the catalogue, viz. stars from 0h. to 6h. of R.A. observed during the years 1837 to 1881, whilst the second gives the separate observations. That this great undertaking has advanced so far towards completion is chiefly owing to the energy which has characterized the Paris Observatory under the directorship of Admiral Mouchez, and to the strength it has derived from the School of Practical Astronomy which was for several years connected with it. When Admiral Mouchez succeeded to the direction in 1878, barely one-third of the necessary observations had been secured, and the annual number of observations obtained was only about 6000 or 7000, a total which, however considerable in itself, was very inadequate in view of the 300,000 required to complete the original programme of a minimum of three observations in each element for the 47,390 stars of Lalande's catalogue. The gift by M. Bischoffsheim of the fine Eichens meridian-circle, and the assistance furnished by the pupils of the astronomical school have, however, raised the yearly average to 25,000 or 28,000 observations, and rendered it possible to commence the publication of results. As the observations include not only those made since Leverrier became Director, but also some 20,000 or 30,000 made between 1837 and 1854, under Arago's superintendence, but left unreduced by him, they have been divided into three periods, viz. 1837–53, 1854–67, and 1868–81, and severally reduced to the mean epochs 1845, 1860, or 1875. Observations subsequent to 1881, about one-fourth of the entire number, will be published separately, and a separate supplementary catalogue will also be formed of those stars which it has been found necessary to re-observe owing to the disproportion between the number of observations secured in the two elements, due to the R.A.'s in so many cases having been observed with the transit instrument, whilst the declinations were taken with the mural circle, the transit circles having been erected only in 1863 and 1877 respectively. The present section of the catalogue contains 7245 stars, and represents about 80,000 observations in both elements. It gives for each of the three periods the number of observations, the mean date, the R.A. and N.P.D. reduced to the mean epoch, and a comparison with Lalande. The precessions for 1875 are also added. The introduction, by M. Gaillot, who has superintended the reduction, contains a discussion of the probable errors of the observations, and is followed by a comparison of the present catalogue with Auwers' Bradley, and an important investigation by M. Bossert of the proper motions of a large number of stars, followed by a table of errors in Lalande's catalogue, which the present and other catalogues have brought to light.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 APRIL 15–21.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 15

Sun rises, 5h. 5m.; souths, 11h. 59m. 53·6s.; sets, 18h. 55m.: right asc. on meridian, 1h. 36·2m.; decl. 10° 1′ N. Sidereal Time at Sunset, 8h. 32m.

Moon (at First Quarter April 19, 12h.) rises, 7h. 23m.; souths, 15h. 9m.; sets, 23h. 4m.: right asc. on meridian, 4h. 46·0m.; decl. 18° 18′ N.

GEOGRAPHICAL NOTES.

THE Russian Geographical Society elaborated at its last meeting the following programme of work for the next summer. M. Kuznetsoff will continue his geo-botanical work on the northern slope of Caucasus, and M. Rossikoff will continue his survey of the Caucasian glaciers on the little-known southern slope of West Caucasus. M. Listoff will also resume his exploration of the caves containing layers of ice in Crimea. Pendulum measurements will be done by Prof. Sokoloff in Poland and West Russia; and an Expedition of three persons will be sent out for the exploration of the Kola peninsula.

THE following details of the Brazilian Expedition, headed by Dr. von Steinen, have been received from Dr. Ehrenreich, one of the members of the Expedition. Their object was to investigate the Kuluene River, a tributary of the Xingu. Dr. Ehrenreich gives the following as the chief results of the Expedition: (1) the discovery of great Caribbean races in the centre of South America, named respectively the Bakairi and the Nahugua; (2) the discovery of the Kanayura and Anite tribes, who still speak the ancient Tupi language, and use remarkable weapons, amongst which is the very peculiar arrow fling. Surveys of the Kuluene were made and many ethnographical specimens have been collected, forming a complete picture of the original culture of these Indians, who, even to-day, do not know the use of metal, but are still in the period of implements made of flint, bone, and fish teeth.

OUR ELECTRICAL COLUMN.

J. T. BOTTOMLEY showed that the temperature of a wire conveying electric currents varied with the air-pressures surrounding it, and that a wire which remained dull at ordinary atmospheric pressure incandesced when a moderate vacuum was obtained. M. Cailletet has been working in the opposite direction. He has shown that a current which would fuse a wire under ordinary pressure will scarcely raise it to redness when the pressure is sufficiently great. These experiments show how essential free convection as well as radiation is to the incandescence of filaments in glow-lamps, as well as to the heating of conductors.

LECHER (*Rep. der Physik*, xxiii. p. 795) has experimented on the much-vexed question of the counter-electromotive force of arc lamps, and he finds that its existence is not proved, that the observed difference of potential which is expressed by the formula $a + bl$ varies with temperature, and that it is probably due to discontinuity in the current.

CONSIDERABLE attention has lately been devoted to the potential difference between the various constituents of a voltaic cell by direct measurement, an operation facilitated by Helmholtz's capital observation that this difference between an electrode of mercury flowing in drops through a capillary tube and an electrolyte is *nothing*. The mercury thus acquires the potential of the electrolyte, and can be measured. Moser (*Beiblätter*, xi. p. 788) has thus measured the Daniell and Clark cells, and Miesler has been following it up. Thus in the Daniell cell—

$Zn \mid ZnSO_4$	$= +\ 1{\cdot}06$	volt
$ZnSO_4 \mid CuSO_4$	$= +\ {\cdot}22$	,,
$CuSO_4 \mid Cu$	$= -\ {\cdot}22$	,,
Total PD ...	$1{\cdot}06$	,,

In the Grove cell—

$Zn \mid H_2SO_4$	$= +\ 1{\cdot}06$	volt
$H_2SO_4 \mid HNO_3$	$= +\ {\cdot}36$	,,
$HNO_3 \mid Pt$	$= +\ {\cdot}20$	,,
Total PD ...	$1{\cdot}62$	,,

He makes the PD—

$C \mid HNO_3$	$= +\ {\cdot}38$	volt
$C \mid H_2CrO_4$	$= +\ {\cdot}62$	,,
$H_2SO_4 \mid H_2CrO_4$	$= +\ {\cdot}5$	,,
$PbO_2 \mid H_2SO_4$	$= +\ 1{\cdot}3$	,,
$H_2SO_4 \mid Pb$	$= +\ {\cdot}9$	,,

all the measurements, except that of the Grove cell, according fairly well with known and accepted measurements.

HERTZ, WIEDEMANN, AND EBERT have been experimenting on the influence of rays of high refrangibility on electrical discharges, and M. Hallwachs has been verifying their results. He finds that a well-insulated disk of zinc charged with electricity rapidly loses its charge when the rays of an arc lamp fall upon it. It is more rapid with negative than with positive charges.

PENDULUM SEISMOMETERS.

PENDULUM SEISMOMETERS are among the oldest forms of instruments employed to record earthquake motion upon a stationary plate. In 1841 crude forms of such seismometers were used to record shocks at Comrie in Scotland. The objections to the older forms of these instruments are that they are not provided with any arrangement to magnify the motion of the earth, the writing indices are not sufficiently frictionless, and the value of the records are destroyed because the pendulums almost invariably swing (see "Experiments in Observational Seismology," by J. Milne, Trans. Seis. Soc., vol. iii. p. 12). The first pendulum seismometer with which I am acquainted which has a multiplying index is the one described, constructed, and successfully employed by Dr. G. Wagener (see Trans. Seis. Soc., vol. i. p. 55). From Dr. Wagener's account of this instrument it was the inventor's intention to counteract any tendency of the pendulum bob to swing by the inertia of the multiplying index, and from his experience with the instrument, owing to frictional resistance or otherwise, it seems that even if the pendulum was set in motion it quickly came to rest.

The multiplying arrangement, or "indicating pendulum," in Wagener's instrument was a lever, which we will call $a\ b\ c$, 25 inches in length (Fig. 1); the upper end of this at a geared

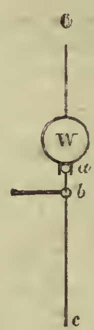

FIG. 1.

in the base of the main pendulum bob W by a ball-and-socket joint. One inch below, at b, a second ball-and-socket joint connected the lever with the earth. Now if a remained at rest, and b, being connected with the earth, moved backwards and forwards, a multiplied representation of this movement was produced at c, 24 inches lower down. The question which arises is whether W tends to remain at rest, and what effect the jointed system $a\ b\ c$ exerts upon it.

Imagine that an impulse is received towards the right, so that the point of suspension of W at o, and the point b, move to the right. The tendency of W is therefore to move to the right. If the centre of oscillation of $a\ b\ c$ relatively to b as a centre of percussion is *below* b, then a will move to the right and assist W in its swing; if, however, the centre of oscillation is *above* b then W will be retarded in its motion. In Dr. Wagener's instruments the centre of oscillation was below b, and hence the index retarded W by its inertia and friction only. Still, the instrument was the first one where there was an attempt to use an "indicating

pendulum," first as a multiplying index, and secondly as a means to check the motion of a large pendulum. In pendulum seismographs, which I have largely used in Japan (see Trans. Seis. Soc., vol. iv. p. 91), *a b* was loaded with a brass ball, and thus the centre of oscillation raised above *b*. The moment that *a b* exerted on W was not, however, sufficient to prevent W from swinging, and its movements were retarded and rendered "dead beat" by frictional resistance directly applied to the surface of W, which was a disk of lead suspended horizontally. During the last two years I have had several seismographs constructed in which *a b* was long; and, as near to *a* as possible, a weight sufficiently large to render W feebly stable was placed. This important suggestion of loading *a b* originated with Mr. T. Gray. Later, Mr. Gray drew attention to the necessity of rendering an ordinary pendulum, for small displacements, absolutely astatic, and he suggested various means by which this might be accomplished (Trans. Seis. Soc., vol. iii. p. 145).

In the same publication, vol. v. p. 89, Prof. Ewing, attacking the same problem, described a duplex pendulum, a modified form of which he described in vol. vi. p. 19. In vol. viii. p. 83, Prof. Sekiya described an improved form of Prof. Ewing's instrument (see also NATURE, vol. xxxiv. p. 343). In the duplex pendulum seismograph an ordinary pendulum is rendered astatic for small displacements by placing an inverted pendulum beneath it, and so uniting the bobs of the two pendulums that any horizontal motion is common to both, and the jointed system so proportioned that neutral or feebly stable equilibrium is obtained. Although these instruments are, for seismometrical work, theoretically good, in practice such of them as I have had, which are the best to be obtained in this country, present many serious objections. Among these objections I may mention the following: (1) the difficulty of adjustment; (2) the difficulty of inserting and removing smoked glass plates; (3) the fact that the pointer being cranked at its upper end it does not give so satisfactory a record in directions at right angles to the plane of the crank as is desired; (4) their incapability of recording an earthquake of greater amplitude than 5 mm.

By introducing arrangements for adjustment, alteration in the form of the recording index, &c., these instruments might be improved. Possibly in the instrument recommended by Prof. Ewing for use in Observatories (see NATURE, vol. xxxiv. p. 343), although it appears to be practically similar to those I have in Tokio, the objections may not be so serious.

The instrument of this class which I have in all respects found the most satisfactory is, in its essential features, shown in Fig. 2,

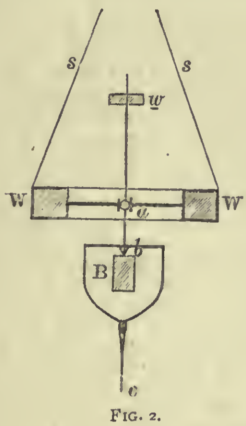

FIG. 2.

in which W represents a lead ring about 7 inches in diameter, with a small tube, *a*, fixed in a plate at its centre. W is supported by three strings or wires, *s*. The indicating pointer is *w a b c*, prolonged downwards, at the lower end there being a needle as a writing-point sliding in a small tube. *w a b* is a light steel rod with a ball forming a universal joint on the tube at *a*, and a point, *b*, pivoting in the fixed steel bar B. The stability of the system is readily altered by raising or lowering the *small* weight *w*. For small displacements neutrality is obtained when $\frac{w}{W} = \frac{p^2}{Ll}$ where $p = ab$, L the length of the main pendulum, and l the length of the inverted pendulum.

The whole is carried on a tripod about 2 feet 3 inches high, stiffened in the centre by a small transverse table which carries the bar B. W is so suspended that it can be readily shifted laterally or vertically. Below there is a small shaft which carries the smoked plate. By means of a wedge this can be raised or lowered, and the plate brought to any degree of contact with the sliding pointer. This portion of the apparatus is so simple that a record-receiving surface is instantly adjusted or removed by the movement of a handle connected with the wedge. The instrument is an outcome of instruments which have preceded it, and it may be regarded as a modification of an old type where *a b c* has been prolonged upwards and the balance load placed above *a* instead of being between *a* and *b*. Its chief recommendations are: (1) its smallness; (2) the simplicity and fewness of its parts; (3) the ease with which it may be used; (4) its large range of motion; (5) the accuracy of its diagrams. The test for accuracy has been made by placing the instrument upon a specially designed shaking table, the absolute movements of which are recorded by a multiplying lever.

Comparing the diagrams given by the machine with those given by the table, it is found that for all small displacements, whether in right lines or complicated curves, the diagrams, 20 or 30 mm. in length, are practically identical. For diagrams 50 mm. in their greatest dimensions, composed of a complication of curves if anything greater in complexity than those yielded by ordinary earthquakes, some differences occur, the extent of which may be judged of by the accompanying diagram, Fig. 3. Figs. 4

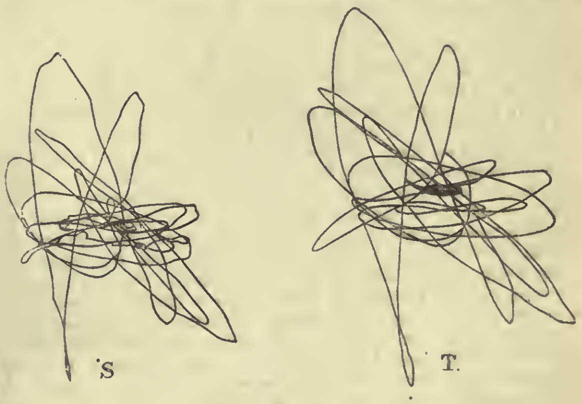

FIG. 3.

and 5 are examples of the diagrams obtained for small displacements. These diagrams are fair specimens, but have not been selected as particularly good examples. The multiplication of the table diagram, marked T, is 6·3, while that of the seismograph, marked S, is slightly over 6.

Diagrams of the old type of seismograph with the weight on *a b* have also compared favourably with the table motion. I regret, however, to say that the diagrams given by one of Prof.

FIG. 4.

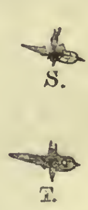

FIG. 5.

Ewing's duplex pendulums, with the exception of their amplitude, in no way resembled the table motion. This instrument was adjusted to have extremely feeble stability. With a second of Prof. Ewing's instruments, which was adjusted by Prof. Sekiya's assistant, who understood the machine, the distortion was not so great, but the diagrams were complicated by the swinging of the pendulum after the shaking had ceased. The pendulum in this instance had a period of about two seconds, which was much too short.

JOHN MILNE.

THE CULTIVATION OF OYSTERS.

A REPORT from the British Consul at Baltimore on the oyster-fisheries of Maryland, which has just been laid before Parliament, contains much interesting information respecting the cultivation of oysters. The method of farming most successful in America consists in depositing clean oyster-shells upon the bottom, just before the spawning-season, to which the young attach themselves, and then placing among the shells a few mature oysters to furnish eggs and young. As soon as the young oysters caught in this manner are large enough to handle, they are distributed over the bottom. Another system is by artificial propagation, properly so called—that is, by producing the seed-oyster itself, or procuring it by methods less simple than the shell-sowing process. This method is due to a discovery by Dr. W. K. Brooks that the *Ostrea virginiana*, or American oyster, is not, like the *Ostrea edulis*, or oyster of Northern Europe, hermaphrodite, but is exclusively male or exclusively female. The eggs of the European oyster are fertilized within the valves of the parent, while in the case of the American oyster, fertilization takes place in the broad and open waters. By experiment Dr. Brooks discovered how artificial fertilization could be procured, and the next great step of finding a simple and practical method of rearing the young oysters which have been hatched artificially was the work of M. Bouchon Brandslé, the French naturalist, who experimented with Portuguese oysters, which, like the American variety, are of distinct sexes. He succeeded in rearing many seed-oysters fit for planting. Another highly important industry which is springing up in the United States, and which also owes its existence to a careful study of the habits of the bivalve, is that of "muzzling" oysters, by which they can be sent long distances in their shells with perfect safety. Until recently, the general practice was to pack the raw oysters in ice, but a sudden rise of temperature is liable to render a whole week's supply useless. Oysters feed twice a day; and always at the still moment preceding the turn of the tide, and at no other time, except when feeding, do they open their shells. When taken out of their natural element, they attempt to feed at regular intervals, and so soon as the shells open, the liquor they contain is all lost, the air takes its place, and the oyster is covered with a thick coating of slime, which is the first stage of decomposition. As long as the shells are closed, the oyster is fit to eat; it feeds on the liquor in the shell, and will thus keep in good condition for a considerable time. To secure the keeping of the shells closed, a method has been invented of tying them with stout wire, which can be done with great rapidity, and now arrangements are being made for despatching American oysters in their natural condition all over the civilized world.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science, February, 1888, contains:—On the Photospheria of *Nyctiphanes norvegica*, G. O. Sars, by Rupert Vallentin and J. T. Cunningham (Plate 23). The authors give an account of their examination of the luminous organs of this little crustacean; it is a distinctly northern form, being absent from the Mediterranean and the warmer parts of the Atlantic. It is abundant on the west coast of Norway; the adults seem to live on the bottom and never swim far from the ground, while the young, up to half or three-quarters the size of the adult, occur abundantly at the very surface, and at all intermediate depths. Mr. Murray found swarms in the Faroe Channel, and it seems common in the the Clyde sea-area; the authors took it in abundance off Brodick Bay. The histological details of the luminous organs are given in detail, and agree for the most part with those of G. C. Sars.—On the early stages of the development of a South American species of Peripatus, by W. L. Sclater (Plate 24). These details are worked out from a species found by Mr. Sclater in Demerara, and called by him *P. imthurni*; the early stages present great differences when compared with those described by M. Sedgwick in *P. capensis*.—On the anatomy of *Allurus tetraëdrus* (Eisen), by Frank E. Beddard (Plate 25). The specimen described came from Teneriffe; there are several structural differences between this genus and Allolobophora.—On the development of the Cape species of Peripatus; Part iv. the changes from the G stage to birth, by Adam Sedgwick, F.R.S. (Plates 26-29).—On the occurrence of numerous Nephridia in the same segment of certain earthworms, and on the relationship between the excretory system in the Annelida and in the Platyhelminths, by Frank E. Beddard (Plates 30 and 31).—On the anatomy of the Madreporia, iv., by Dr. G. Herbert Fowler (Plates 32 and 33). The author gives the result of his investigations of the species of seven more genera of the Madrepores, which, among other important results, seem to establish a relationship between the external body-wall and the corallum, which depending on the presence or absence of cœnenchyma may yield a distinctive morphological character. In all those genera in which a cœnenchyma is found, whether they belong to the Perforata or Imperforata, the body-wall rests on the little spikes or echinulations which stud the surface of the corallum. A new species of Seriatopora is described as *S. tenuicornis*; it was found by Dr. S. J. Hickson at the Celebes; it comes near *S. caliendrum*.

Transactions and Proceedings of the New Zealand Institute for 1886, vol. xix. (Wellington, May 1887).—The principal contents of this volume, edited as usual by Sir James Hector, are as follow:—*Zoology*: E. Meyrick, monograph of New Zealand Noctuina, describes sixty-three species.—W. M. Maskell, on the "honeydew" of Coccidæ, and the Fungus accompanying these insects; Further notes on New Zealand Coccidæ; On the freshwater Infusoria of the Wellington district. In the second paper a new genus and two new species are described; in the last many new species are described, and several well-known British forms are recorded; all these papers are illustrated.—G. V. Hudson, on New Zealand glow-worms.—T. W. Kirk, notes, double earth-worm; New species of Ixodes; *Zootoca vivipara*, in New Zealand; New species of Alpheus.—A. Purdie, *Pasiphila lichenodes* sp. nov., and descriptions of larvæ of three species of the genus.—A. T. Urquhart, on new species of Araneidea; On the work of earth-worms.—W. W. Smith, notes on New Zealand earth-worms, gives some very interesting details.—W. Colenso, deformed bill of a Huia; New species of Hemideina; Gestation of a species of Naultinus.—T. Jeffery Parker, on *Palinurus lalandii* and *P. edwardsii*, decides that there are constant though slight differences between the two species; *P. edwardsii*, Hutton, being the New Zealand form, the other being the Cape of Good Hope form.—C. W. Robson, new giant cuttle-fish (*Architeuthis kirkii*).—J. A. Newell, anatomy of *Patinella radians*.—T. F. Cheeseman, Mollusca of the vicinity of Auckland.—J. Adams, land Mollusca of the Thames gold-fields.—A. Reischek, Hauturu Island and its birds; Ornithological notes.—S. Weetman, Moa remains on the Great Barrier Island.—R. Haeusler, Foraminifera from Hauraki Gulf.—P. Goyen, descriptions of new spiders.—*Botany*: J. Buchanan, new native plants; *Hemitelia smithii*, a branching specimen.—T. F. Cheeseman, on the New Zealand species of Coprosma.—W. Colenso, on tree ferns; On some new Phænogamic plants; On some new Cryptogamic plants; Fungi recently discovered in New Zealand.—Catherine Alexander, on the glands in the stem and leaf of *Myoporum lætum*.—T. W. Rowe, on the development of the flower of *Coriaria ruscifolia*.—J. Baber, medicinal properties of some New Zealand plants.—D. Petrie, descriptions of new native plants.—*Geology*: J. Park, ascent of Ruapehu, the exact height was not apparently determined, "about 9000 feet high."—There is a series of important papers on the eruption of Tarawera Mountain and Rotomahana, by J. A. Pond and S. Percy Smith, Major Mair, L. Cussen, Archdeacon Williams, E. P. Dumerque, and H. Hill.—Prof. F. W. Hutton, on the geology of the Trelissick or Broken River Basin, Selwyn County; On the so-called gabbro of Dun Mountain; On the geology of the country between Oamaru and Moeraki; On the geology of the Valley of the Waihao in South Canterbury.—A. McKay, the Waihao greensands and their relation to the Ototara limestone.—Sir J. von Haast, notes on the age and subdivisions of the sedimentary rocks in the Canterbury Mountains, based upon the palæontological researches of Baron von Ettingshausen.—W. S. Hamilton, notes on the geology of the Bluff District.—J. Goodall, on the formation of Timaru Downs.

Reale Istituto Lombardo, March 8.—This number is mainly occupied with E. G. Celoria's determination of some new orbits of the double stars OΣ 298 in the constellation of Boötes and β Delphini. The results of thirty-nine distinct observations are tabulated, and compared with previous more or less approximate determinations of these orbits by Burnham, Dawes, Dembowski, Dunér, Engelmann, Asaph Hall, Perrotin, Schiaparelli, Seabroke, Struve, and Wilson.

Rivista Scientifico-Industriale, March 31.—Influence of magnetism on the electric resistance of solid conductors, by Dr. Faè. In this paper the author explains the conclusions already announced for cobalt and antimony, and describes his further researches on other bodies in connection with the influence of magnetism on their electric resistance. He concludes generally that the resistance of the principal solid conductors undergoes modifications in the magnetic field, such modifications being perceptible enough in the highly magnetic or diamagnetic metals, but most conspicuous in bismuth. In all other metals it is very slight, and at times quite inappreciable. Under like conditions the resistance in the direction of the lines of force increases both for the magnetic and diamagnetic metals, while in the direction normal to the lines of force it diminishes in the first and increases in the second, although under special conditions iron and steel behave exceptionally. These variations of resistance make it probable that Hall's phenomenon depends in effect on a transitory change produced by the magnetism in the structure of the metals, and causing a rotatory variation in the electric resistance.—Dr. Luigi Fritsch describes an industrial product of the nitrate of ethyl.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 2.—"On the Voltaic Circles producible by the mutual Neutralization of Acid and Alkaline Fluids, and on various related Forms of Electromotors." By C. R. Alder Wright, D.Sc., F.R.S., Lecturer on Chemistry and Physics, and C. Thompson, F.I.C., F.C.S., Demonstrator of Chemistry in St. Mary's Hospital Medical School.

About the beginning of the present century it was noticed that when platinum plates are immersed respectively in an acid and an alkaline fluid (*e.g.* diluted sulphuric acid and caustic potash solution), and connected with a galvanometer, a much stronger current flows at first than after passing awhile: which circumstance may be explained by supposing that in virtue of the chemical action taking place between the two fluids a current is generated, the flowing of which necessarily causes electrolysis of the liquids, so that the plates become "polarized" by the evolution thereon of hydrogen and oxygen respectively, whereby an inverse E.M.F. is set up, gas battery fashion. It was shown subsequently by Becquerel that when *nitric* acid is thus used in conjunction with caustic potash a much more powerful continuous current can be generated, the passage of which is accompanied by a continuous evolution of oxygen from the plate immersed in the alkali, whilst the nitric acid is simultaneously reduced, forming lower oxides of nitrogen: whence the term "pile à oxygène" applied to the combination. In this arrangement the hydrogen supposed to be formed electrolytically can never actually make its appearance in the free state, being oxidized whilst nascent by the nitric acid; so that as the gas battery inverse E.M.F. is not developed, the continuous current passing is not so much weakened; the oxygen set free by electrolysis consequently passes off continuously at the other plate.

It occurred to the authors that, if this reasoning be correct, firstly, other oxidizing acid liquids besides nitric acid should be able to act in the same way, causing continuous oxygen evolution at the plate immersed in the alkali. Secondly, by parity of reasoning, if ordinary dilute sulphuric acid be used on the one side opposed to an alkaline fluid also containing some readily oxidizable substance dissolved therein, continuous *hydrogen* evolution should, under favourable circumstances, be produced at the plate in the acid, the oxygen evolved at the other plate being acted upon while nascent by the oxidizable substance present, so as to be suppressed just as the hydrogen is in Becquerel's "pile à oxygène." Thirdly, whether oxygen or hydrogen be continuously evolved, the quantity liberated should be proportionate to the current passing; so that, if a silver voltameter be included in the circuit, for every milligramme-equivalent (108 mgrms.) of silver deposited 1 mgrm.-equivalent of gas should be liberated; *i.e.* 8 mgrms. of hydrogen occupying at 0° and 760 mm. 5·6 c.c.; or 1 mgrm. of hydrogen occupying 11·2 c.c.

A number of cells were arranged, consisting of two porcelain basins or beakers, one containing the acid and the other the alkaline fluid united by a siphon tube, or by a thick wick, containing or wetted with a strong solution of the salt formed by the union of the acid and alkali (*e.g.* sulphate of soda when sulphuric acid and caustic soda were used, and so on). A plate of platinum foil was placed in each fluid attached to a platinum wire, and arranged under an inverted graduated tube filled with the liquid pertaining to that side of the cell, so that any evolved gas could be collected and measured, loss of gas from evolution at the surface of the wire outside the tube being avoided by coating the wire with gutta percha or paraffin wax. A small silver voltameter with a gold plate as negative electrode was always included in the circuit, so as to permit of the deposited silver being determined. Numerous experiments thus made are described, the results of which were always in sensible accordance with the above previsions, a considerable variety of acid oxidizing fluids and alkaline oxidizable solutions being employed.

These results render it probable that, if, instead of a platinum plate and an oxidizable substance in solution, there be used simple caustic soda or ammonia, and an oxidizable metal, the oxide of which is soluble in the alkaline fluid, continuous currents might be set up (in certain cases at least), even though the metal used have of itself no visible action on the alkaline fluid, apart from its absorbing oxygen dissolved therein or in contact therewith; for instance, metallic tin or lead in contact with caustic soda, or copper immersed in ammonia solution. On trying such experiments, continuous evolution of hydrogen from the surface of the platinum plate immersed in the acid was found in many instances to be readily brought about, the amount evolved being (as might *a priori* be anticipated) proportionate to the current passing, *i.e.* to the quantity of silver deposited in a silver voltameter included in the circuit. By employing an alkaline solution of potassium cyanide, it was found easy to produce the same result when certain metals of the non-oxidizable class (gold, silver, palladium, and mercury, but *not* platinum) were used instead of really oxidizable ones.

In most cases the quantity of metal taken into solution in the alkaline fluid was practically identical with that equivalent to the current passing, calculated on the assumption that the nascent oxygen due to the electrolysis combined with the metal *to form the lowest oxide* thereof, in the various cases respectively. In some few instances a slight excess of metal was dissolved, obviously due either to local action or the effect of small quantities of dissolved air. Two well-marked exceptions to the general rule, however, were noticed: one was *tin*, which when dissolved in caustic soda invariably went into solution to an appreciably less extent than corresponded with SnO; instead of fifty-nine parts of tin being dissolved for every 108 of silver deposited in the volameter, only quantities amounting to 93 to 97 per cent. of that amount were dissolved, indicating that some little quantity of SnO_2 was formed as well as SnO, although the latter largely predominated. The other exception was *mercury*, which in contact with potassium cyanide dissolved to only half the extent due to formation of Hg_2O, *mercuric* potassio-cyanide being produced. Copper, whether in contact with ammonia or with potassium cyanide, on the other hand, always dissolved in proportions corresponding with Cu_2O, a little excess instead of deficiency being usually noticeable through the secondary action of dissolved air.

In all these experiments, the results obtained are precisely those due to electrolysis of the salt formed by the neutralization of the acid and alkali in accordance with the scheme (for sulphuric acid and soda)—

$$\left\{\begin{array}{l} H_2SO_4 \mid Na_2SO_4 \mid Na_2SO_4 \mid 2NaOH \\ H_2 \mid SO_4Na_2 \mid SO_4Na_2 \mid SO_4Na_2 \mid H_2O + O\,; \end{array}\right.$$

where either the hydrogen or the oxygen is suppressed, whilst nascent, by combination with the fluid in contact with which it is evolved, or with the metal in the case of oxygen in the cells last described.

Accordingly it might be expected that in all actions of this kind a quantity of acid on the one hand, and of alkali on the other, proportionate to the current passing, will disappear as such on account of the mutual neutralization thus indirectly brought about. The authors have made a number of titration experiments with a view to obtaining numerical evidence on this point, with the general result of finding that such neutralization always takes place. It may be noticed that if cells be constructed with platinum electrodes immersed respectively in an alkaline fluid containing an oxidizable substance dissolved therein, and an acid fluid containing an oxidizing agent (*e.g.* caustic soda solution of pyrogallol, and sulphuric acid solution of chromic anhydride), continuous currents of very considerable power may be obtained when the internal resistance is diminished sufficiently by using cells of considerable magnitude; *e.g.* when made of

the stoneware and inner porous vessels usually employed for Grove's cells, the porous vessel being cemented into the outer stoneware vessel (by paraffin wax or other unattacked material) in such a fashion as to divide it into three compartments separated one from the other by porous dividing walls; the acid and alkaline fluids being placed in the two outermost compartments, and the innermost one being filled with a solution of a neutral salt, *e.g.* sodium sulphate.

March 1.—"On Electrical Excitation of the Occipital Lobe and adjacent Parts of the Monkey's Brain." By E. A. Schäfer, F.R.S., Jodrell Professor of Physiology in University College, London.

The following are the results of my own observations:—Electrical excitation of the posterior limb of the angular gyrus, of the upper end of the middle temporal gyrus[1] (which is continuous with it), of the whole cortex of the occipital lobe, inclusive of its mesial and under aspects and of the quadrate lobule, causes conjugate deviation of the eyes to the opposite side. The movement is not, however, in all cases a simple lateral deviation, but the lateral movement may be combined with an upward or downward inclination according to the part stimulated. Thus—

(1) Excitation of a superior zone which comprises on the external surface the posterior limb of the angular gyrus, the upper (posterior) end of the middle temporal gyrus, and the part of the occipital lobe immediately behind the external parieto-occipital fissure and on the mesial surface the quadrate lobule immediately in front of the upper end of the internal parieto-occipital fissure and the occipital lobe for a short distance behind the upper end of that fissure, produces, besides the lateral deviation, a downward inclination of the visual axes which is sometimes—especially when the stimulation is applied at or near the mesial surface—so marked as greatly to obscure the lateral deviation.

(2) Excitation of an inferior zone comprising the whole of the inferior surface of the lobe, the lower part of the mesial surface, and the posterior or lowermost part of the convex or external surface, produces, besides the lateral deviation, an upward inclination of the visual axes, which, like the downward movement resulting from stimulation of the superior zone, may be so marked as partly to obscure the lateral deviation.

(3) Excitation of an intermediate zone which comprises the greater part of the external surface (where it gradually broadens out laterally) and extends over the margin of the great longitudinal fissure to include a narrow portion of the mesial surface, produces neither upward nor downward inclination of the visual axes, but a simple lateral movement.

If, as is highly probable, the movements of the eyes, which occur on excitation of the occipital lobe and adjacent parts, are the result of the production of subjective visual sensations, these effects of excitation of the several parts of that lobe and the adjoining portions of the brain would appear to indicate—

1. A connection of the whole visual area of each hemisphere with the corresponding lateral half of each retina. (This has already been ascertained to be the case from the result of removing the whole of the area on one side, bilateral homonymous hemianopsia being thereby produced.)

(2) A connection of the superior zone with the superior part of the corresponding lateral half of each retina.

(3) A connection of the inferior zone with the inferior part of the corresponding lateral half of each retina.

(4) A connection of the intermediate zone with the middle part of the corresponding lateral half of each retina.

"A Comparison of the Latency Periods of the Ocular Muscles on Excitation of the Frontal and Occipito-Temporal Regions of the Brain." By E. A. Schäfer, F.R.S., Jodrell Professor of Physiology in University College, London.

Conjugate deviation of the eyes to the opposite side is produced by excitation of entirely different regions of the cerebral cortex.

Of these parts, excitation of which produces this result (conjugate deviation of the eyes to the opposite side), one, viz. the frontal area, is distinguished from the rest by the fact that its removal produces paralysis of that movement. This fact has been seized upon by Ferrier as indicating an important functional difference, the movements in the one case being probably caused by the direct action of this part of the cortex upon the centre of origin of the nerves to the ocular muscles; but in all other cases by indirect action, the movement when, *e.g.*, the visual or auditory region is stimulated being the result of visual or auditory impressions (subjective sensations) being provoked in the brain by the excitation, and these impressions producing indirectly the action in question. Others have supported the view that in all cases the movement is the result of the setting up of subjective sensations, but that in the case of the frontal area these are tactile or are connected with the muscular sense.

It seemed to me that light would be thrown upon the question if the period of latent stimulation of the ocular muscles were accurately determined under exactly the same conditions for the frontal and posterior (temporal and occipital) areas respectively. The result of this determination, which I have made in a number of monkeys, is to show that the latent period is longer by some hundredths of a second in the case of stimulation of the occipital lobe, or of the superior temporal gyrus than when the frontal area is stimulated; thus indicating that in the former case the nervous impulses must be transmitted through at least one more nerve centre than in the latter.

[1] Excitation of the upper end of the superior temporal gyrus gives a similar result. Since this is commonly accompanied by a movement of the opposite ear, it is usually considered that subjective auditory sensations have been called up by the excitation.

Geological Society, March 28.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On some eroded agate pebbles from the Soudan, by Prof. V. Ball, F.R.S. The majority of the pebbles in a collection made by Surgeon-Major Greene in the Soudan, and presented by him to the Science and Art Museum in Dublin, are of very similar character to the agate and jasper pebbles derived from the basalts of India. It may be concluded inferentially that they came originally from a region in which basaltic rocks occur to a considerable extent. A certain number of them are eroded in a manner unlike anything noticed in India, though it is probable that similar eroded pebbles will eventually be found there. Throughout India, wherever there is a deficient subsoil-drainage or excessive evaporation and limited rainfall, salts are apparent either in supersaturated subsoil-solutions or as crystallizations in the soil. They are most abundant in basaltic regions, and in a lake occupying a hollow in the basalt in Berar carbonate of soda is deposited in abundance from the water, which becomes supersaturated during the summer. The author commented on the efficacy of such a liquid as a solvent of silica, and noticed the selective action of the agent which had affected the Soudan pebbles and had corroded some layers more than others; he suggested that, while this might be to some extent due to differences in composition, it was more probably owing to differences of nodular constitution. He considered it unnecessary to refer to the action of humic acid, because, while the salt to which the solvent action is attributed would be capable of doing such work, and would be probably abundant in the region referred to, we could not expect any great amount of humic acid in the same area. This paper gave rise to a discussion, in the course of which remarks were made by the President, Mr. Whitaker, Mr. Irving, Mr. De Rance, and Sir Warington Smith.—On the probable mode of transport of the fragments of granite and other rocks which are found embedded in the Carboniferous Limestone of the neighbourhood of Dublin, by Prof. V. Ball, F.R.S.—The Upper Eocene, comprising the Barton and Upper Bagshot formations, by J. Starkie Gardner and Henry Keeping, with an appendix by H. W. Monckton.

Royal Microscopical Society, March 14.—Dr. R. Braithwaite, Vice-President, in the chair.—The Rev. A. H. Cooke exhibited a number of photomicrographs of the odontophores of Mollusca, as an attempt to illustrate this group of objects by photography; he also referred to the valuable results obtained in the definition of species by the application of the method.—Mr. E. M. Nelson exhibited and described a new form of mechanical stage, in which two points were moved by milled heads in rectangular directions, carrying the slide with them, the slide being pressed against them, when they were withdrawn, by the hand.—Mr. C. L. Curties exhibited a new combination condenser, which, in addition to the condenser, also contained an iris diaphragm, a spot lens, and a polarizing prism.—Mr. Crisp exhibited a Collins's aquarium microscope which could be fixed by suction to the glass side of the tank; also Klonne and Müller's aquarium microscope for examining objects in a small aquarium or trough specially constructed for the purpose, and fitted with movable diaphragm slides; also a new form of Thury's 5-tube microscope for class purposes, having a reflecting prism made to rotate, so as to exhibit the object upon the stage alternately to

each of five observers.—Mr. G. Massee read a paper on the type of a new order of Fungi, Matuleæ.—Mr. J. Rattray gave a *résumé* of his paper, "A Monograph of the genus *Aulacodiscus*," the subject being illustrated by diagrams, and by a tabulated list of groups of allied species.—The Chairman announced that the date of the next *conversazione* had been fixed for April 25.

Entomological Society, April 4.—Dr. D. Sharp, President, in the chair.—Mr. H. Goss exhibited a large number of insects lately received from Baron Ferdinand von Mueller, F.R.S., of Melbourne, which had been collected by Mr. Sayer on Mount Obree, and the adjoining ranges in New Guinea, during Mr. Cuthbertson's recent expedition there under the direction of the Royal Geographical Society of Australia. The collection comprised Coleoptera, Lepidoptera, Hemiptera, Diptera, Hymenoptera, and Orthoptera. The Lepidoptera included twenty species of butterflies belonging to the genera *Calliplæa, Chanapa, Hamadryas, Melanitis, Mycalesis, Hypocysta, Tenaris, Hypolimnas, Cyrestis, Neptis, Acræa, Danis, Pithicops, Appias, Ornithoptera*, and *Eurycus*.—Mr. Osbert Salvin, F.R.S., exhibited, and made remarks on, about sixty specimens—no two of which were alike—of a species of butterfly belonging to the genus *Hypolimnas*, all of which had been caught by Mr. Woodford near Suva, Fiji, on one patch of Zinnias.—Mr. H. T. Stainton, F.R.S., exhibited, on behalf of Mr. G. C. Bignell, cases of *Thyridopteryx ephemeræformis*, collected near Charleston, U.S.A. Mr. Stainton said he hoped Mr. Bignell would not introduce this pest into England.—Mr. W. F. Kirby exhibited, and read notes on, about twenty species of South African dragon-flies lately received from Mr. Roland Trimen, F.R.S., of Cape Town. The collection included some new species.—Mr. Goss read a letter from Mr. Bignell, correcting a statement made by Mr. Poulton at the March meeting of the Society, to the effect that the variety *Valezina* of the female of *Argynnis paphia* did not occur in Devonshire. Mr. Bignell said that the variety *Valezina* was included in Mr. Reading's "Catalogue of Devonshire Lepidoptera"; and he had himself taken specimens of this variety in Bickleigh Vale, Devon.—Mr. Waterhouse read a paper entitled "Additional Observations on the Tea-bugs (*Helopeltis*) of Java," and exhibited a number of specimens of these insects. He said that the species infesting the Cinchona in Java was supposed to have been introduced from Ceylon in tea, but that he had discovered that the species on the tea and on Cinchona in Java were distinct, and that both species were distinct from *Helopeltis antonii* of Ceylon.—Herr Jacoby read a paper entitled "New, or little-known, species of Phytophagous Coleoptera from Africa and Madagascar."—A letter was read from Mr. E. C. Cotes, of the Indian Museum, Calcutta, asking for the assistance of British entomologists in working out certain groups of Coleoptera, Neuroptera, Orthoptera, Diptera, and Hymenoptera in the Indian Museum. A discussion ensued, in which Mr. McLachlan, F.R.S., Dr. Sharp, Mr. Waterhouse, Herr Jacoby, and Mr. Distant took part.

PARIS.

Academy of Sciences, April 3.—M. Janssen, President, in the chair.—A new theory of the equatorial *coudé* and of equatorials in general (continued), by MM. Lœwy and P. Puiseux. In the present paper the authors deal with the new processes for determining the position of the polar axis, concluding with some remarks on the bend of the arm. Six distinct methods are given for determining the constant n, and five for λ.—Results of comparisons of the standard Peruvian unit of measure and the international metre made by M. Benoit, presented by M. Wolf. From these comparisons, which have been made at the International Bureau of Weights and Measures, it appears that the Peruvian standard is substantially in the same condition as when it was constructed by Langlois in 1735. But it is also made evident that the Peruvian arc, measured with this standard, has been hitherto incorrectly compared with the other terrestrial arcs. In fact it is somewhat shorter than was supposed, and in a future paper the author will point out the consequences to be drawn from this error as affecting the form of the globe.—On the relations of atmospheric nitrogen with vegetable soil, by M. Th. Schlœsing. The author here deals with an objection that might be raised against the results of his previous experiments. The objection is based on the consideration that vegetable humus, like all dead organic matter, is a prey to two different kinds of microbes, one working in the absence, the other in the presence, of oxygen. But the conclusions previously arrived at do not appear to be materially affected by this circumstance.—On the blizzard of March 11 and 12 in the United States, by M. H. Faye. Comparing the public reports with the remarks of Dr. G. Hinrichs, Director of the Iowa Weather Service, the author concludes that a blizzard is a local snowstorm accompanied by an extremely sudden fall of temperature, and controlled by a general cyclonic movement passing over regions subject to great extremes of climate. The phenomenon is analogous to such atmospheric disturbances as the Russian *bora* or *buran*, the *khamsin* or sandstorms of the Sahara, the *föhn* of the Alps, all of which are modified by the different local conditions.—Remarks accompanying the presentation of a work on the Elasmotherium, by M. Albert Gaudry. From the specimens obtained from Russia a more correct idea can now be formed of this huge pachyderm than was hitherto possible. It flourished in the Quaternary epoch, and, notwithstanding several aberrant features, appears on the whole to have somewhat closely resembled the rhinoceros. Surviving till the close of the Glacial period, it became gradually modified, like the elephants and ruminants, to the altered climatic conditions, under which a subtropical vegetation was replaced by herbaceous plants.—On a disposition, by means of which powerful objectives may be employed in meridian observations, by M. G. Bigourdan. By the arrangement here described the great meridian instruments, such as those of Greenwich and Paris, which at present can scarcely observe stars beyond the twelfth magnitude, may be placed on a level with the equatorials.—Observations of the Sawerthal Comet made at the Observatory of Nice with the 0·38 m. Gautier equatorial, by M. Charlois. These observations, covering the period from March 14 to March 21, give the right ascension, polar distance, and other data for the comet and three comparison-stars.—On the velocity of sound, by MM. J. Violle and Th. Vautier. From the experiments here described it is placed beyond doubt that the velocity of the sound-wave diminishes with its intensity; also that the pitch of the sound has no influence whatever on the velocity of its propagation. The slight differences observed appear to be due solely to the different intensities of the sound-wave in the respective cases.—Photographic experiments on the penetration of light in the waters of the Lake of Geneva, by M. F. A. Forel. Comparing his present researches with those of previous years, the author finds that for the chloride of silver the limits of absolute darkness range from 45 metres in July to 110 in March; that the variations in these limits run parallel with those of the limits of visibility; and that the water of the lake is much more limpid in winter than in summer, the difference being mainly due to the greater abundance of organic matter held in suspension during the latter season.—On the latent heats of vaporization for some extremely volatile substances, by M. James Chappuis. The author points out that his own previously announced conclusions have been substantially confirmed by those recently announced by MM. Cailletet and Mathias.—On the laws of chemical equilibrium, by M. H. Le Chatelier. In connection with the discussion on the theory of the thermodynamic potentials, the author here shows how, starting with the hypothesis of MM. Gibbs and Duhem, and employing the same methods, the general formula indicated by M. Van t' Hoff may be established in an extremely simple way.—On the active crystallized matter of the poisoned arrows used by the Somali people, by M. Arnaud. This is an extract from the Wabaio plant, a species of *Carissa*, the poisonous extract from which (wabain) is shown by analysis to be a compound of carbon, hydrogen, barium, and oxygen, with the formula $C_{30}H_{46}O_{12}$.—On the adulteration of olive oils, by M. R. Brullé. A mixture of ordinary nitric acid and the albumen of jerked beef is shown to be an excellent chemical reagent for rapidly detecting the presence of one or more vegetable oils in the olive-oil of commerce.—On a simple and practical method of detecting and analyzing the impurities contained in the alcohols of commerce, by M. L. Godefroy. The reaction here described is extremely sensitive and accurate, detecting a millionth part, or 1 c.c. of impurities in 1000 litres of alcohol.—M. Eugène Dupuy describes some interesting experiments on dogs, cats, and rabbits, in connection with the motor functions of the brain. The results seem to be at variance with the theory usually advanced to explain the mode of production of movements or paralysis originating in the brain.

Astronomical Society, March 7.—M. Flammarion, President, in the chair.—M. Valderrama sent a drawing of a sunspot with white spots in its interior on January 15. M. Schmoll showed a drawing of the same on January 14. According to M.

Trouvelot, this appearance may be explained by a bridge crossing the spot, and sufficiently thin in some parts to escape detection.—MM. Giovannozzi, at Florence, and Bruquière, at Marseilles, sent some observations on the zodiacal light, which has been very bright; M. Gourdet, observations on 66 Ceti; and M. Guiot on Mira Ceti and ν Leporis.—M. Dumenil, at Yebleron, observed a meteor on February 19 whose trace remained visible for five or six minutes.—Observation of a fine meteor at Paris on February 24 by M. Mabire at 7 p.m.—M. de la Fresnaye submitted a plan of binocular telescope with total reflecting prisms to bring the two oculars within convenient distance for the two eyes.—M. Armelin, writing upon the calendar reform, said that it was perhaps entering on a practical phase.—The meeting thanked Mr. Holmes for his letter published in the *English Mechanic*. His observation of the *comes* to Polaris with a 1½-inch is thought remarkable.—M. Flammarion read a paper on a probable connection between the movements of our sun and those of α Centauri.—General Parmentier, reading a paper on the asteroids, remarked that the new planets discovered do not fill up the gaps to which he formerly called attention.—Various communications: on the lunar eclipse of January 28, by M. Moussette; a drawing of Plato, by M. Schmoll; observations on the aurora borealis, by M. Trouvelot; on a natural classification of double and multiple stars, by M. Flammarion; Vogel's chart of stellar spectra, presented by M. Secretan.

BERLIN.

Physical Society, March 16.—Prof. von Helmholtz, President, in the chair.—Doctor Koepsel demonstrated two energy-meters constructed on different principles by Messrs. Siemens and Halske, and explained the arrangements of the same.—Prof. Lampe spoke on a deficiency in elementary text-books of mechanics—namely, that they do not employ the elliptic functions so fully treated of by Gauss and Schellbach. The speaker then showed by a series of examples how easy it is to solve a number of mechanical problems by the use of these functions.—Prof. Helmholtz next showed how the nature of elliptic functions can be made clear to persons unacquainted with them by means of the movement of a pendulum.—He then briefly communicated the results of an investigation by Prof. Töpler, of Dresden, which he had yesterday laid before the Academy of Sciences: it contains a new method for the measurement of the magnetism and diamagnetism of gases. An index drop of petroleum is placed in a glass tube bent at a very obtuse angle; on one side of the index is the gas which is to be investigated and on the other side is atmospheric air. When placed between the poles of a powerful electro-magnet, the index is moved according as the gas is more or less strongly attracted than the air: the amount of displacement is measured by a microscope. The delicacy of the method is extremely great. It was in this way observed that oxygen is most magnetic, then come air and nitric oxide; nitrogen, hydrogen, carbonic oxide, carbonic acid gas, and nitrous oxide, on the other hand, are diamagnetic. The method employed in the above research can also be applied to the solution of various other problems, as, for instance, the determination of the pressure of small columns of gases.

Physiological Society, March 23.—Prof. Munk, President, in the chair.—Dr. Benda spoke on the structure of ganglion-cells, demonstrating at the same time, by means of specimens, his method of hardening the brain and spinal cord, which consists in treating them with nitric acid and potassium chromate. His further communication dealt with certain differences, now largely reconciled, in the results obtained by the speaker and by Prof. Flesch, of Bern, who was present at the meeting. The two observers now agree that certain ganglion-cells readily take up colouring-matter, while others do not, and to these Prof. Flesch attributes a difference in physiological function. Both observers further admit the existence of dark granulations in the protoplasm of the cells, but opinions differ as to the significance of the same.—Dr. Claude du Bois Reymond stated that he had long ago planned an investigation of the pupil when in darkness, and that this intention had only become realizable since the introduction of instantaneous photography by means of the momentary illumination produced by magnesium. Miethe, the discoverer of the method of momentary illumination with magnesium, has in this way taken a photograph of his own pupil after it had been exposed to complete darkness for forty minutes. As shown by the two photographs which were exhibited the result was most surprising: the diameter of the pupil was 9 to 10 mm., while the iris was at the same time reduced to a width of 1½ to 2 mm.—Prof. Gad gave an account of experiments which had been made by Sawyer, at his suggestion, with a view to determining whether the separation of irritability and conducting power, which is so often observed by neuropathologists, has any real physiological existence. When a part of the sciatic nerve, in accordance with Grünhagen's method, was exposed for some time to the action of a current of carbonic acid gas, it was found to be capable of conveying impulses generated by stimuli applied to parts of the nerve more centrally situated, but was itself insensitive to electrical stimulation applied directly to it, as Grünhagen had already found. When that part of the nerve inclosed in the chamber was exposed to the action of diluted vapour of alcohol, the result was exactly the opposite, the conducting power being lost but the irritability retained.—Prof. Gad demonstrated on prepared skulls and on living animals, the curious and scarcely known movements of chewing which may be observed in rats. The incisors of the lower jaw are capable of lateral movement in two halves united together by ligaments, and the larger part of the work done in gnawing is carried on by means of the scissor-like movement of the two incisors. The above has recently been very fully brought to notice by Künstler.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Reports of Geological Explorations during 1885-86-87 (New Zealand).—Système Silurien du Centre de la Bohême, vol. vii. Part 1, Cystidées: J. Barrande (Prague).—Watt's Dictionary of Chemistry, vol. i.: Morley and Muir (Longmans).—A Treatise on Electricity and Magnetism, vol. ii.: Mascart and Joubert, translated (De La Rue).—Elementary Chemistry: W. S. Furneaux (Longmans).—Natural Laws and Gospel Teachings: Rev. H. W. Morris (R.T.S.).—Early Prose and Poetical Works of Taylor, the Water Poet (Hamilton).—Noctes Ambrosianæ: Prof. J. Wilson (Hamilton).—First Lessons in Geometry, 2nd edition: B. H. Rau (Madras).—Abhandlungen der k. b. Gesellschaft der Wissenschaften Math. Naturw. Classe, vii. Folge, 1 Band (Prag).—Perforated Stones from California: H. W. Henshaw (Washington).—Work in Mound Exploration of the Bureau of Ethnology: C. Thomas (Washington).—Education in Bavaria: Sir P. Magnus (New York).

THURSDAY, APRIL 19, 1888.

SCIENTIFIC PROGRESS IN ELEMENTARY SCHOOLS.

A VERY remarkable Report has been received by the London School Board from a Special Committee appointed by it a year ago "to consider the present subjects and modes of instruction in the Board schools, and to report whether such changes can be made as shall secure that children leaving school shall be more fitted than they now are to perform the duties and work of life before them." [1]

The Committee, of which Mr. William Bousfield was chairman, was a strong one, representing well the various sections of the London Board. It has produced a Report of twenty-one folio pages, including no less than thirty-one recommendations, and followed by voluminous minutes of evidence given by scientific men and others, who have paid attention to elementary instruction, teachers of special subjects, inspectors, *employés* of the Board, working-men representatives, and others.

This important document is the outcome of several movements. The London Board has, throughout its existence, endeavoured to promote the teaching of science by means of systematic object-lessons; and has made several attempts to give a more practical turn to the instruction. In December 1884, a previous Special Committee reported on technical education, affirming the principle that it was not the duty of the Board to attempt to teach any particular trades, but that it was its duty so to direct the education of its scholars that they could easily take up any special work afterwards, and suggesting various ways by which this might be promoted. Since then the conviction has rapidly grown in the public mind that the teaching is too bookish; the supremacy of the three R's has been rudely assailed; and many people have asserted that other things, such as Lord Reay's three DR's (drill, drawing, and 'droitness), are equally important.

The Report—starting with this definition of education: "the harmonious development of all the faculties, bodily and mental, with which the child is endowed by Nature," —points out the deficiencies of the present curriculum. It has an earnest paragraph on moral education, and makes various remarks upon the present teaching of history, geography, social economy, and art. But its main criticism is "that the physical or bodily side of education, including the development of muscular strength, of the accuracy and sense of colour and proportion of the eye, and of the pliancy and dexterity of the hand, is almost entirely neglected; and that the mental or brain work, which occupies the great bulk of the time in schools of all kinds, is composed far too much of appeals to the memory only, resulting, at the best, in the retention in the child's mind of a mass of undigested facts, and far too little of the cultivation of intelligence." The Kindergarten principle is strongly approved of, and the first recommendation is: "That the methods of Kindergarten teaching in infant schools be developed for senior scholars throughout the standards in schools, so as to supply a graduated course of manual training in connection with science teaching and object-lessons."

These, then, are the two main directions of progress that are indicated—the knowledge of Nature, and the power of work; the development of the perceptive faculties, and the education of the senses—and these two are to go hand in hand.

Object-lessons are common in elementary schools, but much is said, both in the Report itself, and in the evidence of Sir John Lubbock and other witnesses, in regard to their improvement, and the importance of good collections of objects. Yet it appears from the appendix that only about forty minutes per week on an average are actually given to these lessons in boys' and girls' schools, and we know from the Annual Reports of the British Association on the teaching of science in such schools that the present regulations of the Government Code are actually diminishing the amount of the teaching of geography and elementary science. The Special Committee, therefore, very properly recommend that application be made to the Education Department to grant more freedom of choice in the selection of class-subjects; and that the provision for object-lessons, and lessons on natural phenomena, should be taken into account in boys' and girls' schools in assessing the merit grant, as is the case at present with infant schools. The Scotch Code has within the last few weeks allowed that either elementary science or English may be taken as the first class-subject, which is a hopeful sign of progress. The favourite scientific subjects taught at present in the London schools are animal physiology and algebra; but the Special Committee favour the teaching of mechanics and the fundamental notions of physical science by means of special teachers on the peripatetic plan; and they recommend "that the teaching of all subjects be accompanied, where possible, by experiments and ocular demonstration, and that the necessary apparatus be supplied to the schools."

As to manual instruction, it exists in infant schools wherever Kindergarten exercises are practised, but in boys' schools there is often no practice of the kind except in writing. In London, and perhaps in most large towns, drawing is generally taught, and it is universally allowed that this is at the very foundation of technical instruction. The Committee recommend "that all manual instruction should be given in connection with the scientific principles underlying the work, and with suitable drawing and geometry." Drawing to scale is invaluable for teaching accuracy in work. But drawing does not give the best idea of form, and there is a conventional element about it which puzzles little children. Hence modelling in clay is also recommended. The Board started a class for the use of tools in carpentry at Beethoven Street School, Kensal, but the outlay was disallowed by the Public Auditor. Six such classes, however, are being carried on at the expense of the City Guilds Technical Institute. There is little doubt that the present disability will be shortly removed, and that eventually a work-room or laboratory will become an essential part of every large Board school. How best to give manual instruction is still a matter of discussion and experiment. Good observations about it will be found in

[1] "School Board for London. Report of the Special Committee on the Subjects and Modes of Instruction in the Board's Schools, with Appendices." (Hazell, Watson, and Viney, 52 Long Acre.)

the evidence of Mr. Henry Cunynghame, Mr. Davis, of Birmingham, and Profs. Unwin and Perry. Mr. Ricks, one of the Board inspectors, has drawn out an elaborate scheme for the development of the Kindergarten system throughout all the standards of a school in the directions spoken of.

Girls are more fortunate than boys in the matter of manual instruction. They are taught needlework universally, and very often cookery. The latter may be considerably extended. Domestic economy also in its various branches should be taught, through practical work, and with reference to scientific principles—as in washing, laying fires, and ventilating rooms.

But how is time to be obtained for the introduction of this perceptive and practical instruction? On that point the Committee are very distinct, and there is a singular unanimity among the witnesses that the attention now paid to spelling and grammar is excessive, if not educationally worthless. There is a curious table, too, in the appendix, which gives the results of inquiry as to the subjects of instruction most or least preferred in the various schools. Grammar is so unpopular with both boys and girls that it almost always attains that bad pre-eminence. Spelling or dictation comes second. In fact there is no doubt that the children dislike what they feel does not add either to their pleasure, or their real knowledge. It is proposed "that the time now given to spelling, parsing, and grammar generally, be reduced."

There are two points on which we should have liked to see some recommendations of a more vigorous character. The one refers to the teaching of arithmetic, which as laid down by the Code is thoroughly unscientific. The other point is this: there are recommendations in regard to evening classes, the more extended use of the pupil-teachers' schools, and the grouping together of the upper standards of several schools in poor neighbourhoods; but this might have been carried much further, and have included the establishment of such valuable institutions as the central schools which are doing such good work in many of the provincial towns, especially in the North of England.

Nevertheless, these recommendations, if they are all allowed to take effect, will mark an era in education. The Special Committee are happily able to add: "It is significant that these changes are demanded alike by educational theorists, teachers, men of science, leaders of industry, and statesmen, and it rests with the Board to carry them into actual fact." The Bill of Sir Henry Roscoe, and that on technical education which is promised by the Government, must also have an important bearing on the scientific development of elementary instruction. We await the results of the discussions that must ensue with the deepest interest.

THE NERVOUS SYSTEM AND THE MIND.

The Nervous System and the Mind: a Treatise on the Dynamics of the Human Organism. By Charles Mercier, M.B. (London: Macmillan and Co., 1888.)

THE time may come when the psychological historian will be required to trace the genealogy and career of such terms as "molecular movement," "discharge," "explosion," "unstable matter," as applied to mental operations, as well as the familiar expression "environment." Whoever else may have contributed to their use, they will be traced back in the main to Herbert Spencer. When once the brain was recognized as the organ of mind in a special sense, chiefly through phrenological observations in which Mr. Spencer was himself at one time engaged (he was, if we mistake not, a member of the London Phrenological Society), the physical basis of mind was naturally described in terms applied to material bodies and employed in physics. The combination of atoms forming molecules being regarded as the fundamental element of the substance of the nervous system, molecular movements were correlated with mental operations. Every corpuscle in the gray matter of the convolutions of the brain was regarded as "a reservoir of molecular motion." It followed that the destructive molecular changes of which the granular protoplasm in the corpuscles is the seat were accompanied by a disengagement or discharge of motion. For the purpose of decomposition or waste, the amount of which is the measure of the force evolved, the remarkable supply of blood received by the cerebral convolutions was seen to be necessary; as also for the recomposition or repair which succeeds waste. Spencer drew some of his analogies from chemical explosions, taking for instance the explosion of the percussion cap and powder in a pistol to symbolize the setting up of decomposition in an adjacent ganglion-cell by (in the case of the retina) a disturbed retinal element. He showed that a partially-decomposed ganglion-cell propagates a shock through the afferent nerve to a large deposit of "unstable matter" in the optic centre, "where an immense amount of molecular motion is thereupon disengaged." The transmission of waves of molecular motion through nerve-fibres is compared by Spencer to "a row of bricks on end, so placed that each in falling knocks over its neighbour. . . . Each brick, besides the motion it receives, will pass on to the next the motion it has itself gained in falling."

These and similar propositions have for long become household words. The terms referred to have become a part of psychological, and to a large extent medical, language. One well-known outcome of Spencerian teaching has been its elaborate application to the study of epilepsy, by Dr. Hughlings Jackson, who has been always anxious to acknowledge the source from which he drew his inspiration. Dr. Mercier's book is another stream from the same source. He makes an acknowledgment of similar indebtedness in his preface. We do not think he is justified in his complaint that "the classical works on Mind ignore altogether its association with the body, and study it from a stand-point so purely introspective as to offer no obvious advantage to the alienist, to whom the concomitant disorders of body are so conspicuous and so important." Holding this opinion it became "absolutely necessary" for Dr. Mercier to prepare the present volume. The writings of Bain, Laycock, and Maudsley, no less than Spencer, are nothing if they do not insist upon the association of mind and body. The very last charge that can be fairly brought against these classical works is that they altogether ignore their correlation. The best evidence of the direction and complexion of the teaching of authors of modern works on psychology is contained in Dr. Mercier's statement that "everyone

nowadays admits that the evolution of mind and the evolution of the nervous system proceeded *pari passu*, and indeed are but two aspects of the same process." It is hardly consistent with a further statement that this way of regarding them is not only neglected but "derided and scouted." Dr. Mercier asks for our sympathy for having been for the last ten years as "the voice of one crying in the wilderness." Other voices, however, have for long been heard there, if indeed that can be called a wilderness which is peopled by the number who admit the above-mentioned proposition in regard to the evolution of the mind and the nervous system.

This work expounds Spencerian doctrines with much fulness of diction, and in a style which is forcible, not to say somewhat dogmatic. We find Spencer's illustration of molecular movements from bricks on end reproduced, and we may quote the following passage as a fair example of the author's style :—

"Imagine a brick set up on end. To do this requires the expenditure of force. Now, if the ground is shaken the brick falls, and liberates in falling a force equal to that expended in raising it. Again, imagine a brick set on end with another brick placed across the top of it. The upper brick can now be knocked off the lower, and the force which raised it be liberated, while the lower brick is left standing, with the force that raised it still in store. It is evident that a brick balanced on the top of another one will be displaced by a gentler shake than is required to knock down the single brick. . . . Now suppose more and more bricks are added until we have quite a complicated structure composed of loose bricks. It is easy to see how readily a top brick could be knocked off. . . . Now if we imagine these bricks to be connected to the pile by elastic bases, so that when they have been knocked down they will slowly rise again, with perhaps a little help, to their erect position, we shall have a diagram which will represent very roughly what we suppose to be the mechanism of the nervous discharge" (p. 23).

Dr. Mercier's copious vocabulary clothes an idea in many folds of attire. It is, we think, sometimes overloaded and too diffuse. Endowed with a large organ of comparison, he illustrates his theme with a redundant variety of illustrations or makes one illustration do duty in many forms. Great facility of expression enables him to enforce his views, though it may be at the risk of producing weariness by excessive iteration. He revels in the description of molecules—their form, their relative position, their polarity, their life, their behaviour, and their destiny. M. Renan has been said to know more about St. Paul than the apostle knew himself. Similarly Dr. Mercier would, we are quite sure, be found to know more about the molecules of the brain than, were they gifted with consciousness, they would know themselves. He might write a charming story entitled "The Biography of a Cerebral Molecule." The author divides his subject into three sections: Nervous Process, Conduct, and Mind, the first underlying the other two. In treating of "nervous discharge" he argues that the building up of a molecule implies force ; this remains latent, stored up in the gray matter. It is liberated at intervals—that is, during functional activity. The rearrangement of atoms in the molecule may be called "decompounding," while the process of destruction is more properly termed "decomposition." Thus, then, the former, together with the liberation of force accompanying it, is the "discharge." It tends to spread. How is the liberated force replaced? Dr. Mercier cannot tell. All that can be said is that it is a part of the general system of bodily nutrition. Passing on to "nervous resistance," it is assumed that there is a balance of tension and resistance in the gray matter of the brain. The subject is worked out ingeniously, and as fully as it admits of. Necessarily much is altogether inferential. The hypothetical nature of the doctrines taught by the Spencerian school no doubt deters not a few from adopting them. Such persons say that they are not scientifically proved, and they challenge those who insist on their importance to show that they can practically help the physician in his treatment of mental affections. A homely simile illustrates the doctrine of continuous resistance. A charged soda-water bottle resembles the tension of a charged nerve-cell. Withdraw the cork, and the resistance of the narrow neck causes an intermittent escape. The contents "come blobbing out in a succession of intermittent bursts," and so, according to the author, the narrow necks of nerve-cells—the fibres which proceed from them—cause analogous results.

One chapter is devoted to the co-ordination and inhibition of muscular action. Nervous discharges are regarded in terms of the latter. The discharge of an area of gray matter occasions normal movements. The simultaneous beginning, duration, and ending of muscular action depend upon the simultaneous issue of a current of force to each muscle under its influence (p. 67). The nerves of muscles connnect them with the cells of the gray matter of the brain, and muscular force depends upon the amount of nerve-discharge. Co-ordinated movements are secured by the group of nerve-elements called a nerve-centre. The initiatory impulse may come directly from the outside world—the environment. In some instances, however, this action is indirect and distant, as, when reflection ends in acts set going by "currents starting from the highest centres." To terminate the action set up, another stimulus is necessary, unless exhaustion itself terminates it. Here comes in the element of control or inhibition to which all nerve-centres are presumed to be subject, and by which they are retained in a condition of mobile equilibrium as surely as the planets in their orbits by the opposition of attraction to their own inertia. It is forcibly argued that this influence is derived from centres having other functions, and not from one exclusively set apart for this purpose. Inhibition is, in short, a higher degree or power of the resistance which causes the intermittent escape of nervous force. A wide question is here raised, and there is not as yet a consensus of opinion among physiologists in regard to it. "Movements" are dealt with in much detail. The section on the co-ordination of movements is an elaborate study of the subject. In the discussion of the nervous mechanism of co-ordination and inhibition, occasion is taken to give a minute description of Jacksonian epilepsy. In inhibition the centres which supply the impulse to start and accelerate, supply also the impulse which arrests and retards. In walking, for instance, the centres which actuate and regulate it are so arranged that they control those below, they themselves being under the control of still higher centres. If the action of the head-centre is suspended, the local and vegetative functions

are still performed. There is no paralysis. The early stage of drunkenness is a good example. There is the uncontrolled action of the centres usually subordinate to the highest controlling, but now non-functioning, centre. There is in such an instance, "the withdrawal of the stimulus of frequent positive impulses." In later stages there is something more than temporary suspension or inhibition; there is destruction of the highest centres and actual paralysis. Under "Conduct" Dr. Mercier considers the human organism and the environment along with the adjustment of the former to the latter. He carefully follows the lines of Spencer, and points out that the study of mind belongs neither to the first nor to the second, but only to their adjustment.

Our space does not admit of our following the author in his study of the "Constitution of Mind," in which he endeavours, with, we think, imperfect success, to prove that the feelings cannot be disordered without disorderofthe intelligence. Were this theoretically true, so far from having a "practical bearing of great moment," it would be an instance of an abstract theoretical proposition being, strictly speaking, true, while for all practical purposes experienced alienists tell us they find it necessary to admit a moral insanity with an average amount of intelligence. Alienists will no doubt discuss this and other conclusions stated in the third part of this work, and we leave the task in their hands. The most original portion of the work is that in which Dr. Mercier classifies cognitions and feelings, dissenting as he does from the classification of Spencer in several important particulars, upon which we cannot enter.

There will, of course, be the same criticism on the position taken by the author as is frequently offered to that of his master. True, there is no denial of mind; on the contrary, emphasis is laid upon the absolute distinction between mind and matter; but the complaint will be made that all the functions of life are explained by the brain's molecular and molar action in adjustment to environment, without taking into account the influence of what is admitted to be "mind"—in other words, thought and feeling. The circle, it will be objected, is completed without allowing for the action of at least one important factor. Dr. Mercier, for instance, writes to this effect:—"He who gets himself vaccinated is procuring a change in his constitution adapted to the existence in the outside world of the contagium of small-pox. He is procuring the adjustment of his organism to a set of conditions in his environment." What, asks the objector, is the position of the "he"? In what relation does this personal pronoun stand to the organism? How is it possible to ignore it in the explanation of mental manifestations, or what is called the adjustment of organism to environment?

Dr. Mercier advances no further than his predecessors in enabling us to answer these questions. It does not help us to insist upon the "fathomless abyss" that separates mind from matter. We get no further under his guidance than the "rearrangement of molecules in the gray matter of the superior regions of the nervous system." We are told that no process of change in the latter can cause a change of consciousness. To Dr. Mercier's mind this is "unthinkable"; therefore it is not to be thought of. Equally unthinkable is the proposition that a change in consciousness can cause a change in molecular arrangement. The two changes are, it is said, invariably simultaneous. No doubt, as the author says, the student who grasps these notions has half his difficulties surmounted. To overcome difficulties, however, by evading them and confessing our ignorance is somewhat dispiriting, and some would think pusillanimous. Dr. Mercier, while granting the existence of mind on the one hand, and movements on the other, will neither allow of such expressions as "psycho-motor" nor give us an equivalent; for the terms he himself employs exclude the mental factor altogether, although he is forward to admit its existence. There is a break in the circuit, and yet the latter is presented to us as if it were complete. On the remaining links of the chain, the work before us is a painstaking and connected, and therefore valuable, dissertation. If this missing link can only be postulated, and cannot be brought within the range of practical psychology, it must be acknowledged that the science is defective in a most essential particular. If the relation between mind and matter is unthinkable, it is not alleged that mind is so, and therefore there does not seem to be any scientific objection to the employment of terms which recognize some causal relation between mind and matter. Still less do we find in the employment of such terms the "blasphemy" which so painfully grates upon the psychologically tender conscience and rigid orthodoxy of our author Seeing, moreover, that there is an appreciable lapse of time between an idea or willing, motion, the whole of which need not be occupied in the transmission through nerve-fibres, there seems at least as much justification for using the term "ideo-motor" as many terms which describe or imply a theory which, like Dr. Mercier's own hypothesis, is confessedly inferential. And further, the expression may be, like a host of others, defective in comprehensiveness and precision, and yet be the most easily understood.

In conclusion, we would say that Dr. Mercier's work may be read with profit by the class for which it is intended, so long as it is understood that it treats of only one aspect of the relations between mind and body, and so long as it does not obscure the recognition of those great truths of cerebral physiology and mental pathology, which are not in dispute, and the teaching of which will continue to enlighten the student of psychology, when the theories of the philosophers are exploded or forgotten.

POPULAR METEOROLOGY.

L'Atmosphère—Météorologie Populaire. By Camille Flammarion. (Paris: Librairie Hatchette et Cie., 1888.)

THIS is a re-issue of a popular work that first appeared in the year 1872, and which has been enlarged and brought up to date.

Of all the subjects which are interesting not only to men of science but to people in general, there are few more important than that of the atmosphere, since, without its aërial envelope, our planet would pursue its path round the sun in silence and without life, as is the case with our moon, which bears evidence on its surface of nothing but death and desolation. The existence of an atmosphere makes all the difference in the world to a

cooled star; for, with one, its life is stirred up by millions of beings of various kinds which are always changing, by trees and shrubs and different kinds of plants which adorn its surface and supply man and beast with the food and nourishment necessary to sustain life.

Again, when we consider that, of the myriads of meteorites which people space, twenty millions, with weights varying from tons to the minutest possible specks, are met with by the earth every twenty-four hours, a new function of the atmosphere is revealed, for owing to its buffer-like action they fall harmless, and indeed almost unperceived, on the surface of our planet.

Since a knowledge of the atmosphere and its laws must be of more *service*—though not of greater interest—to those whose lot it is to sail the ocean than to those who sit at home at ease, no country should foster meteorology with more gladness than England, so many of whose subjects are under the influence of the "vital fluid," which the author gives as a definition of the atmosphere.

The volume is divided into six books, each of which contains about eight chapters. In the first book is described the atmospheric envelope, the method of determining its height and chemical composition, finishing with a chapter on sound and the history of the invention and development of the balloon which was tried at Paris in 1884, with some most interesting descriptions of ascents which from time to time have been made, including a table of the highest inhabited places, highest mountains, and the distribution of the various species of birds as regards the height to which they fly.

Light and the optical phenomena of the air are next dealt with. Reflection and refraction are first discussed, followed by the beauties of sunrise and sunset, the grandeur and magnificence of which it is almost impossible to describe. We find that not enough mention is made of the absorptive power of the atmosphere which produces at those times all the most beautiful colours. A very interesting phenomenon is here referred to—a total eclipse of the moon with the sun still above the horizon, which is brought about solely by the refraction of the atmosphere.

Then follow illustrations and descriptions of all the various kinds of rainbows, halos, and mirages which have been seen both on land and at sea.

The third book, which is by far the largest and most important of all, is on temperature. When we come to consider the enormous amount of solar heat that is poured on to the earth's surface, we may have some idea of the work which our atmosphere is continually doing for us. The atmosphere, as the author says, is in truth a huge machine, on whose action everything on our planet which has life is dependent. There are in this machine neither wheelwork, pistons, nor cogs, nevertheless it does the work of several millions of horses, and this work has for its end and effect the preservation of life.

Next we come to the waters of the earth, which play one of the greatest parts in the working of the atmosphere. All day long, and every day, water is being carried away from the earth's surface in the form of vapour, and it is chiefly in this way that the action of the sun's rays on the face of our planet is reduced. The amount of water evaporated each year, as the author states, amounts to 721 billions of cubic metres. The enormous quantity of heat which has produced this effect could melt per year eleven thousand millions of cubic metres of iron, a mass whose volume would exceed several times that of the Alps. Following this are some very interesting chapters on the seasons, containing a great many tables of the highest and lowest barometric and thermometric readings which have been taken at various places, concluding with an account of the distribution of the temperature on the surface of the globe.

The wind and general circulation of the atmosphere are the subjects of the next book, including a chapter on ocean currents, showing how the wind is influenced by them. The course of the Gulf Stream, which plays such an active part with the climate of various places, and is the most important of all currents, is here described, with a map showing its course and that of various other currents. The atmosphere, as we know, is threaded with winds, as the sea is with currents, some of which are more or less constant, others variable. But there are still other kinds of winds, especially those that characterize certain countries and certain parts of the ocean, which are more violent and destructive than the ordinary kind, such as cyclones, the simoom, &c.

In the next book the various forms and kinds of clouds are described, and illustrated by splendid coloured plates, which give very good ideas of their form, with the results obtained by M. N. Ekholm, of Hagström, of the heights of the various forms of clouds. This will be read with great interest in connection with Mr. Ralph Abercromby's latest observations.

Electricity and the various forms and ways in which it appears in our air are discussed in the sixth and last book; the aurora, the most curious and most beautiful of all forms which are assumed by it, being fully treated. These wonderful displays, which are seen to perfection in the Polar regions, and which during the long winter there tend to change its monotony by shooting forth brilliant rays of light, and illuminating a region which would otherwise be in darkness, are here described in a graphic manner, woodcuts and coloured plates illustrating the various forms they assume.

The concluding chapter is on the prediction of weather—a subject which at the present day is carried on to such a great extent, and which to a country such as ours is invaluable in giving us warning of storms that would otherwise come upon us and do much destruction.

The volume is thoroughly well written. It is profusely illustrated throughout, and there are fifteen plates printed in chromotypography and two hand-coloured plates. No pains seem to have been spared to make it an intellectual and enjoyable book; the object having been to produce a work giving a broad outline of the various causes of every-day occurrences in the atmosphere.

W. L.

OUR BOOK SHELF.

Life in Corea. By W. R. Carles, F.R.G.S. With Illustrations and Map. (London: Macmillan and Co., 1888.)

THIS is a valuable and interesting account of a country about which little definite knowledge has hitherto been accessible. There are some aspects of his subject with which Mr. Carles does not profess to deal. Apart from such incidents as happened before his own eyes, he has

nothing to tell us about the system of government, or the relations between the king and his nobles, the people and the serfs, in Corea. On the other hand, he gives a full and sometimes a very vivid account of everything he himself had opportunities of directly and carefully studying, and his book is worthy of serious attention, mainly because it consists of the results of his own personal observation. Mr. Carles went to Corea for the first time in 1883, when he not only visited the capital, Soul, but undertook, with some friends, an interesting journey inland. The object of this excursion was the inspection of a silver working, which proved to be very unworthy of its reputation. The scenery, Mr. Carles says, never failed to charm, and the people were invariably civil. At Soul he had some difficulty in obtaining anything really characteristic of native taste and skill. In the curio shops the only distinctly native article seemed to be a kind of iron casket inlaid with silver, the pattern of which was sometimes very delicate. In the spring of 1884, Mr. Carles took up his quarters at Chemulpo as H.M. Vice-Consul in Corea; and one of the best chapters in the book is that in which he sums up his impressions of Chemulpo and the neighbourhood, bringing together various facts of scientific interest, and indicating problems as to tidal and other phenomena about which he is still uncertain. In this chapter Mr. Carles offers a suggestion which is certainly worthy of the attention of men of science. He says:—

"With so much of interest on all sides, I could not help regretting that no information was ever asked for by the outside world on points which the opening of Corea would be likely to clear up. It seemed impossible that one could not be of use to some science in collecting facts which had hitherto been unattainable; but apparently consular officers are not consulted except on commercial questions. If scientific men would follow the example set by Chambers of Commerce, and ask for information which they expect to be within the reach of out-of-the-way posts, they would generally confer a boon on the officer by giving him a new special interest, and they might sometimes learn what they sought for."

Early in September 1884, Mr. Carles received instructions to undertake a journey along the high road from Soul to China, as far as the frontier town of Wi-ju; then from Wi-ju eastwards across the mountains to Kong-ge; thence south to Gensan, on the east coast; and from Gensan to Soul. In the course of this journey he watched closely for any indication of conditions favourable to industry and trade, but his observation did not lead him to take a sanguine view of the immediate future of the Coreans. Displaying little enterprise, they are extremely poor, and the prevailing opinion among them seems to be that the Government alone is capable of doing anything for the improvement of their circumstances. At Song-do, the old capital, admirable pottery used to be made, but when the seat of the government was transferred to Soul, the trade fell off, "and the workmen, refusing to follow the Court, gradually abandoned their industry, the knowledge of which has now been forgotten." Speaking of the religion of the Coreans, Mr. Carles says that, although Buddhism has been under a ban during the supremacy of the present dynasty, there is hardly a mountain valley off the main roads in which there is not a Buddhist temple; and often he came across figures of Buddha carved in relief on rocks. Fetichism still survives, and is manifested, among other ways, in the presentation of offerings to particularly fine trees. Mr. Carles gives an account of a conspiracy which caused serious trouble at Soul in 1884; and in a concluding chapter there are some careful notes on the Corean language. The interest of the book is greatly increased by the illustrations, which are mostly reproductions of some paintings in sepia by a Corean artist at Gensan.

Navigation and Nautical Astronomy. Compiled by Staff-Commander W. R. Martin, R.N. (London: Longmans, Green, and Co., 1888.)

THIS book, which has been accepted by the Lords Commissioners of the Admiralty as a text-book for the Royal Navy, is one that has been wanted for some time, as it contains the whole theory and practice of nautical astronomy in one part. The method of arranging the various problems is very good. The theory of a problem is always proved first, then the problem is worked in a theoretical manner, and lastly in the manner used by navigators, so that one gets everything to do with any one problem in two or three pages, whereas most books on this subject are divided into two parts, a theoretical and a practical. The method adopted by Staff-Commander Martin ought to prove a great advantage to all persons using his book, more especially beginners. The work is divided into two parts, the first being devoted to the various methods of fixing ships' positions by the land, and of navigating a ship by what is known as "dead reckoning." In this part also the various methods of chart construction are very fully explained, and it ought to be mentioned, for the information of naval officers, that the examples relating to charts are as much as possible arranged to be used with the "Officers' Atlas," which is supplied to each man-of-war. The examples ought therefore to be of great service to junior officers. The second part treats of the theory and practice of nautical astronomy; the method of arrangement we have already described. The volume is accompanied by the requisite charts and diagrams.

H. C. L.

A. Johnston's Botanical Plates. (Edinburgh: A. Johnston, 1888.)

THESE are coloured plates, 35 × 25 inches in size, intended for use in elementary schools. In the first instalment of nine plates, members of the following natural orders are shown: Ranunculaceæ, Papaveraceæ, Linaceæ, Acerineæ, Solanaceæ (two examples), Scrophulariaceæ, Corylaceæ, and Liliaceæ. The plants already illustrated appear to have been chosen at random, but when the series is completed a fair representation of the more important orders will no doubt be provided. The plates are well executed and boldly coloured, so that the chief external characters of the plants shown will be sufficiently obvious to the class. Some details of the structure of the flower have also been given, but these figures are rather meagre. Still, this is not a serious objection, as the chief aim of botanical teaching in elementary schools must always be to teach children to know plants by sight. For this purpose these plates, judging from the few already published, seem admirably adapted.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Injuries caused by Lightning in Africa.

IN a copy of NATURE published on December 11, 1884 (vol. xxxi. p. 127), I noticed a statement by Herr von Danckelman that in all the publications relating to Africa, accounts of injuries caused by lightning are so rare that he scarcely found any literature concerning the use of lightning-conductors or the frequency of accidents caused by lightning in the tropics. After an unbroken residence of twelve years in the Egyptian Equatorial Province, I can give to your meteorological readers a little information on the subject in question, and I venture to submit

the following list of injuries which occurred during the years 1878–86. It must, however, be understood that this is not to be regarded as a complete list of the accidents which occurred, for during the years 1878–80 I was nearly always travelling about, and was therefore unable to collect information of a satisfactory character.

Year.	Name of station.	Lat. north.	Description of accident.
1884 ...	Bor	... 6 12 ...	Man killed; house burnt.
1880 ...	Lado	... 5 1 ...	Tree felled.
1882 ...	,,	... ,, ...	Man killed.
1886 ...	,,	... ,, ...	Two empty houses burnt.
1883 ...	Redjaf	... 4 44 ...	Two men badly burnt.
1886 ...	,,	... ,, ...	Woman killed.
1883 ...	Wandi	... 4 46 ...	Flagstaff felled; man bruised.
1882 ...	,,	... ,, ...	House burnt.
1880 ...	Kabajendi	... 4 37 ...	Storehouse burnt.
1883 ...	Muggi	... 4 8 ...	Two girls killed.
1885 ...	,,	... ,, ...	House burnt; girl paralyzed.
1881 ...	Labore	... 3 55 ...	Two boys killed.
1879 ...	Chor Aju	... 3 48 ...	Tree felled.
1881 ...	Dufilé	... 3 34 ...	House, with sheep, burnt.
1883 ...	,,	... ,, ...	Tree felled.
1883 ...	Wadelai	... 2 37 ...	House burnt.
1883 ...	,,	... ,, ...	House, with calves, burnt.
1878 ...	Magungo	... 2 14 ...	Woman killed.
1880 ...	Mahagi	... 2 2 ...	Flagstaff felled.
1878 ...	Kiroto	... 2 ...	Tree felled.

Captain Casati reports—

1881 ...	Neolopo (Monbuttu)...	Man badly burnt.
1886 ...	Djuaia (Unyoro) ...	Woman killed.
1886 ...	,, ,, ...	One man killed; one burnt—died in two days.
1886 ...	,, ,, ...	Tree felled near observer's house.

These cases were all observed in our stations, with the exception of two—one occurring in Wandi, in December 1882, and one in Redjaf, in November 1886. They all took place in the rainy, that is to say, in the cooler season. From the list you will see that two or three times every year we suffer some damage from lightning-strokes. It therefore does not appear that these accidents are so rare as Herr von Danckelman supposes, at least in this part of Africa, and if travellers do not report such accidents, it is probably because of their short stay in definite places. I noticed, in Schweinfurth's "Im Herzen von Africa," i. pp. 345–46, that six women were killed by a single flash of lightning. I may be also permitted to remark that in Unyoro and Uganda, countries which have a greater elevation than our own, the frequency of destructive lightning-strokes is much greater. Uganda is the only country boasting of a lightning-conductor. Mr. A. M. Mackay has erected one there, to protect King Mwanga's palace. Monbuttu, too, although having a lower elevation than Uganda and Unyoro, is celebrated for the frequency of accidents caused by lightning.

In more northern latitudes—namely, at Fashoda, Khartum, and Berber—destructive lightning-strokes are nearly unheard of, whilst in Sennar they are not altogether infrequent.

It is curious to notice that the Sudan Arabs have firmly conceived the idea that with every flash of lightning a piece of meteoric iron is thrown to the earth. They believe that whoever is able to secure such a piece of iron has gained a great treasure, because they think that swords and knives made out of it can never be surpassed in quality, and that their possession gives immunity from danger in battle, and affords protection against lightning-strokes. Sheik Nasr, who is the Chief of the Takkala Mountains, is said to have resisted all Egyptian attacks, and preserved his and his people's independence, on account of his possession of such a sword. Another superstition is, that fire kindled by a flash of lightning cannot be extinguished until a small quantity of milk has been poured over it. There seems to be some connection between these beliefs, inasmuch as water is believed to spoil meteoric iron: when working it, the blacksmith uses milk instead of water.

EMIN PASHA.

An "Instructive" Bibliography of the Foraminifera.

UNDER the title of "The (!) Bibliography of the Foraminifera," a remarkable production was published by Mr. Anthony Woodward in the *Fourteenth Annual Report of the Geographical and Natural History Survey of Minnesota* (St. Paul, 1886), and the work has lately been followed by a supplement—one of a series—in the *Journal of the New York Microscopical Society* for January 1888. Had the compiler not issued this supplement, previous criticisms might have sufficed, but, as he has again produced an extraordinary and untrustworthy list, it is incumbent on us to bring the work and its demerits before the notice of those who may be tempted to expect good results from using it.

"The" Bibliography, as it first appeared, occupied some 120 pages of the Minnesota Report, and it was hailed with some satisfaction. When put to the test, however, it was found to be absolutely untrustworthy—dates, pages, volumes, and other important details being incorrect. It therefore became necessary for the worker to see and examine every unknown or new entry, and to correct when necessary. The result fully justified this labour, for the whole thing was soon found to be comparatively useless in its uncorrected condition. To begin with, it was evident from the number and nature of the typographical errors that the proofs had not been corrected. Apart from this, however, there are more serious defects, for which excuse must be difficult. The compiler uses freely Mr. Brady's excellent bibliography appended to the *Challenger* Report on the Foraminifera, but he does more—he reproduces in his lists precisely the same printers' errors that appeared in Brady! It is therefore evident that the American compiler neither saw the books he entered in his lists, nor troubled to verify the entries. Here are a few examples:—

P. 251.—Terquem's papers on the Foraminifera of the Oolitic series. "Pt. 1, in the *Bulletin de la Soc. d'Histoire Nat. du Dép. de la Moselle*, 1868; the remainder published by the author." Some of these "remainder" were published in the *Mém. Ac. Imp. Metz*, and it is so stated on the separate copies.

P. 271.—Neugeboren, J. L. Bericht zu den in den Jahrg. LII. und LIII., &c. This is nonsense, it was a printer's error for I., II., and III. In the same entry Brady gives a wrong volume; Woodward does the same!

P. 224.—Reade, J. B. Mr. Brady gives a wrong date; Mr. Woodward copies him, and does the same.

The names of authors form another stumbling-block. Some of these are positively offensive.

P. 196.—Karrer, F., L. F. Pourtales, &c. Two papers, both on the same page in Brady. The paper quoted should read Pourtales, L. F.

P. 218.—King, Wm. This is true, but if the paper had been consulted, the compiler would have found that the Foraminifera were described by Jones, T. R., in King, Wm., &c.

P. 225.—Seguenza. This paper was written by Brady on Seguenza's genus!

P. 226.—Stewardson, G. This author is probably Dr. George Stewardson Brady, F.R.S.!

P. 227.—Thompson, W. Sir C. Wyville Thomson is confused with a somewhat obscure author of fifty years ago.

P. 266.—Jozsef-tol, S. Can one believe that this is the compiler's serious attempt at Dr. Jozsef Szabo, of Budapest!

In all these cases, and numerous others besides, it would have been to the compiler's credit if he had placed "[not seen]" at the end of his entry, for it is surely far worse to acknowledge acquaintance with papers, and to quote them thus carelessly, than to have never seen them at all.

The next offence is the frequent duplication of entries. The following examples will suffice:—

Pp. 228, 229.—Wallich on the Radiolaria as an order of the Protozoa. A reference to the *Pop. Sci. Rev.* would have shown this.

P. 244.—Leymerie, Mém. sur le terrain à Nummulites, &c. Again a reference would have shown these entries to be the same.

P. 268.—Koch, Ueber einigen, &c. The same remark applies to this as to the last, and indeed to all similar carelessnesses.

The quotation of *notices* of papers from various scientific journals, unaccompanied by references to the original places of

publication is a frequent and a grossly careless error, for in every case the information is forthcoming. Examples are :—

P. 225.—Siddall, NATURE, vol. xv.—instead of *Annual Report Chester Soc. Nat. Sci.*

P. 230.—Williamson, NATURE, vol. xvii.—instead of *Proc. Manchester Lit. Phil. Soc.*

P. 250.—Suess, *Quart. Journ. Geol. Soc.*, xxvi.—instead of *Verh. k. k. geol. Reichs.*

Moreover, the hopeless nature of his published errata may indicate that the author was somewhat ashamed of his work, and it is difficult to understand why the book was not stopped and reprinted, before it was allowed to pass into circulation.

Enough has now been said of the original work—that is, the first attempted list ; we will now pass on to the supplement I. In this, at least, we might have hoped that the compiler would have profited by experience, and used more care. There is certainly a difference in the proportion of typographical errors, but such details as volumes are still rather wild (*Bull. Soc. Géol. France*, for 1886, is quoted here and there as vol. x., xiv., &c.). We gather from the perusal of his supplement many things we could not understand in the original work. We recognize that the compiler is neither a born bibliographer, nor acquainted with scientific literature. We observe with satisfaction that the words "[not seen]" occur more frequently than in the earlier work, but can it be possible that the author has seen a copy of Silvestri's paper noted on p. 62? It is exceedingly rare, it does not exist in English libraries, and the writer of this has only seen two copies, both of which were sent to him from Italy. It would have been interesting to learn the pagination of so scarce a paper : the title as it at present stands is strongly suggestive of a bookseller's catalogue. And surely it was worth the compiler's while to quote Ehrenberg properly (p. 65) while the book was presumably lying open before him? The book also is known as "*Monatsbericht*" not "*Verhandlungen*," that is a secondary title. A very careless error is seen on p. 57, where *Orbitolina conoidea*, Alb., and *O. discoides*, Alb., are quoted. The original gives Albin Gras as the authority, whose paper on the subject, moreover, is well known. There should not have been confusion here. On pp. 64, 65, 71, 72, and 74, the same careless duplication of entries occurs as seen in the first attempted bibliography. But worse than all, perhaps, is the rendering of different versions of the title of one publication. A good instance of this is seen on pp. 66, 67, where six variants of *Verh. k. k. geol. Reichs.* are used, some (*Ver. K. K. Geol.*) being quite unintelligible to the uninitiated. On p. 72 we see two versions of *Ann. Soc. Belge Microsc.*, and only those familiar with the book would recognize readily "*Vierteljahrsschrift d. Zür. Natur. Gesellsch.*" (p. 74), with its chief word abbreviated. The compiler should remember that there is no necessity to quote, but, if he quotes, he should quote correctly.

It is needless to waste space on such clumsinesses as Prof. Wm. King, S.C.D. (? D.Sc.) (p. 1), or *Jahrbuch. Geol. Reicht.* It is also advisable to have some method even in printing. The compiler of this list uses roman and *italics* indiscriminately for titles of works (p. 71, Steinmann—where more prominence is thus given to the review than to the original work), while on p. 63, in the entry Alth, the word *Rozprawy* begins the title of the book, and has nothing whatever to do with the title of Dr. Alth's paper.

Many of these errors and defects might have been avoided had the compiler been accustomed to public libraries, or even endeavoured to find out the common books of reference, always at hand in these places. No bibliographer should ever think of working in scientific literature without his Carus and Englemann, his Scudder, and his Bolton, and for an American to omit to do so is sinful. No greater mistake was ever made by a writer than that made by the compiler, when he wrote in his preface that he had enjoyed facilities not enjoyed by many scientific students, those facilities afforded by the great public libraries of New York. We know what the resources of those libraries are, and the production which calls for this letter does not shake our faith in them. "Instructive" this bibliography certainly is, but not in the sense intended by its compiler.

CHAS. DAVIES SHERBORN.

Density and Specific Gravity.

MAY I ventilate a point in mechanical definition which has perplexed students within my experience—the use of the words density and specific gravity?

We are usually told that the quantity of matter in a body—as it is now called, the mass of the body—is proportional to the volume and density conjointly. This is Newton's definition of density (see also Thomson and Tait's "Natural Philosophy," § 208). Thus, if M be the mass, V the volume, and ρ the density of a body, we have—

$$M = \rho V \quad . \quad . \quad . \quad . \quad . \quad (1)$$

if the unit of mass be taken as the unit of volume of a substance of standard density.

Again, we are told that specific gravity is the ratio of the weight of the given body to the weight of an equal volume of some standard substance (Besant's "Hydrostatics and Hydrodynamics," § 13). Since weights are simply proportional to masses, it follows that the numerical values of specific gravities and densities are exactly the same. It would seem better, under these circumstances, to use one word only to express the one physical property. Accordingly, we find that specific gravity is disappearing from many of our best books (I think from Thomson and Tait's "Natural Philosophy," for example), though it still holds its place to puzzle students in examinations, and therefore teachers are compelled to make the best of it they can.

But this is not the whole evil. The definition of specific gravity is usually followed by the equation—

$$W = sV \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where W is the weight, s the specific gravity, and V the volume of the body. This equation is, no doubt, usually accompanied by the caution that the unit of weight chosen is not the unit of force proper to other dynamical equations, and for this reason the equation

$$W = \rho V g \quad . \quad . \quad . \quad . \quad . \quad (3)$$

is far to be preferred.

If equation (2) is of practical value, would it not be as well to define specific gravity in accordance with it, and say that specific gravity is the weight of unit volume of the substance? Thus, the specific gravity of water would be expressed by 62·5 lbs. avoirdupois in British units, or by 1 gramme in C.G.S. units. I believe this would have the advantage of conveying a perfectly definite idea to minds which dislike such abstractions as mass and density.

L. CUMMING.

Rugby, March 31.

"Coral Formations."

MR. MELLARD READE last week (April 5, p. 535) pointed out an error in my calculations which I had myself discovered when too late, and had intended to correct in sending you a further note on some experiments which are now in progress.

Mr. Reade seems to make use of my arithmetical blunder, and apparently attempts to discredit my experiments, and the new views as to coral-reef formations ; but I leave the matter to those who have a practical knowledge of the subject.

The corals experimented upon were of the class known as hard corals, and consequently the amount dissolved must be much smaller, I imagine, than that dissolved from the softer varieties, such as Porites. The first experiment (p. 462) gives the highest result, but I have no reason to doubt that the rate of solution deduced therefrom is far below that actually taking place in the tropical areas of the Pacific and Indian Oceans.

I do not consider that Mr. Reade has given an answer to Mr. Irvine's pertinent question, though he would have it appear that an answer is patent to everyone, and he must not take up your space with such a trivial matter.

Mr. Murray, speaking of his tow-net experiments in his Royal Institution lectures, says :—"I give this calculation more to indicate a method than to give even the roughest approximation to a rate of accumulation of deposits. The experiments were too few to warrant any definite deductions" ; and he is evidently satisfied that we have no knowledge, other than relative, as to the rate of accumulation of calcareous deposits.

It is at once evident to all who have used the tow-net, that Mr. Murray's experiments afford a very slender basis for calculations. Probably not more than one-fourth of the water in the track of the tow-nets actually passed through the nets, and not more than one-half of the organisms that entered them were retained ; the Coccospheres, Rhabdospheres, and small Foraminifera, for instance, passing through and escaping with the

water. Then, Mr. Reade supposes all the organisms in the bulk of water taken to die and fall to the bottom each day. Mr. Murray, in his calculations, supposes only one-sixteenth part to die each day. From the same data the former makes out a rate of accumulation of deposit of 1 inch in 29 years, the latter a rate of 1 inch in 470 years. Dana estimates the growth of a reef at not greater than one-sixteenth of an inch in one year, *i.e.* 1 inch in 16 years. Yet it will be admitted that a reef must grow much more rapidly than a deep-sea deposit. What then would justify us in accepting these figures as in any way representing what is now taking place in Nature? The fact is we much want definite information on the rate of growth of these calcareous deposits, and if Mr. Reade has the information his language would warrant, he should make it known for the benefit of science.

We know that these deposits do accumulate to hundreds of feet in thickness in some places, notwithstanding solution; and it seems to me that, as we can imitate in the laboratory the conditions of solution while we cannot those of secretion by organisms, then by experiments in this direction we may at least arrive at a knowledge of the minimum rate of accumulation of oceanic calcareous deposits. JAMES G. ROSS.

14 Argyll Place, Edinburgh, April 14.

Bernicle Geese on Coniston Lake.

THIS afternoon while walking by this lake I saw four large birds flying overhead. These birds, after making several circuits in the air, pitched on the lake. I had with me an excellent pair of field-glasses, and as I succeeded in approaching within 20 yards of them, I was enabled to examine them with sufficient accuracy to convince me that they were Bernicle geese (*Anser leucopsis*, Yarrell). What struck me as most worthy of remark was their extreme tameness, as they allowed me, first on land, and then in a boat, to approach within 20 yards of them. They were in excellent plumage, and seemed in good condition. After remaining about three hours swimming about on the lake, they rose, and after circling round once or twice, flew off in a northerly direction.

May I ask if this is a rare bird to see in the Lake District at this time of year? I have inquired in the neighbourhood, and do not think they could have come from any private water. Several people who have been here for many years assure me they have never seen this bird on the lake before, and this has certainly been my own experience. Is it possible their extreme tameness was due to fatigue? WILLIAM R. MELLY.

Tent Lodge, Coniston Lake, Lancashire, April 8.

The Muzzling of Oysters.

THIS practice, described in the current number of NATURE (p. 572) as owing "its existence to a careful study of the habits of the bivalve," is by no means new, though probably original on the part of the American naturalists. Our London fishmongers have muzzled oysters on a large scale from a time that is immemorial among them. Barrelled oysters are all very carefully muzzled, but without wires, as anybody may learn by watching an expert in the process of barrelling. It will be seen that he lays the oysters one by one carefully in tiers up to the top of the barrel, and then lays another tier rising *above* the level of the top. Having done this, he places the lid of the barrel on this exuberant tier, and thumps and rattles the barrel on a stone pavement or other solid ground until, by close packing of the whole, it descends to the level of the barrel top. The mass of oysters being thus compressed so as to render the slightest gaping of any one quite impossible, he firmly nails down the head of the barrel.

Experience has proved that oysters thus effectively muzzled may take long slow journeys (as they did in the old coaching days) and be kept fresh and without loss of flavour for two or three weeks, provided the barrels are unopened. If, however, they are loosely barrelled, a few days are too many. In some old country houses the barrels, unopened, were placed in salt water, and thus kept until required, but whether this was advantageous I cannot say.

W. MATTIEU WILLIAMS.

The Grange, Neasden, April 13.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

I.

I.—PROBABLE ORIGIN OF SOME OF THE GROUPS.

I. NEBULÆ.

IN a paper communicated to the Royal Society on November 15, 1887, I showed that the nebulæ are composed of sparse meteorites, the collisions of which bring about a rise of temperature sufficient to render luminous one of their chief constituents—magnesium. This conclusion was arrived at from the facts that the chief nebula lines are coincident in position with the fluting and lines visible in the bunsen burner when magnesium is introduced, and that the fluting is far brighter at that temperature than almost any other spectral line or fluting of any element whatever.

I suggested that the association or non-association of hydrogen lines with the lines due to the olivine constituents of the meteorites might be an indication of the greater or less sparseness of the swarm, the greatest sparseness being the condition defining fewest collisions, and therefore one least likely to show hydrogen. This suggestion was made because observations of comets and laboratory work have abundantly shown that great liability to collision in the one case, and increase of temperature in the other, are accompanied by the appearance of the carbon spectrum instead of the hydrogen spectrum.

The now demonstrated meteoric origin of these celestial bodies renders it needful to discuss the question in somewhat greater detail, with a view to classification; and to do this thoroughly it is requisite that we should study the rich store of facts which chiefly Sir William Herschel's labours have placed before us regarding the various forms of nebulæ, with the view of ascertaining what light, if any, the new view throws on their development.

To do this the treatment must be vastly different from that—the only one we can pursue—utilized in the case of the stars, the images of all, or nearly all, of which appear to us as points of light more or less minute, while, in the case of the nebulæ, forms of the most definite and, in many cases, of the most fantastic kind, have been long recognized as among their chief characteristics.

It will at once be evident that since the luminosity of the meteorites depends upon collisions, the light from them, and from the glow of the gases produced from them, can only come from those parts of a meteor-swarm in which collisions are going on. Visibility is not the only criterion of the existence of matter in space; dark bodies may exist in all parts of space, but visibility in any part of the heavens means, not only matter, but collisions, or the radiation of a mass of vapour produced at some time or other by collisions. The appearances which these bodies present to us may bear little relation to their actual form, but may represent merely surfaces, or loci of disturbances.

It seemed proper, then, that I should seek to determine whether the view I have put forward explains the phenomena as satisfactorily as they have been explained on the old ones, and whether, indeed, it can go further and make some points clear which before were dark.

To do this it is not necessary in the present paper to dwell at any great length either on those appearances which were termed *nebulosities* by Sir William Herschel or on irregular nebulæ generally; but it must be remarked that the very great extension of the former—which there is little reason to doubt will be vastly increased by increase of optical power and improvement in observing conditions and stations—may be held to strengthen the view that space is really a meteoritic plenum, while the forms indicate motions and crossings and interpenetra-

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S.

tions of streams or sheets, the brighter portions being due to a greater number of collisions per unit volume.

When we come to the more regular forms we find that they may be generalized into three groups, according as the formative action seems working towards a centre, round a centre in a plane, or nearly so, or in one direction only; as a result we have globular, spheroidal, and cometic nebulæ. I propose to deal with each in turn.

Globular Nebulæ.

The remarkable appearance presented by the so-called planetary nebulæ requires that I should refer to them in some detail. Sir William Herschel does not describe them at any great length, but in his paper on "Nebulous Stars" he alludes to the planetary nebulosity which in many cases is accompanied by a star in the centre, and finally comes to the conclusion that "the nebulosity about the star is not of a starry nature" (Phil. Trans., vol. lxxxi. p. 73, 1791).

Sir John Herschel, in his valuable memoir published in Phil. Trans., 1833, describes them as "hollow shells" (p. 500). It was so difficult to explain anything like their appearance by ordinary ideas of stellar condensation that Arago, as quoted by Nichol ("Architecture of the Heavens," p. 86), abandoning altogether the idea that they represented clusters of stars or partook in any wise of a stellar constitution, imagined them as hollow spherical envelopes, in substance cloudy and opaque, or rather semi-transparent; a brilliant body invisible in the centre illuminating this spherical film, so that it was made visible by virtue of light coming through it and scattered by reflection from its atoms or molecules. The mystery was explained to a certain extent by Lord Rosse, who (Phil. Trans., 1850, vol. cxl. p. 507) states that nearly all the planetary nebulæ which he had observed with his colossal instruments up to that time had been found to be perforated. In only one case was a perforation not detected, but in this ansæ were observed, introducing into the subject for the first time the idea of nebulous bodies resembling to a certain extent the planet Saturn. But Lord Rosse, although he thus disposed of the idea of Arago, still considered that the annular nebulæ were really hollow shells, the perforation indicating an apparently transparent centre.

Huggins and Miller subsequently suggested that the phenomena represented by the planetary nebulæ might be explained without reference to the supposition of a shell (or of a flat disk) if we consider them to be masses of glowing gas, the whole mass of the gas being incandescent, so that only a luminous surface would be visible (Phil. Trans., vol. cliv. p. 442, 1864).

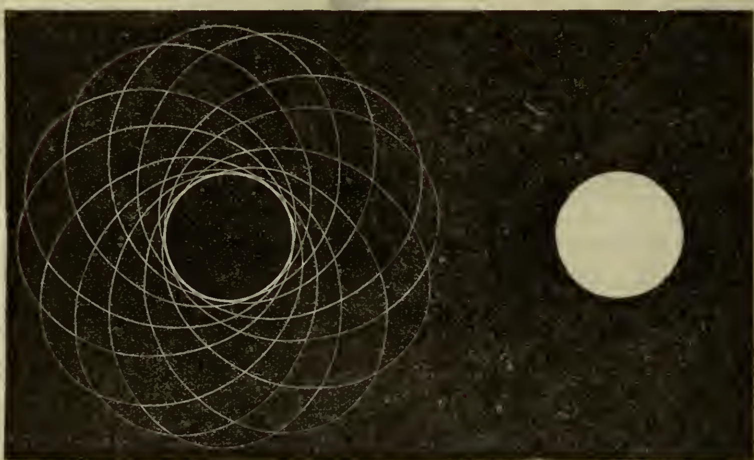

FIG. 1.—Suggested origin of the appearance presented by a planetary nebula. The luminosity is due to the collisions occurring along the sphere of intersection of the elliptic orbits of the meteorites. The left-hand diagram is a cross-section of the meteoric system, and the right-hand one shows the appearance of the collision shell as seen from a point outside.

It will be seen that all these hypotheses are mutually destructive; but it is right that I should state, in referring to the last one, that the demonstration that these bodies are not masses of glowing gas merely has been rendered possible by observations of spectra which were not available to Messrs. Huggins and Miller when their important discovery of the bright-line spectrum of nebulæ was given to the world.

It remains, then, to see whether the meteoritic hypothesis can explain these appearances when it is acknowledged that all the prior ones have broken down. Let us for the sake of the greatest simplicity consider a swarm of meteorites at rest, and then assume that others from without approach it from all directions, their previous paths being deflected. There will be at some distance from the centre of the swarm a region in which collisions will be most valid. Meteorites arrested here will begin to move in almost circular orbits round the common centre of gravity.

The major axes of these orbits may be assumed to be not very diverse, and we may further assume that, to begin with, one set will preponderate over the rest. Their elliptic paths may throw the periastron passage to a considerable distance from the common centre of gravity; and if we assume that the meteorites with this common mean distance are moving in all planes, and that some are direct and some retrograde, there will be a shell in which more collisions will take place than elsewhere. *Now, this collision surface will be practically the only thing visible, and will present to us the exact and hitherto unexplained appearance of a planetary nebula—a body of the same intensity of luminosity at its edge and centre—thus putting on an almost phosphorescent appearance.*

Such a collision surface, as I use the term, is presented to us during a meteoric display by the upper part of our atmosphere.

I append a diagram, Fig. 1, which shows how, if we thus assume movement round a common centre of gravity in a mass of meteorites, one of the conditions of movement being that the periastron distance shall be somewhat considerable, the mechanism which produces the appearance of a planetary nebula is at once made

apparent. The diagram shows the appearance on the supposition that the conditions of all the orbits with reference to the major axis shall be nearly identical, but the appearances would not be very greatly altered if we take the more probable case in which there will be plus and minus values.

Globular Nebulæ showing Condensations until finally a Nebulous Star is reached.

If we grant the initial condition of the formation of a collision-shell, we can not only explain the appearances put on by planetary nebulæ, but a continuation of the same line of thought readily explains those various other classes to which Herschel has referred, in which condensations are brought about, either by a gradual condensation towards the centre, or by what may be termed successive jumps, showing that they are among the earliest stages of nebular development.

To explain these forms we have only to consider what will happen to the meteorites which undergo collision in the first shell. They will necessarily start in new orbits,

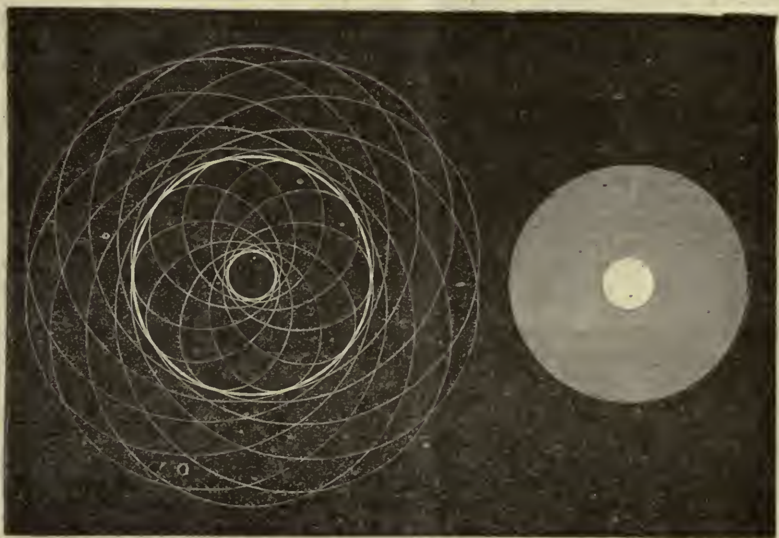

Fig. 2.—Suggestion as to the origin of a globular nebula with a brighter central portion. As in the former case, the luminosity of the fainter portion is due to the collisions which occur along the sphere of intersection represented by the larger circle. After collision the meteorites will travel in new orbits, and there will be an additional sphere of intersection, represented by the smaller circle. The left-hand diagram is a cross-section, and the right-hand one represents the appearance of the two collision shells as seen from a point outside.

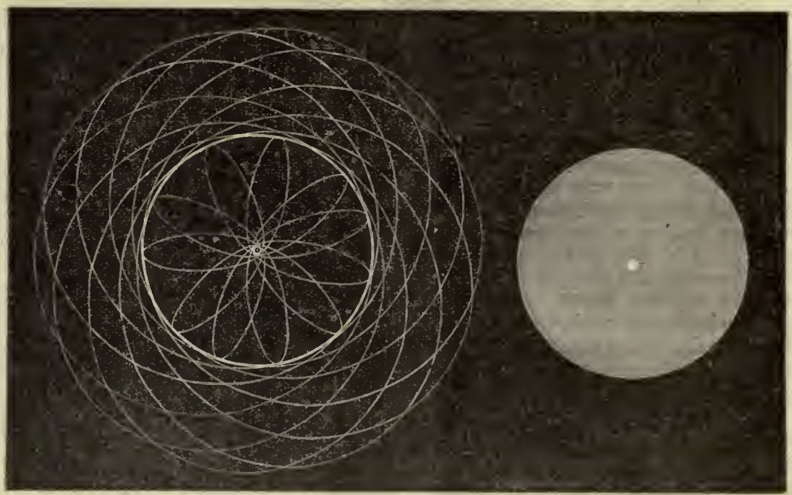

Fig. 3.—Suggestion as to the origin of a nebulous star. The orbits of the inner set of meteorites are very elliptic, so that the shell of intersection appears almost as a point. As in the previous cases, the left-hand diagram represents the meteoric systems in section, and the right-hand one the appearance from a point outside.

and it is suggested that an interior collision-shell will in this way be formed.

In consequence of the collisions the orbits will have a tendency to get more and more elliptic, while the pericentric distance will at the same time be reduced; the swarm will, in consequence of this action, gradually brighten towards the centre through collisions being possible nearer the centre, and ultimately we shall have nebulæ with a distinct nucleus, the nucleus then representing the *locus* of most collisions. This brightness may be sudden in places, or quite gradual, according to the collision conditions in each swarm. The final stage will be a nebulous star.

Effects of Subsequent Rotation.—Spheroidal Nebulæ.

In such meteor-swarms as those we have considered, it must be that rotation is sooner or later set up. Otherwise it would be impossible to account for the spheroidal

nebulæ at all. I am aware that in Newton's opinion the cause of this rotation was not mechanical, but the moment we assume a meteoric origin of these globular clusters it is straining the facts to assume that the intake will be exactly the same at all points, and the moment the bombardment is more or less localized, rotation must follow sooner or later. Sir William Herschel, in his paper of 1811 (p. 319), says: "If we consider this matter in a general light, it appears that every figure which is not already globular must have eccentric nebulous matter, which, in its endeavour to come to the centre, will either dislodge some nebulosity which is already deposited, or slide upon it sideways, and in both cases produce a circular motion; so that, in fact, we can hardly suppose a possible production of a globular form without a subsequent revolution of nebulous matter, which in the end may settle in a regular rotation about some fixed axis."

Given, then, a globular swarm with a rotation around an axis, we have to discuss the phenomena produced by collisions under a new set of circumstances.

Here at once we have to account for the fact that the nearly spherical forms are very short-lived, for they are very rare; we seem to jump, as it were, from globes to very extended spheroids.

If it be conceded that from the above considerations we are justified in supposing that the elliptic and other spheroidal nebulæ really represent a higher stage of evolution than those presented to us in the globular form, it is clear that on the meteoritic hypothesis the greater part of the phenomena will represent to us what happens to such a system under the condition of a continuous bombardment of meteorites from without.

So soon as we have a minor axis, there will at first be more collisions parallel to it; the result of this will be that the equatorial plane will be intensified, and then, later on, if we conceive the system as a very extended spheroid, it is obvious that meteorites approaching it in directions parallel to its minor axis will now have fewer chances of collisions than those which approach it, from whatever azimuth, in what we may term the equatorial plane. These evidently, at all events if they enter the system in any quantity, will do for the equatorial plane exactly what their fellows were supposed to do for the section in Fig. 1, and we shall have on the general background of the symmetrically rotating nebula, which may almost be invisible in consequence of its constituent meteorites all travelling the same way and with nearly equal velocities, curves indicating the regions along which the entrance of the new swarm is interfering with the movements of the old one; if they enter in excess from any direction, we shall have broken rings or spirals.

This was suggested in my last paper. Various rings will indicate the regions where most collisions are possible, and the absence of luminosity in the centre by no means demonstrates the absence of meteorites there.

Researches by Lord Rosse and others have given us forms of nebulæ which may be termed sigmoid and Saturnine, and these suggest that they and the elliptical nebulæ themselves are really produced by the rotation of what was at first a globular rotating swarm of meteorites, and that in these later revelations we pick up those forms which are produced by the continued flattening of the sphere into a spheroid under the meteoric conditions stated. It is worthy of remark that all the forms taken on by the so-called elliptic nebulæ described by the two Herschels, and by the spiral, sigmoid, and Saturnine forms which have been added to them by the labours of Lord Rosse and others, are recalled in the most striking manner by the ball of oil in Plateau's experiment, when rotations of different velocities are imparted to it. It is my intention to repeat Plateau's experiments, and to take instantaneous photographs of the various phenomena presented, and to place them side by side with the drawings of nebulæ, of which they are almost the exact counterparts.

The Saturnine form may, indeed, in some cases represent either the first or last stages in this period of the evolutionary process. I say *may* represent, in consequence of the extreme difficulty in making the observations, so that in the early stages a spherical nebula, beginning to change into a spheroid, may have its real spheroidal figure cloaked by various conditions of illumination.

The true Saturnine form must, as in the case of Saturn itself, represent one of the latest forms in the meteor-swarm, because, if it be not continually fed from without, collisions must sooner or later bring all the members of the swarm to the centre of figure.

Cometic Nebulæ.

I do not know that any explanation has, so far, been suggested as to the origin of these curious forms, which were first figured by Sir William Herschel, and of which a number have recently been observed in the southern hemisphere ("Melbourne Observations"). It is clear that in them the conditions are widely different from those hitherto considered in this paper. I think that the meteoritic hypothesis satisfactorily explains them, on the supposition that we have either a very condensed swarm moving at a very high velocity through a sheet of meteorites at rest, or the swarm at rest surrounded by a sheet all moving in the same direction. It is a question of relative velocity.

If we consider the former case, it is clear that the collision region will be in the rear of the swarm, that the collision will be due to the convergence of the members of the sheet due to the gravity of the swarm, and that the collision region will spread out like a fan behind the swarm.

The angle of the fan, and the distance to which the collisions are valid, will depend upon the velocity of the condensed swarm.

Nebulous Origin of some Bodies which appear as Stars.

From this point of view it is also possible that many stars, instead of being true condensed swarms due to the nebulous development to which we have referred, are simply appearances produced by the intersection of streams of meteorites. They are, then, simply produced by an intensification of the conditions which gave rise to the brighter appearances recorded by Herschel here and there in his diffused nebulosities. The nebulous appendages sometimes seen in connection with stars strengthen this view.

II. STARS WITH BRIGHT LINES OR FLUTINGS.

I pointed out in my last paper that those stars in the spectra of which bright lines had been observed were in all probability the first result of nebulous condensation, both their continuous spectrum and that of the surrounding vapour being produced by a slightly higher temperature than that observed in nebulæ in which similar though not identical phenomena are observed.

I have recently continued my inquiries on this point: and I may say that all I have recently learned has confirmed the conclusions I drew in my last paper, while many of the difficulties have disappeared. Before I refer to these inquiries, however, it is necessary to clear the ground by referring to the old view regarding the origin of bright lines in stellar spectra, and to the question of hydrogen.

Reference to the Old View by which it was supposed some of the Bright-line Phenomena might be accounted for.

In the views which, some years ago, were advanced by myself and others, to account for the bright lines seen

in some of the "stars" to which reference has been made, the analogy on which they were based was founded on solar phenomena; the "stars" in question being supposed to be represented in structure by our central luminary. The main constituent of the solar atmosphere outside the photosphere is hydrogen, and it was precisely this substance which was chiefly revealed by these stellar observations and in the Novas, in which cases it was sometimes predominant. A tremendous development of an atmosphere like that of the sun seemed to supply the explanation of the phenomena.

Acting on this view in 1878,[1] I attempted to catch these chromospheric lines in *α* Lyræ, abandoning the use of a cylindrical lens in front of the slit with this object in view.

Further, it was quite clear that if such gigantic supra-photospheric atmospheres existed, their bright lines might much modify their real absorption-spectra; even "worlds without hydrogen" might be thus explained without supposing a *lusus naturæ*, and so I explained them.

That this view is untenable, as I now believe, and that it is unnecessary, will, I think, be seen from what follows. A long series of newly described phenomena, which are absolutely incomprehensible while it is applied to them, find, I think, a simple and sufficient explanation. I must hold that the view is untenable, because how a body constituted in any way like the sun could change its magnitude from the thirteenth to the sixth every year or so, or change its hydrogen lines from bright to dark once a week, passes comprehension; and the more closely a "star" resembles the sun the less likely are such changes to happen. Even the minor evolutionary changes are inexplicable on this hypothesis, chiefly because in a completely condensed mass the temperature must be very high and constant, while I have shown that the spectrocopic phenomena are those of a specially low temperature; and I may now add that many of the objects are extremely variable in the quantity and quality of the light they emit.

Another cause of the appearance of the hydrogen lines has been suggested by Mr. Johnstone Stoney (Proc. Roy. Soc., vol. xvii. p. 54). He considers it due to the clashing together of the atmospheres of two stars, the outer constituent of the atmosphere—hydrogen—alone being raised by the friction to brilliant incandescence.

Another objection we can urge against the old view is that all bodies in the universe cannot be finished suns in the ordinary sense, and that it leaves out of account all possible processes of manufacture, not only of single stars, but of double and multiple systems, at all stages between nebula and sun; while the new one, by simply changing the unit from the star to each individual constituent, it is hardly too much to say, explains everything, though it is perfectly true that in some of the steps a considerable acquaintance with spectroscopic phenomena is necessary to realize the beauty and the stringency of the solutions.

[1] ". . . The sun which we see, the sun which sends us the majority of the light we receive, is but a small kernel in a gigantic nut, so that the diameter of the real sun may be, say, two million miles. Suppose then that some stars have very large coronal atmospheres; if the area of the coronal atmosphere is small compared with the area of the section of the true disk of the sun, of course we shall get an ordinary spectrum of the star; that is to say, we shall get the indications of absorption which make us class the stars apart; we shall get a continuous spectrum barred by dark lines. But suppose that the area of the coronal atmosphere is something very considerable indeed, let us assume that it has an area, say fifty times greater than the section of the kernel of the star itself; now, although each unit of surface of that coronal atmosphere may be much less luminous than an equal unit of surface of the true star at the centre, yet, if the area be very large, the spectroscopic writing of that large area will become visible side by side with the dark lines due to the brilliant region in the centre where we can study absorption; other lines (bright ones) proceeding from the exterior portion of that star will be visible in the spectrum of the apparent *point* we call a star. Now it is difficult to say whether such a body as that is a star or a nebula. We may look upon it as a nebula in a certain stage of condensation; we may look upon it as a star at a certain stage of growth."—Proc. R.S. 1878, No. 185, p. 49.

The Question of Hydrogen in the Case of Bright-Line Stars.

It may be convenient also that I should summarize the various conditions under which the lines of hydrogen are observed in the meteorite swarms we are now considering.

In the "nebulæ" we begin with the widest interspaces. Future investigation may show that, as I have suggested, those in which the hydrogen lines are absent are the most widely spaced of all. Be this as it may, it is a matter of common knowledge that with the brighter nebulæ, such as that of Orion, to take an instance, we have hydrogen associated with the low-temperature radiation of olivine. That the hydrogen is electrically excited to produce this glow is proved by the fact that the temperature of the meteorites themselves must be very low; otherwise the magnesium would not show itself without the manganese and iron constituents, and the continuous spectrum would be much brighter and longer than it is.

In the former paper I showed that in my laboratory experiments, when the pressure was slightly increased in a tube containing gases obtained from meteorites, the carbon bands began to be visible. We should expect this to happen therefore in a meteor swarm at some point at which the mean interstitial space was smaller than that accompanied by the appearance of the hydrogen lines; and it would be natural that both should be seen together at an early stage and both feeble, by which I mean not strongly developed, as hydrogen is not strongly developed even in the nebula of Orion, none of the ultra-violet lines being visible in a photograph, while the magnesium line is.

The association of the low-temperature lines of hydrogen with the flutings of carbon is therefore to be expected, and I shall subsequently show that we have such an association in the so-called bright-line stars; and even at a further stage of development, in stars like *α* Orionis, the hydrogen is still associated with the carbon.

The Cometic Nature of Stars with Bright Lines in their Spectra.

Seeing that the hypothesis I am working on demands that the luminosity in stars and the bright lines in their spectra are produced by the collisions of meteorites, the spectra of those bodies must in part resemble those of comets, in which bodies by common consent the luminosity is now acknowledged to be produced by collisions of meteorites.

We must, however, first consider the vast difference in the way in which the phenomena of distant and near meteoric groups are necessarily presented to us; and, further, we must bear in mind that in the case of comets, however it may arise, there is an action which drives the vapours produced by impacts outward from the swarm in a direction opposite to that of the sun.

It must be a very small comet which, when examined spectroscopically in the usual manner, does not in consequence of the size of the image on the slit enable us to differentiate between the spectra of the nucleus and envelopes. The spectrum of the latter is usually so obvious, and the importance of observing it so great, that the details of the continuous spectrum of the nucleus, however bright it may be, are almost overlooked.

A moment's consideration, however, will show that if the same comet were so far away that its whole image would be reduced to a point on the slit-plate of the instrument, the differentiation of the spectra would be lost; we should have an integrated spectrum in which the brightest edges of the carbon bands, or some of them, would or would not be seen superposed on a continuous spectrum.

The conditions of observations of comets and stars being so different, any comparison is really very difficult; but the best way of proceeding is to begin with the spectrum of comets in which, in most cases, for the reason given, the phenomena are much more easily and accurately recorded.

But even in the nucleus of a comet as in a star it is much more easy to be certain of the existence of bright lines than to record their exact positions,[1] and as a matter of fact bright lines have been recorded, notably in Comet Wells and in the great comet of 1882.

The main conclusion to which my researches have led me is that the stars now under consideration are almost identical in constitution with comets between that condition in which, as in those of 1866 and 1867, they give us the absolute spectrum of a nebula and that put on by the great comet of 1882.

I am aware that this conclusion is a startling one, but a little consideration will show its high probability, and a summary of all the facts proves it, I think, beyond all question.

While we have bright lines in comets, it can be shown that some of them are the remnants of flutings. Thus in Comet III. of 1881, as the carbon lines died away the chief manganese fluting at 558 became conspicuously visible; it had really been recorded before then. The individual observations are being mapped in order that the exact facts may be shown. It may probably be asked how it happened that the fluting of magnesium at 500 was not also visible. Its absence, however, can be accounted for: it was *masked* by the brightest carbon fluting at 517, whereas the carbon fluting which under other circumstances might mask the manganese fluting at 558 is always among the last to appear very bright and the first to disappear.

In the great comet of 1882, which was most carefully mapped by Copeland, very many lines were seen, and indeed many were recorded, and it looks as if a complete study of this map will put us in possession of many of the lines recorded by Sherman in the spectrum of γ Cassiopeiæ. We have then three marked species of non-revolving swarms going on all fours with three marked species of revolving ones, and in this we have an additional argument for the fact that the absence in the former of certain flutings which we should expect to find may have their absence attributed to masking by the carbon flutings.

We have next, then, to show that there are carbon bands in the bright-line stars.

There is evidence of this. Among the bright lines recorded is the brightest carbon fluting at 517. This is associated with those lines of magnesium and manganese and iron visible at a low temperature which have been seen in comets.

But we have still more evidence of the existence of carbon. In a whole group of bright-line stars there is a bright band recorded at about 470, while, less refrangible than it, there appears a broad absorption band. I regard it as extremely probable that we have here the bright carbon band 467–474, and that the appearance of an absorption band is due to the fact that the continuous spectrum of the meteorites extends only a short distance into the blue.

If we consider such a body as Wells's comet, or the great comet of 1882, as so great a distance from us that only an integrated spectrum would reach us, in these cases the spectrum would appear to extend very far, and more or less continuously, into the blue; but this appearance would be brought about, not by the continuous spectra of the meteorites themselves, but by the addition of the hydrocarbon fluting at 431 to the other hot and cold carbon bands in that part of the spectrum.

There are other grounds which may be brought forward to demonstrate that the difference between comets and the stars now under discussion is more instrumental than physical.

Supposing that the cometic nature of these bodies be conceded, the laboratory work will show us which flutings and lines will be added to the nebula spectrum upon each rise of temperature; and the discussion, so far as it has gone, seems to show that such lines and flutings have actually been observed.

The difficulties of the stellar observations must always be borne in mind. It will also be abundantly clear that a bright fluting added to a continuous spectrum may produce the idea of a bright line at the sharpest edge to one observer, while to another the same edge will appear to be preceded by an absorption band.

III. Stars with Bright Flutings accompanied by Dark Flutings.

I also showed in the paper to which reference has been made that the so-called "stars" of Class III.*a* of Vogel's classification are not masses of vapour like our sun, but really swarms of meteorites; the spectrum being a compound one, due to the radiation of vapour in the interspaces and the absorption of the light of the red- or white-hot meteorites by vapours volatilized out of them by the heat produced by collisions. The radiation is that of carbon vapour, and some of the absorption, I stated, was produced by the chief flutings of manganese.

These conclusions were arrived at by comparing the wave-lengths of the details of spectra recorded in my former paper with those of the bands given by Dunér in his admirable observations on these bodies.[1]

The discovery of the cometic nature of the bright-line stars greatly strengthens the view I then put forward, not only with regard to the presence of the bright flutings of carbon, but with regard to the actual chemical substances driven into vapour. From the planetary nebulæ there is an undoubted orderly sequence of phenomena through the bright-line stars to those now under consideration, if successive stages of condensation are conceded.

I shall return to these bodies at a later part of this memoir.

IV. Stars in which Absorption Phenomena predominate.

I do not suppose that there will be any difficulty in recognizing, that if the nebulæ, stars with bright lines, and stars of the present Class III.*a* are constituted as I state them, all the bodies more closely resembling the sun in structure, as well as those more cooled down, must find places on a temperature curve pretty much as I have placed them; the origin of these groups being, first still further condensation, then the condition of maximum temperature, and then the formation of a photosphere and crust.

We shall be in a better position to discuss these later stages when the classifications hitherto adopted have been considered.

(*To be continued.*)

THE HITTITES, WITH SPECIAL REFERENCE TO VERY RECENT DISCOVERIES.[2]

IV.

THOSE who have attempted to decipher the Hittite inscriptions have not always regarded a fact which may be discerned with tolerable facility. The inscriptions from Hamath, and those from Jerablûs or Carchemish, though no doubt deriving their origin from a common source, yet present, as we know them, two distinct types. Symbols usual and frequently repeated on the Jerablûs monuments are wholly absent from those of

[1] "*Observations of Comet III.*, 1881, *June* 25.—The spectrum of the nucleus is continuous; that of the coma shows the usual bands. With a narrow slit there are indications of many lines just beyond the verge of distinct visibility."—Copeland, *Copernicus*, vol. ii. p. 226.

[1] "Les Étoiles à spectres de la troisième classe," *Kongl. Svenska Vitenskaps-Akademiens Handlingar*, Bandet 21, No. 2, 1885.

[2] Based on Lectures delivered by Mr. Thomas Tyler at the British Museum in January 1888. Continued from p. 562.

Hamath. Other symbols, not difficult to identify as essentially the same, yet assume a form more or less changed. The difference is altogether so considerable that in ancient times the ability to read and fully understand the one type may quite possibly not have involved a facility of perfectly comprehending the other. The difference might be spoken of as one of *dialect*, if that word could be, in this case, appropriately employed. Then, so far as the more considerable monuments in the Museum from Jerablûs or Carchemish are concerned, there is clearly between them a difference in age, and the difference may possibly be very great. As evidence in support of this assertion, I may adduce a symbol which was intended apparently to denote an agricultural implement. When this symbol was given as in Fig. M (1), though probably drawn out of perspective and perhaps already somewhat conventionalized, yet its relation to the actual object would seem to have been not very distant. But when the symbol has become changed in the manner that appears

1 2 3

Fig. M.—Symbols of agricultural implements: 1 and 2, from Jerablûs monuments; 3, from incised bowl.

in (2), there is no difficulty in recognizing that a considerable interval must have elapsed. In (3), on an incised bowl, at present deposited in the British Museum, the same symbol has assumed something of a hieratic form. Though the bowl was found at the site of Babylon, the inscription cut into it obviously belongs to the Carchemish type. Possibly the bowl had been brought from Carchemish as a trophy.

It is conceivable that (1) might denote a kind of harrow, but more probably the vertical portion represents the end of a threshing-sledge, with teeth of stone or iron projecting therefrom. It appears to me very doubtful whether this symbol (which is not found on the inscriptions from Hamath) is ever used with any direct reference to agricultural operations. It is rather to be understood figuratively of severity in warfare and of the devastation of an enemy's country. This is in accordance with the usage of the Biblical books, which, on account of local contiguity, have, in relation to the Hittite inscriptions, peculiar importance. Thus we find, in Amos i. 3, "For three transgressions of Damascus, and for four, I will not turn away [the punishment] thereof; because they have threshed Gilead with threshing-instruments of iron"; and there are other similar passages. Moreover, such metaphorical or figurative employment of material symbols is in accordance with what we know of the use of picture-writing by the American Indians. I ought, perhaps, to add that on the Carchemish inscriptions the threshing-sledge is usually accompanied by what is probably the representation of the more essential parts of a plough somewhat conventionalized. Between the pole (or handle) and the

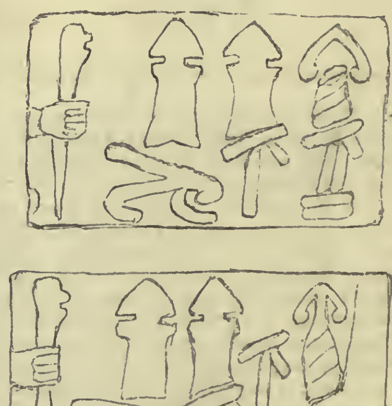
Fig. N.—Probable symbol of plough.

share or tooth, wedges would seem to have been inserted to keep the tooth firm in its place. By an easy metonymy a plough would denote land tilled and cultivated. Fig. N gives this symbol as accompanying Fig. M (2).

The difficulty of explaining the characters of the Hittite inscriptions may result in part from the objects originally depicted being such as are no longer known to us. But probably a much more serious cause of difficulty is to be found in conventionalization and the changes made to facilitate rapid execution. And we must take into account, in addition, the necessity which would arise in some cases for the lateral compression of the representation, if I may so speak, in order that the symbol might be conveniently given in the same line and in association with other symbols. This last remark applies particularly to a symbol which, there is strong reason to believe, represents the *shadoof*, or instrument for raising water, still used in the East. It would have been inconvenient to represent at full length the lever at top, with a weight at one end, and a bucket, suspended by a cord or

Fig. O.—*Shadoof* symbol, from Jerablûs inscriptions.

chain, from the other. Consequently we have the instrument represented with modification, and with the lever shortened. Here again in all probability the symbol is used for the most part figuratively, and not in general with reference to the raising of water or the irrigation of land. People familiar with the swinging up and down of the lever, and of bringing up the bucket of water, might use the symbol of "raising" in a wider sense, or generally of active and efficient operation. It is probably with this latter meaning that it is employed in three out of the five Hamath inscriptions, and in a combination of symbols which is exceedingly interesting and instructive. Two of the three are represented in Fig. P. As to the general subject, the presence of the hand grasping warlike weapons can scarcely leave a doubt; and in accordance with this indication is the spear-head, however ornamented, at the other end of the figure. The two triangular-topped symbols between, probably denote actual conflict. The idea represented conventionally



1

2

Fig. P.—Groups of symbols ending two Hamath inscriptions.

may be that of a mass of warriors who have closed together in deadly combat, or a mass of spears seen together. Under the first of these triangular-topped figures is a symbol which has been supposed to represent an insect. The two symbols together may be taken as meaning "war commencing." In the second place, we have a combination with the *shadoof*, and we may interpret,

"war in active operation." In the third combination the change in both the symbols is to be noted. That at the top may refer to a custom of enwreathing or adorning the arms of warriors to denote success in war, and to celebrate victory; and the change in the *shadoof* corresponds therewith. In (1) the vertical bar is doubled, and two short horizontal bars are added beneath; in (2) we may take it that the same end is attained by lengthening the vertical bar, while, as before, the two short horizontal bars are added, and the ornamentation of the spear is lengthened. This third combination manifestly marks the climax; but it can only indicate this, if, in accordance with what I have already said, the inscriptions are to be read "with the faces." And very important additional evidence is also furnished by these groups as to the ideographic character of the inscriptions.

That a comparatively primitive people, employing the *shadoof*, the plough, and the threshing-sledge, should use figures of these instruments to represent ideas more or less abstract can scarcely excite surprise. Probably, too, a paucity of symbols might lead to those employed being used to denote a plurality of somewhat diverse significations.

A symbol, with regard to the meaning of which the evidence is especially clear, is the symbol of deity or divinity on the Jerablûs monuments. This symbol consists of a straight stroke and a crescent, denoting in all probability Asherah, "the straight," and the goddess

Fig. Q.—The symbol of deity, with various figures on Jerablûs monuments.

Ashtoreth. Such a combination would accord with the close relation between Asherah and Ashtoreth in the Old Testament.[1] But, whether this explanation is admitted or not, that the symbol denotes deity or sacredness can scarcely admit of question. In the first place the symbol occurs invariably *at the top of the line* on the Jerablûs monuments. This fact is itself significant. Then, three times on the "doorway inscription" what are evidently hands, though somewhat conventionalized, are held up towards the symbol in worship, as with the palm upward (1), according to the widely-spread custom, and also, as it would seem, in giving thanks (Fig. T). The symbol is to be seen also above a sacred tree (3), and above a rudely-shaped idol (2), from a fragment found at Jerablûs. This idol may have been a *lusus naturæ*, presenting a distant resemblance to the human face, and but slightly modified by art. And on the rounded pillar from Jerablûs, which bears the most modern, comparatively, of the three considerable inscriptions obtained from this site, we find the same symbol over very curious figures which, as it seems to me, were intended to represent spiritual beings or disembodied souls (4). They are insubstantial εἴδωλα, mere masks as it would appear, and with tail-like prolongations instead of bodies. They are horned, however, and the horn was a sign of dignity and power. On the whole, the evidence of the value of the straight stroke and crescent is, in my judgment, entirely conclusive. I ought to add that this symbol is not found on the inscriptions from Hamath; and thus in all probability is indicated a difference of religious cult.[1]

[1] Asherah was probably a phallic symbol. This accords with the view of Movers ("Die Phönizier," vol. i. p. 560 *sqq.*), and with that of the Rabbins (cf. I. Kings xv. 13, and the commentaries thereon).

An interesting question presents itself as to whether the names of Hamath and Carchemish can be detected on the inscriptions. In reply it may be stated that the name or symbol of the ancient city on the site of Jerablûs may be pointed out with a good deal of confidence.

Fig. R—Name of ancient city on Jerablûs monument.

The oval symbol, which appears at the top in Fig. R, in its origin was intended, no doubt, as a plan of a city. A similar oval form, both of the military camp and of the city (Layard's "Monuments of Nineveh," pl. 77), is to be seen depicted on the Assyrian monuments. And, with regard to the Hittite symbol, it is also worthy of note that not only on the Egyptian monuments is there an analogous circular symbol of "city" or "place," but that a similar symbol, with the like meaning, was found in Mexico, both of circular form, and, as it would seem, also oval. For the latter see Brasseur de Bourgbourg, "Études sur le Système graphique et la Langue des Mayas," Paris, 1869, vol. i. p. 150. From the Assyrian monuments it appears that fortresses were not uncommonly of angular and quadrilateral form. I therefore take the lozenge-shaped figure to denote the idea of "fortress." Like the "city" symbol it has what we may regard as a road or street crossing it; and it has markings indicating, in all probability, gates, at the other corners. Then, as to the eagle, a question of great interest, if of some difficulty, presents itself. The ancient city on the site of Jerablûs we have identified with Carchemish. As already stated, the name Carchemish has been looked upon as denoting "the fortress of Chemosh." The question then occurs, If the lozenge-shaped figure denotes "fortress," does the eagle denote Chemosh? Whatever may be the etymology of "Chemosh," it is sufficiently probable that Chemosh was, like Baal and Moloch, a solar deity. This, indeed, has been previously suggested. And the sun might very well be represented by the eagle, the bird of the sun. Moreover such a view is not purely hypothetical. As is well known, in ancient Egypt, Horus, the god of the rising sun, was represented by the hawk. Then there is reason to think that, in connection with the solar cult, the eagle was worshipped or regarded as a sacred bird at places in or near the Hittite country, and not very far distant from Carchemish.

Looking, then, upon the eagle and upon the second part of the name "Car-chemish" as both representing Chemosh, there remains no difficulty about the first part of the name, as we find, in Assyrian, *caru*, a fortress—a word found also, with comparatively slight modification, in Hebrew (*kir*).

[1] There is another sign, **IL**, which, though less frequent, yet appears as if a variant of the sign of deity usual in inscriptions of the Jerablûs type. This sign somewhat puzzled me till, on the coinage of Mallus, in Cilicia, I found the right angle together with the straight stroke, or *asherah*, the equilateral triangle, and the cone. All these were, no doubt, connected with the goddess Astarte, to whose service Mallus seems to have been especially devoted. It is, in all probability, this deity who appears in winged form on the obverse of the coin, which Mr. Barclay V. Head, the eminent numismatist, assigns to a date earlier than 400 B.C. I ought to add that the sign with the right angle, which probably denotes a different aspect or function of the goddess, occurs apparently in the Hamath inscriptions

With regard to Hamath, though the evidence is weaker, yet probably the city is indicated by a symbol consisting of the vase or receptacle (Fig. S, 1), with the oval character "city" above and the feminine sign below. The word "Hamath" comes very near to one used in Hebrew for a bottle or bulging receptacle.

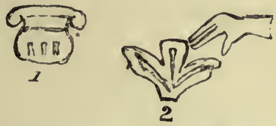


FIG. S.—Symbols on "doorway inscription" from Jerablûs: 1, vase or receptacle; 2, hand seizing vegetation.

The receptacle in the figure, having three vertical marks, and one or two horizontal marks, is a common symbol on the Jerablûs monuments. Probably, as in the bag previously spoken of (and see Fig. T), the three vertical marks denote objects within the receptacle; we may suppose, pieces of metal used as uncoined money. It seems most likely, however, that the difference in external shape of the receptacles indicates a difference in the nature and value of the contents. The symbol of seizing vegetation is another example of the use of ideograph or picture-writing in these inscriptions. That the thing seized is a plant or herb is sufficiently obvious. And from the accompanying symbols there is reason to think that one of the food-producing cereals, when ripe, is intended.

Treated in accordance with the principles which have guided us, and the conclusions previously expressed, the group of symbols concluding the "doorway inscription" in the British Museum will be found to yield probable and consistent results. Beginning from the reader's left, we have a symbol which, probably deriving its origin from the chase, bears some resemblance to the leg of an animal repeated, but inverted. The inverted position would appropriately represent the total defeat of an enemy,

FIG. T.—End of "doorway inscription" from Jerablûs, in the British Museum.

while the repetition or doubling may be regarded as implying plurality, and perhaps flight. Then follow symbols denoting probably repeated thanksgivings to the gods (notice the doubling of the sign of deity). Next comes the bag of treasure with the hand beneath pointing towards the king. Under the king's head is a hand in the attitude of acceptance. Here is essentially what we find on the Yuzgât seal, but the object being accepted is not identical with the bag behind the king. Perhaps it denotes the tribute the payment of which was imposed on the conquered people.[1] Then follows the *shadoof* symbol, which here may well imply the vigorous prosecution of agriculture on the restoration of peace. At the end is the plant with four strokes above it, which may be regarded as signifying that the earth brought forth abundantly, or fourfold.[2] But whether the interpretation I have thus given is accepted or not, the ideographic character of the group is altogether unmistakable.

Allusion was previously made to the name "Zu-zu," or "Su-su" (see p. 539, note) as possibly occurring on the shortest (excepting mere fragments) of the inscriptions from Jerablûs in the Museum. In the first line of the inscription is the most important of the places where the name would be thus read in accordance with the conclusions arrived at with regard to the Tarkutimme inscription. In the group there are two smaller cones and one larger, all crossed by horizontal lines. The two smaller cones will represent, as on the Tarkutimme inscription, a people or nation. This coincidence with the Tarkutimme inscription may give credibility to the supposition of still further agreement. The animal's head resting on the double cone will denote the name of the people. The taller cone would probably denote a king or possibly kings, crossed as it is by horizontal lines. A curve passes from the top down near the side of the taller cone, and above are the two strokes repeated and placed at an angle, which would be read "Zu-zu" or

FIG. U.—Group of symbols from Jerablûs monument in the British Museum.

"Su-su." Connected with the curve is an appendage passing to the head of an animal. Across this appendage (and the curve also after the two have become united) pass horizontal lines, probably lines of plurality. The animal's head, with the appendage, may give the name of a royal dynasty or possibly of a subordinate people.[1] But the chief interest attaches to the larger animal's head. In accordance with what was before said, we may regard it as tolerably certain that the name of the people is repeated. If "Zu-zu" is the correct reading of the strokes above the tall cone, the name of the animal whose head rests upon the double cone ought to be essentially the same. To solve the problem, if we are to be consistent, we must have recourse to the Semitic dialects, and preferably to Hebrew. Here we find a rare word, *ziz* (from a root *zuz* or *ziz*), used of an animal browsing sometimes on the vine (Psalm lxxx. 13, A.V.). It would be difficult to determine what particular species of animal is intended either in the Psalm or on the inscription; but it would seem not unsuitable to suppose that young wild cattle are intended in both. It will be in accordance with what has been said to identify "Zu-zu" with the Zuzim described in Genesis xiv. 5, as dwelling in the country east of the Jordan. And indeed, from an ancient city on the site of Jerablûs, a hostile raid on Bashan, Gilead, and the adjacent country was likely enough to be undertaken. Assyriological research has tended to show that Chedorlaomer and some other names in Genesis xiv. are genuine. It would not be very wonderful if the Hittite monuments should show that this is the case also with the name Zuzim.[2]

The results in decipherment thus set forth are, it may be said, but scanty and imperfect, and, in some cases, as based on slight evidence, may be liable to fall away when a wider induction is attainable. But "all science," it has been said, "is provisional"; and in relation to such a subject as that with which these articles are concerned, it may be sufficient if we should succeed in setting forth just principles, and in making even a slight extension of the boundaries of knowledge.

(To be continued.)

[1] Having regard to the shape of the symbol, one may be reminded perhaps of the wool which was included in the tribute paid by Mesha of Moab to the king of Israel (II. Kings iii. 4).

[2] Cf. Amos i. 3 *seq.*, and the Biblical use of "four" and "fourfold."

[1] It has been suggested that the smaller animal's head is that of a gazelle. If so, in the plural, the name would be in Hebrew "Tsebaim" or "Zeboûm," a name found in Genesis xiv. 2, but possibly this would only be a curious coincidence.

[2] The city indicated on this monument, for the name of which I have suggested "Bamoth-elah" (*ante*, p. 539), may possibly be identical, judging from the ideograph, with Bamoth-in-the-valley of Numbers xxi. 20.

ASA GRAY.

THE following, as yet unpublished, words, almost the last spoken publicly by Asa Gray, have a pathetic interest for all those who knew and loved him. They were uttered in the Free Trade Hall, at Manchester, at the opening meeting of the British Association in August last, in seconding the vote of thanks to Sir Henry Roscoe for his address:—

"For the very great honour of being called upon to second the motion for a vote of thanks to your illustrious President, I am mainly indebted to that deference which is naturally accorded to advancing years, a deference which sometimes—as in the present case—takes one unawares.

'In looking back over the list of Corresponding Members of the British Association, I find myself, much to my surprise, nearly, if not quite, the oldest survivor.

"I recognize, therefore, a certain fitness, on this score, in the call upon me to be the spokesman of those, your brethren from other lands, who have been invited to this auspicious gathering, and to the privilege of listening to the very thoughtful, well-timed, and most instructive address of your President.

"As guests, we desire, Mr. Mayor, heartily to thank the city of Manchester and the officers of the Association for inviting us; we wish to thank you, Sir Henry, for the gratification your address has afforded us.

"Convened at Manchester, and coming myself by way of Liverpool, I would say personally that there are two names which memory calls up from the distant past with unusual distinctness; both names familiar to this audience and well known over the world, but which now rise to my mind in a very significant way. For I am old enough to have taken my earliest lessons in chemistry just at the time when the atomic theory of *Dalton* was propounded, and was taught in the text-books as the latest new thing in science.

"Some years earlier, Washington Irving in his "Sketch-book" had hallowed to our youthful minds the name of *Roscoe*, making it the type of all that was liberal, wise, and gracious. And when I came to know something of botany I found that this exemplar, as well as patron, of good learning had, by his illustrations of Monandrian plants, taken rank among the *Patres Conscripti* of the botany of that day.

"The name so highly honoured then we now honour in the grandson. And I am confident that I express the sentiments of your foreign guests, whom I represent, when I simply copy the words of your President in 1842, now reproduced in the opening paragraph of the address of the President of 1887, transferring, as we fitly may, the application from the earlier to the later Manchester chemist: 'Manchester is still the residence of one whose name is uttered with respect wherever science is cultivated, who is here to-night to enjoy the honours due to a long career of persevering devotion to knowledge.'

"I cannot continue the quotation without material change. 'That increase of years to him has been but increase of wisdom' may indeed be said of Roscoe no less than of Dalton; but we are happy to know that we are now contemplating not the diminished strength of the close, but the manly vigour of the mid-course, of a distinguished career. Long and prosperously may it grow from strength to strength.

"In general, praise of the address which we have had the pleasure of hearing would not be particularly becoming from one whose chemistry nearly ended as well as began with the simple atomic theory of Dalton. But there is one topic which I may properly speak of, standing as I do as a representative of those favoured individuals whom your programme—for lack of a better distinguishing word—calls foreigners. I refer to the urgently expressed 'hope that this meeting may be the commencement of an international scientific organization.' For this we thank you, Mr. President, most heartily. This is, indeed, a consummation devoutly to be wished, and confidently to be hoped for, by all of us, especially by those for whom I am speaking. Not only we Americans, who are of British descent, and who never forget that blood is thicker than water, but as well our Continental associates on this platform, of the various strains of blood which interfused have produced this English race and fitted it for its noble issues—we, each and all, I repeat, accept this name of foreigners only in the conventional sense which the imperfection of language imposes. In the forum of science we ignore it altogether. One purpose unifies and animates every scientific mind with 'one divine intent,' and that by no means the 'far-off intent' of which the poet sings, but one very near and pervading. So we took to heart the closing words of your President's most pertinent and timely address. Indeed, we had taken them to heart in anticipation. And we have come to this meeting one hundred strong or more (in place of the ordinary score) fully bent upon making this Manchester meeting international.

"Far back in my youthful days there was a strong-willed President of the United States, of military antecedents, who once drew up and promulgated an official order which somewhat astounded his Cabinet officers. 'Why, Mr. President!' they said, 'you can't do that.' 'Can't do it!' replied General Jackson, 'don't you see that I have done it?' And so we internationals have come and done it. I am the unworthy spokesman of such a numerous, and such a distinguished array of scientific foreigners as have never been assembled before.

"Next year, if you will, you shall have as many more. When you, too, are ready to cross the Channel or the North Sea, we shall compose only a larger scientific brotherhood. And when you cross again the Atlantic, the brotherhood of science will be the more increased, and its usefulness in proportion.

"In behalf of your foreign guests, I heartily second the motion."

NOTES.

FIFTEEN years have passed since the Marshall Hall Fund was instituted with the twofold purpose of commemorating the late Dr. Marshall Hall, and for the encouragement of research in that branch of natural science which he did so much to develop. The Trust provides "that a prize shall be given every fifth year for the best original work done and recorded in the English language during the previous quinquennium, in physiological or pathological researches relating to the nervous system, and that the prize shall consist of the simple interest derived during the preceding five years from the amount of the capital fund." The first award was made to Dr. Hughlings Jackson, the second to Dr. Ferrier, and this year the Council of the Royal Medical and Chirurgical Society, in whose hands the Fund was placed, have awarded the prize to Dr. Walter Holbrook Gaskell, F.R.S., Lecturer in Advanced Physiology in the University of Cambridge. The Council have invited Dr. Gaskell to give some account of his work before the Society, and a special meeting will be convened for this purpose.

MR. MATTHEW ARNOLD, the tidings of whose death excited universal regret, did admirable service to the cause of education in England. No writer of his time pressed more earnestly on the attention of the public the need of thorough educational reform, and in his full and lucid Report on the Universities and secondary schools of the Continent he showed how far, in almost all matters relating to this essential element of the national life, we had allowed ourselves to be outstripped by some of our neighbours and rivals. Although, of course, convinced that

classical studies must be maintained in our schools and Universities, and personally interested chiefly in this aspect of the subject, Mr. Arnold frankly recognized the great place that must necessarily belong to science in any true system of education.

We print elsewhere a letter from Emin Pasha. Other letters from him have lately appeared in the *Times* and the *Scotsman*. His province is evidently once more in working order, and Emin is at peace with his neighbours. The letters took eight months to reach this country, so we need not be alarmed by the fact that no word has come of Mr. Stanley's arrival. Emin tells us that the country through which Mr. Stanley had to pass is of the most difficult character, full of swamps, and with rivers rendered impassable by vegetation; so that the expedition could not reach the Albert Nyanza before November.

So many new garden plants are annually described in various English and foreign periodicals that some are apt to escape the notice of botanists and horticulturists. From 1860 to 1886 a list was regularly published in the Gardener's Year-Book and Almanac; and during the months of January to May 1887 inclusive the *Journal of Horticulture* gave the names of plants up to October 1886. No later list has appeared. Now it has been decided that a list shall henceforth be given as one of the regular issues of the Kew Bulletin of Miscellaneous Information, and the first of the promised series is presented in the April number. It includes the new garden plants and alterations of names recorded between October 1, 1886, and December 31, 1887. To these have been added the names of authors, which did not appear in former lists. The list will be of great service to horticulturists.

On April 8 a beautiful display of the aurora borealis was observed at Throndtjem. The weather was fine, and there was no wind.

On March 12, at about 2 a.m., a faint shock of earthquake, accompanied by subterranean rumbling, was felt at Drammen, in Norway. It went from east to west.

A severe earthquake occurred at Lintthal (Canton Glarus) on April 2, at 9.10 a.m. At Elm the oscillations were so strong that the walls of the houses were cracked.

On the evening of Wednesday, the 11th inst., shocks of earthquake were felt in various parts of North Wales. At the large Baptist Chapel, Llangollen, while service was proceeding, a shock was distinctly felt, and the walls and ground were seen to shake. Shocks were also experienced at many of the residences in the valley, where the crockery and windows quivered in their places. A farmer residing at the Craig said his farmstead shook so much that he expected it to fall. The shocks were also noticed at Corwen, Bala, and Dolgelly.

Some months ago a Conference was held in Manchester with the object of promoting the interests of the silk industries of the United Kingdom. Various papers were read, and it was ultimately resolved that an Association, to be called the Silk Association of Great Britain and Ireland, should be formed. The objects of the Association are to promote and maintain the silk industry of Great Britain and Ireland in all its branches; to encourage the production of raw silk in India and our colonies; to collect and disseminate amongst its members useful information and statistics connected with or affecting manufacture and commerce in silk; and to promote technical, commercial, and linguistic education, and any necessary Parliamentary legislation; and generally to assist in the expansion and development of the trade. The Association was "inaugurated" at Manchester on March 22, and will hold a general meeting in London in June.

It is announced from Lyons that M. de Chardonnet has succeeded in getting by chemical processes a matter having all the appearance of silk. He adds to an etherized solution of nitrated cellulose (the base of gun cotton) a solution of perchloride of iron, and to this mixture a little of a solution of tannic acid in alcohol. The whole is poured, after filtration, into a vertical reservoir having a horizontal sharp nozzle (with fine passage) at its base, debouching in a vessel of water acidulated with nitric acid. The issuing fluid vein at once becomes consistent, and can be drawn off by a uniform movement. It is dried by passage through a dry air space, and then wound. It is of gray or black aspect; but by means of colouring matter put in the etherized solution the colour may be varied *ad lib.* It is further described as supple, transparent, cylindrical or flattened; of silky appearance and touch; the rupturing weight is 25 kilogrammes per square millimetre. The fibre burns without the flame being propagated; it is unattackable by acids and alkalies of mean concentration, by cold or hot water, alcohol, or ether; but it is dissolved in etherized alcohol and acetic ether.

An attempt was made last year to cultivate the cotton-tree in European Russia, in the neighbourhood of Taganrog, on the Don. We learn that the attempt proved successful, the temperature of the Lower Don being not inferior to that of the valleys south of the forty-first degree of latitude, where the cotton-tree is cultivated in Turkey.

The Board of Trade Journal for April contains a paper in which there are some interesting facts about sponge-fisheries. It seems that an industry in artificial sponges is in process of creation. M. Oscar Schmidt, Professor at the University of Gratz, in Styria, has invented a method by which pieces of living sponge are broken off and planted in a favourable spot. From very small cuttings of this kind, Prof. Schmidt has obtained large sponges in the course of three years, and at a very small expense. One of his experiments gave the result that the cultivation of 4000 sponges had not cost more than 225 francs, including the interest for three years on the capital expended. The Austro-Hungarian Government has been so much struck with the importance of these experiments, that it has officially authorized the protection of this new industry on the coast of Dalmatia.

According to *Allen's Indian Mail*, arrangements are now being made by the Meteorological Department of India for the prompt publication of a regular series of cyclone reports, so as to admit of their issue from two to three months after the date of the storm to which they refer. Hitherto, accounts of cyclones have not been published for a year or two after their occurrence.

The *American Meteorological Journal* for March contains the first of a series of articles by Mr. A. L. Rotch on the organization of the Meteorological Services of Europe, based upon a similar series by Dr. Hellmann, about ten years ago, with the addition of subsequent changes. The first country dealt with is Germany. Of the other articles may be specially mentioned one by Mr. W. M. Davis, on a proposed classification of the winds, according to their physical causes and conditions. The characteristics employed are: (1) the source of energy that excites motion (earth, sun, &c.); (2) the contrasted temperatures (equator, poles, &c.); (3) the period of occurrence; (4) the kind of wind (cyclonic, sea-breezes, &c.). By this means, although no claim to novelty is made, except as to the arrangement of the data, the author proposes to bring together what is known into a convenient shape, and so to separate the unsorted material for further critical examination. Prof. H. A. azen continues the controversy between Dr. Hann and himself as to the behaviour of pressure and temperature in high and low barometric areas, at elevated stations; his theory being that

the low temperature in a cyclone at a mountain station is due to the lagging behind of the minimum pressure, and similarly with respect to the high temperature in an anticyclone.

AN interesting paper is contributed to the April number of the Journal of the Chemical Society by Mr. Ward Couldridge on chlorophosphide of nitrogen. This peculiar compound was shown some years ago by Dr. Gladstone to be represented by the empirical formula $PNCl_2$, but vapour-density determinations revealed the curious fact that in the gaseous state its molecule really possesses the constitution $P_3N_3Cl_6$. Mr. Couldridge prepares it by a method somewhat different from that employed by Dr. Gladstone, and one which gives a better yield. Pentachloride of phosphorus is heated with chloride of ammonium in a flask connected with an upright condenser, so that the pentachloride volatilized returns to the seat of action until it becomes completely decomposed, and the chlorophosphide, which would otherwise be carried away by the escaping hydrochloric acid, crystallizes in the condenser. The whole of the chlorophosphide is subsequently purified by distillation in steam. The reaction is found to be as follows: $3PCl_5 + 3NH_3 = P_3N_3Cl_6 + 9HCl$. Chlorophosphide of nitrogen thus prepared dissolves readily in ether, chloroform, or carbon bisulphide, and separates on evaporation in fine rhombic crystals, which have a most remarkable aversion to water, refusing under any circumstances to be wetted by it. When fused and heated above its boiling-point, it emits a singular odour. It has the proud distinction of being unattacked by all the strong acids, hot fuming nitric alone being capable of making any impression upon it. Mr. Couldridge finds that when dry ammonia gas is led through a hot tube containing the melted chlorophosphide, a somewhat violent reaction occurs resulting in the formation of another remarkable compound known as phospham, $P_3H_3N_6$ or $P_3N_3(NH)_3$. Not only does ammonia behave in this way, but all substituted ammonias, such as the amines, form similar compounds; aniline, for instance, gives a white solid, readily crystallizable from glacial acetic acid, of the composition $P_3N_3(NH \cdot C_6H_5)_6$. Phospham itself is both insoluble in water and infusible at a red heat, but fumes in contact with air, owing to slow decomposition and oxidation. One cannot help remarking how singular it is that the introduction of phosphorus, itself a notable combustible, into the terribly explosive compound of chlorine and nitrogen, should result in the formation of a substance so extremely inert as the chlorophosphide; yet such are the vagaries met with by the chemist.

A SECOND edition of Prof. C. M. Tidy's "Hand-book of Modern Chemistry, Inorganic and Organic," for the use of students, has been issued by Messrs. Smith and Elder. As regards general arrangement, the author has adhered to the plan he first adopted. He especially notes that in writing of chemical compounds he has at times not hesitated to use common language. "If," he says, "I have used the word 'potash,' and the body I mean to imply thereby is understood, I am satisfied. I confess that the growing necessity for having a translation at one's side in attempting to understand the modern scientific paper, is in my opinion a circumstance to be deplored. Danger, moreover, is always to be apprehended when a language has to be invented to support a theory or a formula. A party shibboleth has, no doubt, a charm for its special clique. It serves as a bond of union for the initiated, whilst it prevents the interference of outsiders. But, all the same, it is distracting to the independent worker, and can but prove a hindrance to the general cultivation of science."

MESSRS. G. BELL AND SONS will shortly publish "The Building of the British Islands," a study in geographical evolution, by Mr. A. J. Jukes-Browne. The author tries to restore the geography of the British region at successive epochs of geological time, and to describe the gradual formation or evolution of the British Isles. The book will be illustrated by maps.

MESSRS. ROPER AND DROWLEY will publish immediately "Geology for All," by Mr. J. Logan Lobley, Professor of Physiography at the City of London College, and author of several volumes on geological subjects.

THE valedictory address delivered by Mr. J. W. Taylor as President of the Conchological Society has been reprinted from the *Journal of Conchology*, and issued separately. Mr. Taylor brings together some interesting observations bearing on the variation of British land and fresh-water Mollusca.

MR. THOMAS WILSON, of the Smithsonian Institution, calls attention in the *American Naturalist* to the fact that the importance of the subject of criminal anthropology has not hitherto been so thoroughly appreciated in the United States as in Europe. A step in the right direction, however, has been taken by the New York Academy of Anthropology, which lately held a meeting for the consideration of questions connected with criminal anthropology. These questions were classed under two heads, criminal biology and criminal sociology. In the circular summoning the meeting it was contended that the true way of studying crime is to begin with the study of the criminal himself. "It is impossible," said the writer, "to evolve the criminal out of one's inner consciousness. Knowledge of his peculiarities is essential to any rational treatment of him, and this knowledge can only be gained by systematic, intelligent observation of his physical and mental habits, supplemented by an exhaustive analytical comparison of the facts observed, with a view to their right classification and interpretation."

THE Mitchell Library, Glasgow, has now been ten years in existence, and the Committee, in the Annual Report just issued, express the belief that no consulting or reference library has ever made so much progress in so short a time. Speaking of the character of the reading, they say that it continues satisfactory, and bears evidence of a desire on the part of readers to seek solid information from the abundant resources at their disposal. Unfortunately, the Committee have to report that during 1887 twenty-one books were stolen.

THE Royal Microscopical Society will hold a *conversazione* on Wednesday evening, the 25th inst.

AN Aëronautical Exhibition was opened at the Rotunde in the Prater at Vienna on April 1.

THE additions to the Zoological Society's Gardens during the past week include an Arabian Baboon (*Cynocephalus hamadryas* ♀) from Massowah, presented by Mr. D. Wilson-Barker, R.N.R., F.Z.S.; two White-necked Crows (*Corvus scapulatus*), two Spotted Eagle-Owls (*Bubo capensis*) from South Africa, presented by Captain Henry F. Hoste, s.s. *Trojan*; a Muscovy Duck (*Cairina moschata*) from South Africa, presented by Mr. W. Shuter; four Half-collared Doves (*Turtur semitorquatus*) from Africa, presented by Mrs. Wisely; a Slowworm (*Anguis fragilis*), British, presented by Mr. F. W. Pilkington; two Indian Swine (*Sus cristatus* ♂ ♂) from India, a Greater Vasa Parrot (*Coracopsis vasa*) from Madagascar, a Blue-eyed Cockatoo (*Cacatua ophthalmica*) from South Australia, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, an Asp Viper (*Vipera aspis*) from Italy, deposited; four European Pond Tortoises (*Emys europæa*), European, purchased; two Collared Fruit Bat *Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

HARVARD COLLEGE OBSERVATORY.—The most interesting item in the forty-second Annual Report of the Director of the Harvard College Observatory is the account of the threefod accession to its resources which it has received during the past

year. This consisted of the funds provided by Mrs. Henry Draper for carrying on the photographic study of stellar spectra as a memorial to her late husband; the fund left by the late Uriah A. Boyden for the establishment of a mountain Observatory; and the large bequest of the late Robert Treat Paine. Prof. Pickering points out, however, that the Observatory still stands in need of further endowment, as its new resources are necessarily largely absorbed in those new lines of research for which they were specially designed, and considerable improvements are required in the principal building; and he adds that it is probable that there has never been a time in the history of the institution when so large a return could be obtained from a given expenditure as at present. The most striking results obtained during the year have been those secured by the use of the Henry Draper Memorial Fund in the photographic study of stellar spectra, and which have been already referred to in these columns. Under the Boyden Fund several instruments have been devised and constructed for the automatic registration of the meteorological conditions and general fitness for observing of sites for Observatories, and these have been carefully tested at various elevated stations. The usual observations have also been kept up, including the observation with the meridian photometer of the magnitudes of stars in zones at intervals of 5° in the region covered by the Southern D.M. This work was about half finished, and would, it was expected, be entirely completed within the present year. The east equatorial had been used in the observation of eclipses of Jupiter's satellites and of comparison-stars for variables. A wedge photometer, arranged in a somewhat modified manner, is employed with this telescope, and is to be used in the investigation of the phases of asteroids and in the observation of zones of D.M. stars. The meridian circle is to be engaged in the observation of one of the zones required in the proposed revision of the Southern D.M.

COMET 1888 *a* (SAWERTHAL).—Dr. L. Becker has computed the following elements and ephemeris from observations made on February 18 at the Cape, March 13 at Palermo, and March 27 at Strasburg. From the outstanding deviation of the middle place it may be inferred that unless there be some considerable error in the observations the true orbit will prove to be elliptical.

$$T = 1888 \text{ March } 16{\cdot}96412 \text{ G.M.T.}$$

$$\left.\begin{aligned} \pi - \Omega &= 359^\circ\ 49'\ 45''{\cdot}1 \\ \Omega &= 245\ 30\ 40{\cdot}2 \\ \iota &= 42\ 17\ 47{\cdot}4 \end{aligned}\right\} \text{Mean Eq. } 1880{\cdot}0.$$

$$\log q = 9{\cdot}844562$$

Error of middle place $(O - C)$.

$$\Delta\alpha \cos\delta = -2{\cdot}61\text{s.} \quad \ldots \quad \Delta\delta = +7''{\cdot}1.$$

Ephemeris for Greenwich, Midnight.

GEOGRAPHICAL NOTES.

THE death is announced of Nicholas von Miklucho-Maclay, at the age of forty-two years. M. Maclay's name must be familiar to our readers in connection with New Guinea explorations. He was the son of a Russian nobleman, and studied medicine and natural science at St. Petersburg and at several Dutch Universities. In 1866 he accompanied Prof. Haeckel to Madeira; in 1867 he visited the Canary Islands, and, in 1869, Morocco. He then made preparations for an extended exploration among the Pacific Islands, and especially in New Guinea. He went by South America, Tahiti, and Samoa to New Guinea, and remained for over a year, 1871–72, on its north-west coast, afterwards exploring the south-west coast to the south of Geelvink Bay. In 1874–75 he visited Further India, and especially Malacca, where he explored several districts in the interior, and obtained important results. After visiting the Pelew, Admiralty, and other island groups, Maclay again went to New Guinea (1876–78), devoting himself to the north coast, where he was now well known, and was on friendly terms with several Papuan tribes. Maclay then went to Singapore and Sydney to restore his shattered health, but was in New Guinea again in 1879, afterwards visiting several Pacific islands and going on to Sydney once more. He returned to Russia in 1882, bringing with him rich collections in ethnography and in natural history. M. Maclay afterwards resided for some time in Sydney, where he founded a biological station. He recently returned to Russia, and at the time of his death, we understand, was preparing for publication a complete account of his many years' work. At present the records of his travels, with their rich anthropological results, are to be found mainly in the Proceedings of the Batavia Society and the Russian Geographical Society.

WE also learn of the death of Herr Anton Stecker, who has done some good exploring work in Africa. In 1878 he accompanied Rohlfs to Kufra, and in 1880 he went out at the expense

of the German African Society to Tripoli, and thence by Egypt and Abyssinia to Galla Land. Herr Stecker's observations referred largely to natural history, of which he was a student.

LIEUT. WISSMANN, the African traveller, who was obliged to spend the winter at Madeira on account of ill-health, there had an opportunity of writing the report of his second journey to Africa. The book has just been published by Brockhaus. At present Lieut. Wissmann is engaged on an account of his first expedition to the south of the Congo Basin, in company with Dr. Pogge.

DRS. FRIEDERICH KURTZ AND WILHELM BODENBENDER, both Professors at the Cordoba University (Argentine Republic), have started on a scientific expedition to the East Andes.

FORESTRY IN THE CAPE COLONY.

THE Report of Consul Siler, the United States representative at Cape Colony, which has been just issued, contains a full account of the present state of forestry in that country. He says that of the 214,000 square miles which are comprised in Cape Colony, there are something over 350 square miles covered with large forest trees. These forests lie almost all together near the sea, running nearly parallel to the coast, in the temperate regions of the southern mountain chains. Till recent years the system of felling pursued was a most wasteful and unsystematic one. Far from confining the operations of the woodcutters to certain limited sections or areas, the authorities permitted them to roam about at pleasure, and to pick and choose from among the forests what trees they should cut down. This license had its natural effect: only the choicest trees were cut, and even of these only selected portions were taken away, the rejected parts being left to cumber the ground. It has been estimated by those skilled in woodcraft that by this pernicious system 30 cubic feet of wood were wasted to each one utilized; and thus it is that many forests have totally disappeared, and even those that were not so easily accessible have been sadly impoverished. Till 1880 no steps were taken to preserve this natural wealth that was being so shamefully abused. In that year, however, the question was strongly urged on the attention of the Colonial Parliament. One of the chief defects of the system was pointed out—namely, the total absence of skilled caretakers, those then in charge having received no technical education whatever; and to meet this in some measure Parliament at once voted a sum of money to pay a trained superintendent. The choice fell on Count de Vasselot, who had had wide experience in French forestry at Nancy, and he at once proceeded to lay the foundations of the present forest department at the Cape. One of his first steps was to divide the forests into districts, which he again subdivided into sections, and to direct that felling should proceed in sections, the re-growth of the first section being given time to develop into mature trees before the axe was again used in that section. By this system the entire shutting up of any forest for a time is done away with. At present the period for the "revolution" of fellings is fixed at forty years. The tariffs now vary for standing timber from 2 cents to 6 cents per cubic foot of sound wood; with the exception of stinkwood (*Oreodaphne bullata*), which, being very hard and very valuable, was almost threatened with extermination, for which the price is 24 cents per cubic foot. Poles from 6 inches to 10 inches in diameter are sold at the rate of 2 cents per running foot; spars from 4 inches to 6 inches in diameter at 12 cents per 100 running feet.

The Consul illustrates the general system of managing and preserving the forests now followed in the colony by a minute description of that used in Knysua, the most extensive and most valuable of all the Cape forests. The total area of the Knysua may be roughly stated to be 100,000 acres, and of this magnificent forest almost three-fourths have been impoverished and in fact exhausted by the indiscriminate and reckless system of felling pursued in the past. At present the staff to conserve and replant this forest consists of one conservator, three superior grade officers, and six rangers or guards. Each higher grade officer has the superintendence of a tract of woodland varying in extent from 10,000 to 30,000 acres, in which he surveys the large timber, fixes the limits of the blocks or series, and plans out the boundaries of the various sections. No works are sanctioned without the consent of the Superintendent of Woods and Forests, and, if he has given his approval, the sections are surveyed and the trees fit for felling are marked with an official stamp. The duties of the rangers are to ride about their districts and endeavour to discover any breaches of the forest regulations, and in cases of successful prosecution they are rewarded according to the zeal and ability displayed by them. Besides the officers above-named, there are thirteen foresters distributed over the different woods, whose duty it is to plant, and, if necessary, transplant trees, and to take care of young trees. These men are paid at the rate of $20 a month, are provided with free quarters and ten acres of garden land, and are paid a bonus of $2.50 per 1000 for planting nursery plants, $2.50 per 1000 for 1-foot trees in the forest, or for nursery work and transplanting $5 per 1000 trees. This bonus cannot in the case of any individual forester exceed $200 in the year, without special permission. Each forester is expected to raise at least 40,000 young trees annually. So far as can at present be judged, seeing that the system has had but a few years' trial, it has undoubtedly proved a success. To show the amount of work that some of these foresters get through, it may be mentioned that in King William's Town forests in the year 1885 six foresters planted in the course of the year 138,080 plants in the nursery, and transplanted from the nursery into the forests 63,885 young trees. With the object of encouraging these valuable efforts to preserve the forests and to increase the area under timber, the Colonial Government has laid out several large tracts of land into plantations and nurseries, and although these are but of very recent formation they have already proved their utility in the reafforesting of the country. At the Government nurseries there are at the present moment over one million plants flourishing. In the working of these nurseries and plantations, convict labour has been utilized as largely as possible, and by this means the cost of the convict prisons has largely diminished. One other work in this connection of the Colonial Government is worthy of remark. At the plantation of Tokai, on the Table Mountain range, 150 species of extra-tropical trees have been introduced, and from them plants have been raised, with which it is proposed to reafforest the whole Table Mountain slopes, and already, in the short space of two seasons, 1000 acres have been replanted. From all the Government nurseries plants can be purchased at a nominal rate, and this, together with a recent Act whereby public bodies receive Government aid to the extent of one-half their expenditure on replanting, has given a strong stimulus to, and has aroused general interest in, the science of arboriculture among the colonists. Following the example of many American States, their first "arbor day," in 1886, was proclaimed a public holiday; and so great was its success that it is very likely to become a permanent institution. The Consul concludes his Report by saying that it is confidently hoped that with such machinery at work and with a growing interest in the advantages of tree-cultivation, in the future, Cape Colony will be independent of foreign markets for her timber supply; and that it is probable that the presence of forests, by increasing the rainfall, will bring tracts which are at present barren into cultivation.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 22.—"On the Skull, Brain, and Auditory Organ of a new Species of Pterosaurian (*Scaphognathus Purdoni*) from the Upper Lias, near Whitby, Yorkshire." By E. T. Newton, F.G.S., F.Z.S., Geological Survey. Communicated by Dr. Archibald Geikie, F.R.S.

The fossil Pterodactyl skull, which is the subject of this communication, was obtained from the Upper Lias of Lofthouse, near Whitby, by the Rev. D. W. Purdon, of Wolverhampton. It is the first Pterodactyl found in the Yorkshire Lias, and is a new form, allied to the Continental Jurassic species *Scaphognathus* (*Pterodactylus*) *crassirostris* of Goldfuss. The structure of the skull, including the back, base, and palatal regions, is better shown than in any previously discovered specimen; and in addition to this the brain and parts of the auditory organs have been exposed.

In its present condition the skull is about five and a half inches long; but apparently about two inches of the front are wanting. The elongated snout gives the skull a very bird-like appearance; but its most striking features are the five apertures, surrounded by bone, seen on each side. The orbit is the largest of these apertures; in front of this, and next in size, is the ant-orbital fossa; still further forward is the somewhat smaller external

nostril. Behind the orbit is the temporal space, divided by a bony bar into the supra- and infra-temporal fossæ.

On the upper surface of the skull are to be seen the nasals and prefrontals, on each side of the premaxillary process. The frontals form the upper boundaries to the orbits, and are confluent posteriorly with the parietals. Strong buttresses extend outward from the postfrontal and parietal regions to form the supra-temporal bar. There is on each side a large lachrymal bone forming the greater part of the upper and hinder boundary of the ant-orbital fossa. The jugal and quadrate-jugal are of a somewhat unusual form; the former bounding the lower half of the orbit, and the latter inclosing in an open V the greater part of the infra-temporal fossa. The quadrate is a wide but thin plate seen chiefly at the back of the skull. The base of the cranium is remarkable for its depth and extreme antero-posterior flattening; and viewed from behind a pair of long rods are seen extending from its lower margin, one on each side, to the inner angles of the quadrates. These bones are regarded as the homologues of the basi-pterygoid processes of the sphenoid, such as are seen in some lizards and birds, as for example in the Chameleon and Emu.

From the point of junction of the quadrate and basi-pterygoid process a bone runs along the palate, and dividing anteriorly forms the hinder boundary of the internal nostril, its outer portion joining the maxilla and its inner being continuous with a median bone occupying the position of a vomer. This bony bar, it is thought, represents the palatine and pterygoid bones.

The back of the skull is essentially Lacertilian. A large paroccipital bone extends outwards from the sides of the foramen magnum, and its distal end, expanding, embraces the upper part of the quadrate. The relation which the base of the paroccipital bears to the semicircular canals shows that it must be chiefly formed by the opisthotic element, as Prof. W. K. Parker has shown to be the case in lizards, and not by the exoccipital as it is in birds.

By removing the frontal and parietal bones of the left side, a cast of the brain cavity has been exposed, which there can be no doubt represents the form of the brain, just as closely as does that of a bird's cranial cavity. In proportion to the size of the entire skull, the brain of this Pterodactyl is very small, being not more than one-eighth of its length. Each cerebral lobe is oval in shape, and about as thick as it is wide. The olfactory lobe is small. Behind the cerebrum is a pair of large optic lobes, occupying a prominent position on the sides of the brain, and extending upwards well to the upper surface, but not meeting above in the middle line. The region of the cerebellum has been broken away, and its exact form therefore is somewhat uncertain; but, judging from portions which remain, it is tolerably clear that it extended between the optic lobes, and may have reached as far forwards as the cerebrum. Attached to the side of the medulla oblongata is a large flocculus, such as occurs in this position in birds.

It was the finding of the flocculus which led to the discovery of some parts of the auditory apparatus. On clearing away the stone in this region, a small tube filled with matrix was found arching over the pedicle of the flocculus and dipping down between it and the optic lobe. This tube occupies the position of the anterior vertical semicircular canal in the goose. By tracing the canal backwards and downwards it was found to join another similar tube forming an arch behind the flocculus—that is, in just the position of a posterior vertical semicircular canal. By careful excavation below the flocculus, a portion of a third tube was found, arching outwards in a horizontal plane, and this is believed to be the external semicircular canal.

The similarity between the base of the fossil skull and that of the Chameleon led to the inference that the fenestra ovalis would be found to be similarly placed in both, and by clearing away the matrix from the orbit and temporal fossa this inference was proved to be correct. The form and relations of the quadrate bone make it highly probable that this Pterosaurian had no ear-drum.

A comparison of this fossil with the skulls of known Pterosauria leaves no doubt that it is more nearly related to the *Scaphognathus* (*Pterodactylus*) *crassirostris* than to any other species, but as it differs from that form, and is evidently new, it is to be named specifically *Scaphognathus Purdoni*.

The Pterosaurian skull, as exemplified by this Lias fossil, resembles more the Lacertilian than any other type of Reptile skull; and seeing that the skulls of birds and lizards are in many points very similar, one is not surprised to find in this fossil characters which are also found in both these groups. In considering, therefore, the relation which the Pterosaurian skull bears to those of birds and lizards, the characters should be especially noticed which serve to distinguish between the two groups, thus:—

1. In birds the brain-case is larger in proportion to the size of the skull than it is in lizards.

2. The quadrate, pterygoid, and palatine bones are movable on the skull in birds, but more or less fixed in lizards.

3. In birds the hinder end of the palatine and front end of the pterygoid are brought into close relation with the rostrum of the sphenoid. This is not the case with lizards.

4. The orbit is rarely completed by bone in birds, and never by the jugal; in lizards the orbit is surrounded by bone, and the jugal forms part of it.

5. In birds there is no prefrontal bone, while it is always present in lizards.

6. No bird has a supra-temporal bar of bone, but it is always developed in lizards.

7. In lizards the paroccipital process is large and formed by the opisthotic; in birds the paroccipital is small and formed by the exoccipital.

8. In birds the bones of the cranium are early anchylosed; in lizards they nearly always remain separate.

9. Birds have the premaxillæ large and united into one bone; in lizards they are usually small.

10. The ant-orbital fossa which is present in birds is only occasionally present in lizards.

11. In birds there is always a lower temporal bar of bone extending from the maxilla to the quadrate. This bar is incomplete in all lizards except *Sphenodon*, although well developed in other reptiles.

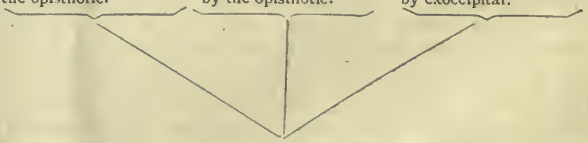
The skull of *Scaphognathus Purdoni* agrees with lizards in the first seven of the above characters; and with birds in those numbered 8, 9, 10. Number 11 need not be considered, as it can scarcely be regarded as distinctive. The greater importance of the first seven characters makes it clear that in the structure of the skull *S. Purdoni* most nearly resembles the Lacertilia.

The brain of *Scaphognathus Purdoni* agrees with that of reptiles in its relatively small size; while the separation of the optic lobes by the cerebellum and the meeting of the latter with the cerebrum, as well as the possession of a distinct flocculus, are important points in which it resembles the brain of the bird. On the other hand, the form of the optic lobes is unlike that of any living bird.

The brain of the American fossil-bird, *Hesperornis*, shows a striking resemblance to that of *Scaphognathus Purdoni*, for not only is it proportionally smaller than in recent birds, but the relation of the cerebellum and cerebrum to the optic lobes is very similar.

The facts above stated seem to show that the Pterosauria are related to the birds in the form of the brain, and to the lizards in the structure of the skull. This, however, does not constitute the Pterosaurian a transitional form between birds and reptiles, in the sense of the Pterosauria having been derived from reptiles, or of the birds having been derived from Pterosauria; but rather points to *Aves*, *Pterosauria*, and *Reptilia* having been derived from some common ancestral type. These relationships may be thus indicated, taking only a few of the characters of each:—

Lizard.	*Pterosaurian.*	*Bird.*
Cerebellum small, optic lobes meeting, paroccipital formed chiefly by the opisthotic.	Cerebellum large and between optic lobes. paroccipital formed chiefly by the opisthotic.	Cerebellum large and between optic lobes. paroccipital formed chiefly by exoccipital.



Ancestral Type.

Cerebellum small, optic lobes meeting, paroccipital small, and formed by both exoccipital and opisthotic.

Mathematical Society, April 12.—Sir J. Cockle, F.R.S. President, in the chair.—The following communications were

made:—Continuation of a former paper on simplicissima, by W. J. C. Sharp.—Synthetical solutions in the conduction of heat, by E. W. Hobson.—Symmetric functions, part ii., by R. Lachlan.—On a law of attraction which might include both gravitation and cohesion, by G. S. Carr.—Messrs. Buchheim, Larmor, and Greenhill spoke upon the various papers.

PARIS.

Academy of Sciences, April 9.—M. Janssen, President, in the chair.—Observations of the minor planets made with the great meridian instrument of the Paris Observatory during the third and fourth quarters of the year 1887, by M. Mouchez. The right ascension, polar distance, and correction of ephemerides are tabulated for thirteen of the minor planets.—On Gompertz and Makeham's laws of mortality, by M. J. Bertrand. Some arguments are advanced to show that, although he does not mention them, Thomas Simpson must have been acquainted with one or both of these laws.—Observations on the fixation of nitrogen by certain vegetable soils, by M. Berthelot. Some remarks are made in connection with the author's previous communications and M. Schlœsing's recent notes on this subject. It is pointed out that M. Schlœsing has not taken sufficient account of the experimental conditions which M. Berthelot has shown to be necessary in dealing with the question of nitrification.—On a new gas-thermometer, by M. L. Cailletet. This instrument, which has been for some time employed by the author, especially in connection with his researches, jointly made with M. Bouty, on the measurement of electric resistances at low temperatures, is described as of an extremely sensitive character, indicating differences of height of 2·36 millimetres for 1° of temperature. Being intended for measuring extremely low temperatures, it is charged with hydrogen as the expanding body.—Report on M. Delauney's astronomical communications, by the Commissioners, MM. Daubrée, Tisserand, and Faye. These communications, which were addressed to the Academy during M. Delauney's residence in Cochin-China, are now resumed in one volume, and are of an extremely varied character. They deal with the distances of the planets from the sun; the distances of the satellites from their respective planets; the distances of certain stellar groups from the central orbs of their systems; the distance of aërolites from the sun, their action on the solar spots, on our volcanoes, on the meteorological phenomena of our atmosphere, and on terrestrial magnetism; formation of the stellar systems, and especially that of Sirius, of which the sun itself, with Procyon, α Centauri, Vega, Arcturus, and others, would appear to be members. These, and other even bolder speculations, seem based on the three laws of distances here formulated by the author.—Observations of Sawerthal's Comet 1888 *a* made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan, and at the Bordeaux Observatory (0·38 m. equatorial), by MM. G. Rayet and Courty. The Paris observations cover the period from March 25 to April 6; those of Bordeaux from April 4-6.—Observations of Palisa's new planet, discovered April 3, 1888, made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Trépied and Sy. These observations, made on April 4, give an estimated magnitude of 12·5 for this planet.—On M. Bertrand's geometrical curves, by M. G. Demartres. These curves are here considered as geodetic lines of ringed surfaces; and the following problem is proposed and discussed: To find the surfaces whose circular generator is inclined at the same angle, *i*, on the same family of geodetic lines, this angle, however, being capable of varying from one generator to the next.—Action of the tetrachloride of carbon on oxygenated mineral compounds free of hydrogen, by M. H. Quantin. It was long ago shown by Geuther that potassa and baryta raised to a red heat in the vapour of the tetrachloride of carbon are transformed to chlorides and carbonates. More recently the experiments of Demarçay and Quantin, since confirmed by Lothar Meyer, have shown that oxides which cannot be attacked by chlorine alone are under the same conditions also transformed to chlorides. In the present paper the author deals more fully with these phenomena, and generalizes the results already obtained.—On the sesquichloride of rhodium, by M. E. Leidié. After examining the processes hitherto employed in the preparation of the anhydrous sesquichloride, the author describes a new method in which the chlorine acts on the alloy of rhodium and tin, $RhSn_2$, described by Debray. He then gives the processes of preparation of some double chlorides formed by the hydrated sesquichloride.—On the passive property of nickel, by M. Ernest Saint-Edme. Having already described the results of his researches on the passivity of steel and iron, the author here deals with some of the conclusions he has obtained from the analogous study of nickel.—Action of the cyanide of zinc on some chlorides, by M. Raoul Varet. The results are described of experiments with the chlorides of mercury and copper, as well as with the alkaline chlorides. The general conclusion is arrived at that the cyanide of zinc does not enter into molecular combination with the chlorides.—Syntheses by means of cyanacetic ether (continued), by M. Alb. Haller. In the present paper the author deals with the higher homologues of acetylcyanacetic ether.—Heat of formation of aniline, by M. P. Petit. The heat of formation of aniline is here determined, both by the wet and dry processes, with fairly uniform results.

THURSDAY, APRIL 26, 1888.

MR. A. C. SMITH'S "BIRDS OF WILTSHIRE."

The Birds of Wiltshire, comprising all the Periodical and Occasional Visitants, as well as those which are indigenous to the County. By the Rev. Alfred Charles Smith, M.A. (London: Porter, 1887.)

BY all ornithologists Wiltshire will be admitted to be a county the birds of which are worthy of a volume; and all ornithologists, who know, even by name and reputation only, Mr. Alfred Charles Smith, will admit that he of all men is the proper author of that volume. Nominally but the Honorary Secretary of the Wiltshire Archæological and Natural History Society, the Rector of Yatesbury has for many years past been its most active officer, and the editor of its organ—the *Wiltshire Magazine*—to say nothing of the various "by-blows" of which he has at times been delivered in the shape of "Tours" in Portugal, Egypt, and Palestine, or of the very laborious and important work on the "British and Roman Antiquities of the North Wiltshire Downs"—that work which so narrowly escaped total destruction—nearly all the copies of the original edition having perished by a disastrous fire while in the binders' hands. Mr. Smith, too, is a Wiltonian of the Wiltonians; not only one of the best-known and most highly-esteemed men in his own county, but one of those who, in these days of universal brotherhood and cosmopolitan sympathies, are year by year becoming rarer. Hence he speaks from the heart when he expresses himself as in his opening paragraphs:—

"The county of Wilts has been sometimes thoughtlessly said to be poor in Ornithology; indeed, I have heard it denounced by superficial observers as exceptionally wanting in the various members of the feathered race; pre-eminent, doubtless, in the remains of antiquity—so these gentlemen are good enough to allow—but in birds a barren field indeed. Against any such verdict I enter a decided protest, and I even maintain, on the contrary, that, taking into consideration that Wiltshire is an inland district, and therefore cannot be expected to abound in birds whose habitat is the sea and the sea-shore, our county will scarcely yield to any other, similarly situated, in the number and variety of the species of birds to be found there; and I now proceed to prove this by statistics.

"Let us first, however, examine the physical aspect of Wiltshire, and we shall see that it is not composed of bleak open downs alone, as its detractors superciliously affirm, but that it can show a great diversity of scenery, and much of it of surpassing beauty. We have, it is true, our broad, open, expanding downs—and what native of Wiltshire does not glory in them and admire them?—but we have at the same time our richly-timbered vales: if we have hill, we have also dale; if we have open plains, we have also large woods and thick forests. Where shall we find more clear and limpid streams, where more green and laughing meadows, than in the valley of the Avon (the northern and southern Avon), the vale of Kennet, or of Pewsey, or of Wily, or of Wardour? Where, again, in all England can we meet with a forest to compare with that of Savernake? And in woods and parks and well-timbered estates, both in the north and south of the county, we are exceptionally rich" (pp. 1, 2).

All who have traversed Wiltshire will readily allow the truth of these words, skilfully put together as they are by our author, in regard to the pleasing variety which its landscape in several parts exhibits, yet it must be confessed that the variety is limited in extent—the same features recurring over and over again, so that one range of downs or one valley repeats another. Both down and valley are alike enjoyable to the utmost, but the contrast between them is mild when compared with that afforded by hill and dale in many another county; and, above all, whatever may be the reason of it, Nature in Wiltshire wears an aspect of sameness, which, after a few days, becomes almost distressing to the stranger, because it is disappointing, though the native may very likely rejoice in the absence of everything that suggests a wild country; and a wild country, it should be needless to observe, gives the hope, if not its realization, of a plentiful crop of birds.

Though we fully admit the strong temptation to which a faunistic writer is exposed of magnifying the area of his field of work, it has been our duty before now in these columns to condemn the inconsiderate yielding to that temptation; and, with the utmost regard for our present author, we are compelled to say that he has fallen—perhaps not so deeply as others—into this besetting sin. We must repeat what we have so often urged before. The real interest (not only scientific, but even sentimental) of a fauna lies in its proper inhabitants—those that are entitled to all the rights and privileges of citizenship—and not in those adventitious aliens,

'Blown from over every main"

—strangers which are the sport of fate, and to whom the offer of letters of naturalization is not only a mockery—for if chance allows they are invariably killed—but an insult to the rightful denizens of the district. However, even on the unprincipled principle—which, by the way, is only admitted in ornithology among all the many branches of natural history—that a species once showing itself in a district should be scored to that district's credit, some proof of the alleged appearance is needed before it be accepted as a fact. Experience proves that there are few compilers of faunas, especially ornithological faunas, who are not ready, we will not say to strain a point, but to receive favourable evidence on easy terms; and indeed a rigid examination of all claims to admission, with a stern rejection of those that cannot be substantiated, is a virtue which has hardly been cultivated until within these later days, and not often even recently.

We have just said that in this respect Mr. Smith is not a grievous sinner; and, after examining his list pretty carefully, we find but sixteen species that we think ought, almost without any doubt, to be excluded on one ground or another—whether the ground be insufficient testimony, manifest importation, or from their proper habitat being so far distant as to render it nearly certain that their recognition within the boundaries of the county was only the accident of an accident. But how much stronger would Mr. Smith's list be if these sixteen species were omitted? and how much stronger still if the (say) forty irregular visitants were also subtracted? Then, and only then, would the ordinary reader know the wealth of Wiltshire ornithology; and, for an inland county, presenting (as we have stated) a not very diversified area, and mainly composed of one geological formation, a very respectable comparison could be made, we are confident, with any other county, however favourably situated. We

are not going to make the calculation—indeed, for comparison's sake, the statistics of many other counties are as yet wanting; but we think it would appear that not many English shires would show a more creditable roll of real inhabitants, whether breeding within its borders, or so regularly visiting it at fixed seasons as to deserve recognition as denizens. Of the former, we think Wiltshire could fairly claim 100, and of the latter 50, making the respectable number of 150, to which might be added 29 for irregular visitants to be legitimately included, after deducting the aforesaid (16 + 40 =) 56 from Mr. Smith's total of 235. Our author may think very hardly of us for thus diminishing the ornithic wealth of his county, but we assure him that he would have little cause to complain of the result were the same rule applied to the so-called "avifaunæ" of other inland shires.

This, however, is a theme we will not pursue. Rather let us speak of the manifest merits of Mr. Smith's volume. One of them stands out pre-eminently in that he has accorded so much space to two species very interesting to all who care for English birds—the Raven and the Heron. Of the former, which in days not so long past had numerous homes in Wilts, an account is given which in years to come will, we are sure, be regarded as of the highest interest, for it is compiled from information obtained by no fewer than 110 correspondents in various parts of the county, and is in itself a proof of well-directed energy. The result is, of course, a mournful one.

"It will be seen that the history of the Ravens of Wiltshire is, alas! rather a history of that which is past and gone than of that which is flourishing to-day; so persecuted, shot down, trapped, and despoiled of their young have these noble birds been at the hands of ruthless gamekeepers and others, who have gone upon the false issue that they are very destructive to game, whereas, with the exception of an occasional raid on a leveret or a rabbit, they do little harm in the preserves, for the Raven cannot bear an inclosed district—he must have plenty of room to disport himself; and as to being 'cabin'd, cribb'd, confin'd' within narrow woods, he eschews them altogether, and only during the breeding-season will he consent to occupy some big tree in the park, generally the highest and most inaccessible he can find, and there he and his mate return, year after year, to occupy their accustomed nursery" (p. 222).

It would seem, from Mr. Smith's information, that out of the twenty-two localities he names, sixteen have wholly ceased to be tenanted by this species, four are doubtful, and in *two* only has the bird certainly still a home. But how many English counties could claim such a distinction as that? Some of the larger landowners, as the Duke of Beaufort, Lords Bath and Pembroke (to their credit be it said), have been disposed to protect this very interesting and (as the writer from his own experience can assert) comparatively harmless species; but gamekeepers' prejudices are almost beyond control, and probably nothing short of a reward given on the hatching-off of a ravenry, combined with dismissal on the murder of a breeding-bird, would insure protection. A scientific man naturally shuns sentiment as such, but curious it is that the owners of historic estates do not perceive the value of all their historic associations; and an ancient Raven-tree, still occupied by the descendants of many a generation, would be no mean adjunct to the glories of Badminton or Bowood, Longleat or Wilton! Where the proprietor does not exert himself, the doom of the species is as certain as that of the Bustard has proved to be.

The Bustard, in popular opinion, is always more associated with the Wiltshire Downs or Salisbury Plain than with any other part of England. But needless to observe that herein, as usual, popular opinion is wrong, and anyone who seeks will find that in reality the association terminated much longer ago than in four or five other counties. Mr. Smith naturally devotes a good deal of space—much of it being, we regret to say, wholly beside the purpose—to this grand bird; and indeed its gilt figure decorates the cover of his volume. We must, however, express ourselves somewhat disappointed at the result, though it is one not unexpected. The statements of the editor of Pennant in 1812, and of Montagu in 1813, are confirmed, and in a small degree supplemented; but, says our author:—

"After this I have no record on which I can rely of any native Wiltshire Bustard; but I have had many statements, to which I listened attentively, from thirty to forty years ago, from old shepherds, farmers, and labourers, several of whom could well recollect seeing these birds on the downs in their early days, but from whom I could obtain no reliable information as to date; for the Wiltshire countryman, good honest soul, is not observant of detail, and as to dates he ignores them altogether—'a long whiles ago' conveniently covering half a century. However, by putting together the information gained from many sources, and by comparing the several statistics which I thought reliable, I arrived at the opinion (perhaps somewhat indistinct and hesitating) that our Wiltshire Bustard lingered on till about the year 1820" (pp. 355, 356.)

This date may be approximately correct; but it is undeniable that for several years later the Bustard inhabited the Wolds of Yorkshire and Lincolnshire, and was not extirpated in Suffolk in 1832, nor in Norfolk until 1838; since which time all the examples that have occurred in England (Wiltshire included) may rightly be regarded as foreign visitors.

Mr. Smith's account of the Heron, before mentioned, is as satisfactory as that which he gives of the Raven; but here it must suffice to say that Wiltshire boasts of seven heronries, besides twenty-two offshoots. Some of the former, however, are but recently established, and fresh colonies are always forming; for in this county, as elsewhere in England, is observable the tendency of these birds to break up and colonize—a fact almost undoubtedly due, as has been pointed out by more than one writer, to the increased difficulty of finding in one spot food for their young, induced by the more complete drainage of the country.

We have left ourselves no space for other matters on which we should like to dwell, as the honest enthusiasm of our author makes us a little blind to his faults—whether of omission or commission—the latter certainly predominating; for in his desire to give information to his readers he says a great deal more than is necessary in a faunistic work, especially as to classification, nomenclature, structure, and so forth—all matters that are best left to experts, and their treatment (which is far from perfect) only swells the volume to an uncomfortable size. We also freely excuse his many old-fashioned ways, which will, however, be no blemish, if they be not a positive blessing, in the eyes of most of his readers. The

most severe critic must admit that the style, without being in the least laboured, is far superior to that of the ordinary writer on natural history, and the book is consequently in the highest degree readable. Many a Wiltshire man, woman, and child will have reason to be grateful to Mr. Alfred Charles Smith.

A HAND-BOOK FOR TRAVELLERS.

Führer für Forschungsreisende. Anleitungen zu Beobachtungen über Gegenstände der physischen Geographie und Geologie. Von Ferdinand Freiherr von Richthofen. (Berlin: Oppenheim, 1886.)

IT is now thirteen years since Dr. Neumayer issued his "Anleitung zu wissenschaftlichen Beobachtungen auf Reisen," a joint production of himself and representatives of various departments of science, the geological section having been contributed by the present author. The volume now under consideration is virtually an enlarged and completely revised edition of that section, which it seemed desirable to publish separately. A re-issue of the complete work is, however, in contemplation. The qualifications which Von Richthofen possesses for the task he has undertaken are of no common order. Himself a traveller of wide experience, whose work on China deservedly ranks as one of the classics of geographical literature, he brings to bear upon his subject a wealth of practical knowledge combined with scientific attainment, in which few are his equals.

In the preface it is explained that the primary object of the work is to enable those travellers whose previous scientific training is not extensive, such as missionaries, merchants, and others, who may be thrown in regions but little explored, to make observations which shall be of permanent value. Under these circumstances, no attempt is made to furnish the reader with references to the literature of the subject which would almost certainly be inaccessible to him, although notice is taken here and there of modern treatises on particular questions. The body of the work opens by an introduction, the scope of which may best be indicated in a general way by stating that it contains such headings as "Outfit," "Modes of Travelling," and "Miscellaneous Practical Hints." These last are especially valuable, and might with advantage be carefully studied by anyone who is starting on a first expedition, on account of their eminently suggestive and practical character. The emphasis laid upon the necessity of noting all observations on the spot, and even upon such minutiæ as having the pencil suspended round the neck so as to be always ready, indicates an experience of the temptations to procrastination which beset travellers in common with humanity at large. Among other divisions of this section may be mentioned "Measuring and Drawing," in which sufficient directions are given for mapping unexplored countries in a preliminary fashion, and also "Climatic and Biological Observations," the latter of which are treated with extreme brevity, as not falling within the author's special province.

The next portion of the book is entitled "Observations upon Externally Modifying Processes," and includes chapters upon rocks and soils, on springs and flowing water. It contains a dissertation of some length on the important subject of glaciers, in which the phenomena accompanying their present existence, as well as the traces of their past action, are carefully described. In another chapter an abstract is given of the present state of our knowledge regarding coral reefs and islands. In addition to the time-honoured theory of Darwin, the most recent researches of Semper, Rein, Murray, and Studer are summarized; one misses, however, the name of Agassiz in this connection, and it is noticeable that, although Dana's soundings off Tahiti are quoted in some detail, no mention is made of the series executed by the *Challenger*, although their results agree well with the author's diagrammatic section of a reef. No one theory is embraced to the exclusion of all others, but stress is laid upon the need for further investigation, and upon the fact that "each reef has its own special history of origin and development." Upraised coral reefs are indicated as being likely to throw light on the question—a suggestion which has been independently carried out by Dr. Guppy in the Solomon Islands with such brilliant results. A few pages give what is known regarding the changes of level of the ocean, and the terms "positive" and "negative displacement" are adopted instead of "sinking" and "upheaval" of the land respectively.

The third section is devoted to "Observations on the Crust of the Earth, on Rocks, and on Mountain Structure." It contains an outline of the principal facts of petrology and of stratigraphical geology.

The author treats his subject in considerable detail; his volume occupies more than 700 pages—that is, a somewhat larger bulk than the whole of Neumayer's original work. Indeed, if a fault is to be found in the book, we should be disposed to say that, considering the fact that only one aspect of Nature is discussed, the amount ot detail is rather excessive. If botany, zoology, anthropology, and all the other matters which have an equal claim upon the traveller's attention, were elaborated in the same fashion, the result would be an encyclopædia of no small dimensions. The work is, however, thoroughly practical in character. There are no lengthened discussions upon abstract questions, but divergent theories regarding unsettled points are summarized in such a way as to indicate how both the traveller who has time at his disposal, and also he who is compelled to hasten through the country, can each make the best use of their respective opportunities.

W. E. H.

OUR BOOK SHELF.

Geometry in Space. Edited by R. C. J. Nixon, M.A. "Clarendon Press Series." (London: Henry Frowde, 1888.)

THIS book is a sequel to "Euclid Revised" by the same author. It consists of one hundred pages, divided into three chapters and an appendix. The first chapter is devoted to the discussion of planes and solid angles, covering much the same ground as Euclid's eleventh book; it contains, besides, some very useful notes on elementary perspective and the drawing of solid figures. This is an excellent feature of the book, and the author might with advantage have given more than a couple of pages to it, for there is no doubt that, to most students, the representation of solid figures, other than the simplest, is a real and often a permanent stumbling-block to the development of the science in their own minds. The second chapter is concerned with polyhedra. It begins with Euler's theorem establishing a linear relation between the numbers of edges, corners, and faces, and Listing's

extension of it. In giving the latter the author speaks of "facets," "sheets," and "interfaces," without having previously defined them, thus leaving a student in some little difficulty as to their precise meaning. Considering the great analytical interest of the algebraical researches of Klein and Cayley in the polyhedral functions and the finite groups of linear substitutions, which represent geometrically the production of congruence of figure by the rotations of the corresponding polyhedra, we think it would add greatly to the interest of the book to show the elementary geometrical relations which interpret the algebraical operations. The mensuration and usual properties of the simple solids are worked out, the method of limits being freely employed. The third chapter is of "Solids of Revolution," and includes Pappus's theorems of mensuration, the extension of the modern geometry of lines and circles to planes and spheres, and an elementary account of surface spherics.

The appendix, which treats of the "Geometrical Theory of Perspective in Space," is from a paper in the *Quarterly Journal of Mathematics* for 1886, by Mr. Alexander Larmor, of Clare College, Cambridge; it contains ten important theorems in the subject.

Throughout the book great brevity of expression is employed with taste and discretion. It bears traces of careful compilation, and is certainly well and suitably printed and illustrated. Interesting theorems and problems are given as exercises at the end of each chapter.

The work may be safely recommended to students and teachers as a clear and precise introduction to the study of solid geometry.

Chambers's Encyclopædia: a Dictionary of Universal Knowledge. (London: William and Robert Chambers, 1888.)

THE process of revising and altering a work of this kind is no easy task. As the publishers tell us, "much has happened during the twenty years it has been before the public which necessitates a different treatment of many articles." This new edition has been thoroughly revised, new articles having been written, and the old ones gone over by eminent authorities, as may be seen from the following list: Alchemy and Atomic Theory, by Prof. Crum-Brown; Ant, by Sir John Lubbock; Alps, by Prof. James Geikie; Arctic, Antarctic, and Atlantic Oceans, by Mr. John Murray; and Atom, by Prof. Tait. While such well-known names as these will command universal respect and confidence, it is to be regretted that some of the subjects, such as that of Astronomy—to take an instance—should leave much to be desired in this particular.

The work is carried out on exactly the same lines as the original edition, the subjects being treated, not in great detail, but so as to afford information interesting to any more or less educated person.

American and colonial subjects are dealt with in this edition more than in former ones, the more important articles on American subjects being written by American authors especially for this re-issue.

The number of maps, both geographical and physical, has been increased, and the illustrations are more numerous, and supersede those of former editions. The printing throughout is excellent.

Messrs. Chambers are to be congratulated upon the issue of a work which, from its merits, deserves to find a place in every home.

Leitfaden der Zoologie für die oberen Classen der Mittelschulen. Von Dr. Vitus Graber. Mit 502 Abbildungen im Texte (darunter 62 farbige) und einem Farbendruckbilde. (Wien: F. Tempsky, 1887.)

EVEN in these days of cheap books, it is surprising to find an octavo volume of nearly 250 pages, with over 500 illustrations, published for the price of less than three shillings of our money. When we add that the information, though of necessity very much condensed, is not only good and exact, but in most cases quite up to date, we have said all that is needed to call our readers' attention to this little volume.

The coloured illustrations in the text are wonderfully effective; one gives a representation of one of Schulze's sections through a Sponge, printed in two colours, in which the horny framework is represented yellow, the pore-canal system blue.

It is interesting to note that at a time when in this country the study of biology is not encouraged in our schools, when it is omitted from the programme of our intermediate education examinations, it should be so taught in the intermediate schools in Austria as to call for the production of such an excellent and cheap introduction to its study.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Coral Formations."

I SHOULD be trespassing too much on the kindness of the Editor of NATURE if I were to refer to all the numerous novel and interesting points in Mr. Bourne's description of Diego Garcia. The retrospective character of the account is something new in the instance of an atoll; and it is not often that a naturalist is able to add to his own observations the twenty-five years' experience of an observer like M. Spurs.

I am, however, at a loss to understand why Mr. Bourne is unable to assent to the theory of subsidence. Prof. Dana, who long since referred to the evidence of upheaval in the atoll regions of the Pacific, nevertheless did not regard such evidence as negativing the theory he supported, nor, in fact, did Mr. Darwin himself. The testimony most required to overturn the theory of subsidence is the testimony which the supporters of that view will accept. I do not find such evidence in Mr. Bourne's paper.

I am also in doubt as to the position of the writer of the paper in regard to Mr. Murray's views. In disagreeing with the importance which Mr. Murray attaches to the agency of solution, he makes no attack on the main position of the new explanation, viz. the building up of the foundations of atolls by organic deposits. Does Mr. Bourne accept this view?

H. B. GUPPY.

I HAVE been much interested by the discussion on coral formations which recently appeared in NATURE, and I venture to send you an extract from a journal kept during my stay in Massowah.

"*Massowah, February* 1888.—The whole of the harbour is fringed with coral reefs formed by species of *Madreporaria* (*perforata*), extending in places a considerable distance from the high-water mark (Turtle Island, for example); in other parts the edge of the reef is quite close to land, and in each case there is less water immediately over the edge of the reef than there is a little way in shore. The outer edges of the reefs go down almost perpendicularly to a depth of 4 or 5 fathoms, while towards the shore the water deepens, at first rather quickly to 3 or 4 feet, then gradually becomes shallow to the beach. The bottom, inside the edges of the reefs, is composed of fine grayish mud—composed chiefly of a mixture of disintegrated coral and fine drift alluvial sand which is blown over from the mainland—while the bottom of the harbour is nearly black mud. Here and there, just inside the edges of the reefs, are found pieces of living coral broken off from the outer edges. Every evidence here shows that the land is rising.

"Large masses of coral much altered by the rain are to be found on the plains of Massowah, which extend three or four miles in south-west, west, and north-west directions. They show unmistakable signs of the undermining action of the sea,

which can still be seen going on around the coast and harbour. At Mokullo, at a depth of 20 feet, I observed masses of coral (*Aperosa*) almost perfect in shape, covered up with alluvium. It is probable that the whole coast from the mountains has been reclaimed by the action of coral builders, and that eventually the group of islands outside will be joined to the mainland."

I noticed a similar formation of the coral reefs in Suakim Harbour; while at Key West, Florida, there was no lessening of the depth of the water on the edge of the reefs.

DAVID WILSON-BARKER.

THE following table, showing some of the results of work done in connection with the solubility of carbonate of lime in sea-water will be of interest. The difference in solubility between heavy dense corals and the lighter porous varieties is very marked.

TABLE I.—*Showing Solubility oj Carbonate of Lime, under different forms, in Sea-water, in grammes per litre.*

Material used.	Temperature.	Exposure.	Mean amount of $CaCO_3$ taken up.	Number of determinations made.
	° C.	Hours	Grm.	
Dead coral, Porites	27	12	0·395	3
Coral sand	27	12	0·032	5
Harbour mud, Bermuda	27	12	0·041	2
Isophyllia dipsacea (Dana), Bermuda	27	12	0·041	6
Millepora ramosa (Pallas), Bermuda	27	12	0·036	7
Madrepora aspera (Dana), Mactan Island, Zebu	27	12	0·073	7
Montipora folioso (Pallas), Amboyna	27	12	0·043	7
Gomastræa multilobata (Qualch), Amboyna ...	10	12	0·073	3
Porites clavaria (Lamk.), Bermuda	10	12	0·093	2

TABLE II.

Weathered oyster-shells	10	12	0·331	3
Mussels allowed to rot in sea-water seven days...	27	168	0·384	2
Crystallized carbonate of lime	10	12	0·123	2
a Amorphous carbonate of lime (freshly prepared)	10	—	0·649	2
b Ditto ditto ditto	−1·66	—	0·610	2
Melobesia, Kilbrennan Sound, Scotland ...	10	12	0·089	3

a and *b*. The carbonate of lime was added as long as it dissolved.

The figures in Table II. will give Mr. T. Mellard Reade facts (so far as laboratory experiments may) upon which to found reasonable views. Mr. George Young, who has made all the determinations under my direction, is one of the chemical staff attached to the Marine Station here.

ROBERT IRVINE.

Royston, Granton, near Edinburgh, April 16.

Note on a Problem in Maxima and Minima.

I SUPPOSE most lovers of elementary geometry who read the communication on the above subject from Mr. Chartres in NATURE of February 2 (p. 320) admired the simple investigation he gave of the problem.

I should like, however, to point out—

(1) That it might be made still more elementary by proving $EB + EC = ED$ without the aid of Book VI.

Let E be any point on the arc of the circumcircle of an equilateral triangle BDC on which the angle D stands, and on ED as diameter describe a circle cutting EB, EC in B′, C′.

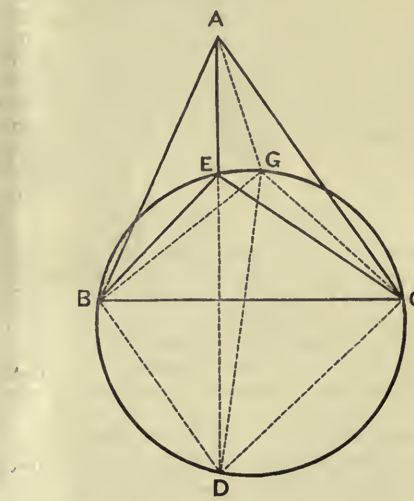
$$\text{Then } \angle B'C'D = \angle BED = \angle BCD.$$
$$\text{Similarly } \angle C'B'D = \angle CBD;$$
$$\therefore \angle B'DC' = \angle BDC;$$
$$\therefore B'C'D \text{ is equilateral.}$$

Hence B′E, EC′ are sides of a regular hexagon inscribed in the circle B′C′D.

$$\therefore B'E + EC' = ED.$$
$$\text{Again, } BD, DB' = CD, DC',$$
$$\text{and } \angle BDB' = \angle CDC';$$
$$\therefore BB' = CC';$$
$$\therefore BE + EC = B'E + EC'$$
$$= ED.$$

(2) If we assume Ptolemy's theorem (conventionally quoted as Euclid, VI. D) we may as well assume the known extension of it to acyclic quadrilaterals given in Todhunter's "Euclid," p. 318, and at the same time generalize the problem thus—

To find a point E within a triangle such that $l \, . \, AE + m \, . \, BE + n \, . \, CE$ may be a minimum; l, m, n being such that any two are together greater than the third.



On BC describe a triangle BCD such that $BC : CD : DB :: l : m : n$; the point required will be the intersection E of AD with the circumcircle of BCD if E is within the triangle ABC.

$$\text{For } BE \, . \, CD + CE \, . \, BD = ED \, . \, BC,$$
$$\therefore m \, . \, BE + n \, . \, CE = l \, . \, ED;$$
$$\therefore l \, . \, AE + m \, . \, BE + n \, . \, CE = l \, . \, AD.$$

But if G is any other point on the arc BEC,

$$m \, . \, BG + n \, . \, CG = l \, . \, GD;$$
$$\therefore l \, . \, AG + m \, . \, BG + n \, . \, CG = l \, . \, AG + l \, . \, GD;$$
$$\therefore l \, . \, AG + m \, . \, BG + n \, . \, CG > l \, . \, AD.$$

And if P be any point within the triangle ABC, but not on the circumference—

$$BP \, . \, CD + CP \, . \, BD > PD \, . \, BC \text{ (Todhunter's "Euclid," [p. 318]);}$$
$$\therefore m \, . \, BP + n \, . \, CP > l \, . \, PD;$$
$$\therefore l \, . \, AP + m \, . \, BP + n \, . \, CP > l \, . \, AP + l \, . \, PD;$$
$$\therefore l \, . \, AP + m \, . \, BP + n \, . \, CP > l \, . \, AD.$$

If l, m, n are proportional to a, b, c, E is the orthocentre of ABC.

If l, m, n are proportional to c, a, b, or b, c, a, E is one of the Brocard points of ABC, and the construction for E is equivalent to that of Mr. R. F. Davis for the Brocard points ("Reprint of Mathematics from the *Educational Times*," vol. xlvii. App. II.).

It will, of course, be seen that the triangle formed by drawing perpendiculars to AE, BE, CE through A, B, C, is the maximum triangle with its sides proportional to l, m, n and passing through A, B, C. Prof. Genese has kindly supplied me with an elementary investigation of the problem, depending on the construction of that triangle.

It may also be seen that the question has an intimate connection with one proposed by Mr. Morgan Jenkins in the *Educational Times* for August 1, 1884:—

If on the three sides of a triangle, ABC, there be described any three triangles, BDC, CEA, AFB, either all externally or all internally having their angles in the same order of rotation, and the angles which are contiguous to the same corner of ABC equal to each other, prove that AD, BE, and CF meet in a point O, which is also the common point of intersection of the circumcircles of BDC, CEA, AFB ("Reprint," vol. xliii. pp. 88–91).

EDWARD M. LANGLEY.

Bedford, April 14.

Self-Induction.

I FIND I am being quoted as having said that an iron conductor has less self-induction than a copper one. You will perhaps spare me a line to disclaim any such statement. It is one which seems to me on the face of it absurd.

OLIVER J. LODGE.

SUGGESTIONS ON THE CLASSIFICATION OF THE VARIOUS SPECIES OF HEAVENLY BODIES.[1]

II.

II.—CLASSIFICATION.

I. FORMER CLASSIFICATIONS OF STARS.

IN the various classifications of the celestial bodies which have been attempted from time to time, nebulæ and comets have been regarded as things apart from the stars; but from what I have stated in the first part of this paper, relating to the origin of the various groups of heavenly bodies, it is clear that it is not only unnecessary but unphilosophical to make such a separation; and indeed, if any such separation were needed, such a result would seem to indicate that the line of evolution is by no means so simple and clear as it really seems to be. But although it is no longer necessary to draw this distinction, it is important that I should state the various spectroscopic classifications which have been attempted in the case of the stars. With this information before us, we shall be better able to see the definite lines on which any new classification must be based to include all celestial forms.

Fraunhofer, Rutherfurd, and Secchi.

When we inquire into the various labours upon which our present knowledge of the spectra of the various orders of "stars" are based, the first we come across are those of Fraunhofer, who may be said to have founded this branch of scientific inquiry in the year 1814.

Fraunhofer not only instituted the method of work which now is found to be the most effective, but his observations at that time were so excellent that he had no difficulty in finding coincidences between lines in the sun and in Venus.

Fraunhofer's reference to his observations runs as follows:—

"I have also made several observations on some of the brightest fixed stars. As their light was much fainter than that of Venus, the brightness of their spectrum was consequently still less. I have nevertheless seen, without any illusion, in the spectrum of the light of Sirius, three large lines, which apparently have no resemblance with those of the sun's light. One of them is in the green, and two in the blue space. Lines are also seen in the spectrum of other fixed stars of the first magnitude; but these stars appear to be different from one another in relation to these lines. As the object-glass of the telescope of the theodolite has only thirteen lines of aperture, these experiments may be repeated, with greater precision, by means of an object-glass of greater dimensions."[2]

He did not attempt to classify his observations on stellar spectra, but, as pointed out by Prof. Dunér ("Les Étoiles à Spectres de la Troisième Classe," p. 3), those that he most particularly mentions are really remarkably diverse in their characteristics.

In these researches Fraunhofer was followed by Rutherfurd, who, in the year 1863, was the first to indicate that the various stellar spectra which he had then observed were susceptible of being arranged into different groups. His paper was published in *Silliman's Journal* (vol. xxxv. p. 71), and, after giving an account of the observations actually made, continues as follows:—

"The star spectra present such varieties that it is difficult to point out any mode of classification. For the present, I divide them into three groups:—First, those having many lines and bands, and mostly resembling the sun, viz. Capella, β Geminorum, α Orionis, Aldebaran, γ Leonis, Arcturus, and β Pegasi. These are all reddish or golden stars. The second group, of which Sirius is the type, presents spectra wholly unlike that of the sun, and are white stars. The third group, comprising α Virginis, Rigel, &c., are also white stars, but show no lines; perhaps they contain no mineral substance, or are incandescent without flame."

Soon afterwards Secchi carried on the inquiry, and began in 1865 by dividing the objects he had then observed into two types. These two types were subsequently expanded in 1867 into three ("Cataloge delle Stelle di cui si e determinato lo Spettro Luminoso," Secchi, Parigi, 1867): first, white stars, like α Lyrae; secondly, yellow stars, like Arcturus; and, thirdly, deeply coloured stars, like α Herculis and α Orionis. The order of these types was not always as stated, but I have not been able to find the exact date at which the order was changed (Dunér, "Sur les Étoiles," p. 128). Secchi subsequently added a fourth type, in which the flutings were less numerous. There is little doubt that Secchi was led to these types not so much by any considerations relating to the chemical constitution of the atmospheres of these bodies as in relation to their colours. His first classifications, in fact, simply separated the white stars from the coloured ones (see on this point "Le Scopirte Spettroscopiche," P. A. Secchi, Roma, 1865).

The fourth type included, therefore, stars of a deeper red colour than those of the third, and Secchi pointed out that this was accompanied by a remarkable change in the spectrum; in fact, of Secchi's four types thus established, the first and second had line spectra and the third and fourth had fluted ones. At that time the important distinction to be drawn between line- and fluted-spectra was not so well recognized as it is at present; and further the relation of spectra to temperature was not so fully considered. Secchi, as a result of laboratory work, however, at once showed an undoubted connection between the absorption flutings in the stars of the fourth type and those seen in the spectrum of carbon under certain conditions; and although this conclusion has been denied, it has since been abundantly confirmed by Vogel and others (see Vogel, *Publicationen*, Potsdam, No. 14, 1884, p. 31).

Relation to Temperature.

At the time that Secchi was thus classifying the stars, the question was taken up also by Zöllner, who in 1865 first threw out the suggestion that the spectra might probably enable us to determine somewhat as to the relative ages of these bodies; and he suggested that the yellow and red light of certain stars were indications of a reduction of temperature (Zöllner, "Photometrische Untersuchungen," p. 243).

In 1868 this subject occupied the attention of Ångström with special reference to the contrasted spectra of lines and flutings. On this he wrote as follows, showing that temperature considerations might help us in the matter of variable stars ("Recherches sur le Spectre solaire," Upsala, 1868):—

"D'après les observations faites par MM. Secchi et Huggins, les raies d'absorption dans les spectres stellaires sont de deux espèces: chez l'une, le spectre est rayé de lignes très-fines, comme le spectre solaire; chez l'autre, les raies constituent des groupes entiers à espaces égaux ou des bandes nuancées. Ces derniers groupes appartiennent vraisemblablement aux corps composés, et je mentionnerai, en particulier, que ceux trouvés dans le spectre de α Orionis ressemblent fort aux bandes lumineuses que donne la spectre de l'oxyde de manganèse. Supposé que ma théorie soit juste, l'apparition de ces bandes doit donc indiquer que la température de l'étoile est devenue assez basse pour que de telles combinaisons chimiques puissent se former et se conserver.

"Entre ces deux limites de température chez les étoiles, limites que l'on peut caractériser par la présence de l'une ou de l'autre espèce des raies d'absorption, on peut s'imaginer aussi un état intermédiaire, dans lequel les gaz

[1] The Bakerian Lecture, delivered at the Royal Society on April 12, by J. Norman Lockyer, F.R.S. Continued from p. 590.

[2] "On the Refractive and Dispersive Power of Different Species of Glass, with an Account of the Lines which cross the Spectrum," Fraunhofer, translated in *Edin. Philosophic Journal*, vol. x., October to April, 1823–24, p. 39.

composés peuvent se former ou se dissocier, suivant les variations de température auxquelles ils sont assujettés par l'action chimique même. Dans cette classe doivent probablement être comprises les étoiles dont l'intensité de lumière varie plus ou moins rapidement, et avec une périodicité plus ou moins constante."

In the year 1873, I referred to this subject in my Bakerian Lecture (*Phil. Trans.* vol. clxiv. pt. 2, 1873, p. 492), in which I attempted to bring to bear some results obtained in solar inquiries upon the question of stellar temperatures. I quote the following paragraphs :—

I. The absorption of some elementary and compound gases is limited to the most refrangible part of the spectrum when the gases are rare, and creeps gradually into the visible violet part, and finally to the red end of the spectrum, as the pressure is increased.

II. Both the general and selective absorption of the photospheric light are greater (and therefore the temperature of the photosphere of the sun is higher) than has been supposed.

III. The lines of compounds of a metal and iodine, bromine, &c., are observed generally in the red end of the spectrum, and this holds good for absorption in the case of aqueous vapour.

Such spectra, like those of the metalloids, are separated spectroscopically from those of the metallic elements by their columnar or banded structure.

IV. There are, in all probability, no compounds ordinarily present in the sun's reversing layer.

V. When a metallic compound vapour, such as is referred to in III., is dissociated by the spark, the band spectrum dies out, and the elemental lines come in, according to the degree of temperature employed.

Again, although our knowledge of the spectra of stars is lamentably incomplete, I gather the following facts from the work already accomplished with marvellous skill and industry by Secchi, of Rome.

VI. The sun, so far as the spectrum goes, may be regarded as a representative of class (β) intermediate between stars (α) with much simpler spectra of the same kind and stars (γ) with much more complex spectra of a different kind.

VII. Sirius, as a type of α, is (1) the brightest (and therefore hottest ?) star in our northern sky ; (2) the blue end of its spectrum is open,—it is only certainly known to contain hydrogen, the other metallic lines being exceedingly thin, thus indicating a small proportion of metallic vapours ; while (3) *the hydrogen lines in this star are enormously distended*, showing that the chromosphere is largely composed of that element.

There are other bright stars of this class.

VIII. As types of γ the red stars may be quoted, the spectra of which are composed of channelled spaces and bands, and in which naturally the blue end is closed. Hence the reversing layers of these stars probably contain metalloids, or compounds, or both, in great quantity ; and in their spectra not only is hydrogen absent, but the metallic lines are reduced in thickness and intensity, which in the light of V., *ante*, may indicate that the metallic vapours are being *associated*. It is fair to assume that these stars are of a lower temperature than our sun.

In the same year, in a letter to M. Dumas, published in the *Comptes rendus*,[1] I again pointed out that, if we consider merely the scale of temperature, a celestial body with flutings in it would be cooler than one which had lines in its spectrum ; and I also pointed out that, taking the considerable development of the blue end of the spectrum in white stars as contrasted with its feeble exhibition in stars like our sun, we had strong presumptive evidence to the effect that the stars like α Lyræ, with few lines in their spectra, were hotter than those resembling our sun, in which the number of lines was very much more considerable, and I added an inference from this : "plus une étoile est chaude, plus son spectre est simple." This related merely, as I have said before, to the consideration of one line of temperature.

[1] "Il semble que plus une étoile est chaude, plus son spectre est simple, et que les éléments métalliques se font voir dans l'ordre de lines poids anatomiques. Ainsi nous avons :—

"(1) Des étoiles très brillantes, où nous ne voyons que l'hydrogène *en quantité énorme*, et le magnésium.

"(2) Des étoiles plus froides, comme notre soleil, où nous trouvons:—

H + Mg + Na.
H + Mg + Na + Ca. Fe, &c. ;

dans ces étoiles, pas de métalloïdes.

"(3) Des étoiles plus froides encore, dans lesquelles tous les éléments métalliques sont associés, où leurs lignes ne sont plus visibles, et où nous n'avons que les spectres des métalloïdes et des composés.

"(4) Plus une étoile est âgée, plus l'hydrogène libre disparait ; sur la terre, nous ne trouvons plus l'hydrogène en liberté."

Vogel's Classification.

In the year following my paper, the most considerable classification which has been put forward of late years was published by Dr. Vogel (*Astr. Nach.*, No. 2000), who, basing his work on the previous types of Secchi, and taking into account the inference I drew in my letter to Dumas, modified Secchi's types to a certain extent, but always along one line of temperature, the leading idea being, as I gather from many remarks made in Dunér's admirable memoir, to be referred to presently, that the classification is based upon descending temperatures, and that all the stars included in it are supposed at one time or other to *have had* a spectrum similar to that of α Lyræ.[1]

This classification is as follows :—

CLASS I. *Spectra in which the metallic lines are extremely faint or entirely invisible.*—The most refrangible parts, blue and violet, are very vivid. The stars are white.

(*a*) Spectra in which the lines of hydrogen are very strong.

(*b*) Spectra in which the lines of hydrogen are wanting.

(*c*) Spectra in which the lines of hydrogen and D_3 are bright.

CLASS II. *Spectra in which the metallic lines are numerous and very visible.*—The blue and violet are relatively weaker ; in the red part there are sometimes faint bands. The colour of the stars is clear bluish white to deep reddish yellow.

(*a*) Spectra with numerous metallic lines, especially in the yellow and green. The lines of hydrogen are generally strong, but never as strong as in the stars of Class I. In some stars they are invisible, and then faint bands are generally seen in the red formed by very close lines.

(*b*) Spectra in which besides dark lines and isolated bands there are several bright lines.

CLASS III. *Spectra in which besides the metallic lines there are numerous dark bands in all parts of the spectrum, and the blue and violet are remarkably faint.*—The stars are orange or red.

(*a*) The dark bands are fainter towards the red.

(*b*) The bands are very wide, and the principal are fainter towards the violet.

It is pointed out that if this classification be true, there must be links between all the classes given. Now it is perfectly obvious that if this classification includes in its view all the stars, and if there is a line of ascending as well as descending temperatures—that is to say, if some of the stars are increasing their temperatures, while others are diminishing them—the classification must give way.

It is not difficult to see, in the light of my communication to the Society of November 17, that it has given way altogether, and principally on this wise.

The idea which underlies the classification is that a star of Class I. on cooling becomes a star of Class II., and that a star of Class II. has as it were a choice before

[1] "Car selon la théorie il faudra que tôt ou tard toutes les étoiles de la première classe deviennent de la seconde, et celles-ci de la troisième" (Dunér).

it of passing to Class III.*a* or Class III.*b*. Thus under certain conditions its spectrum will take on the appearance of Secchi's third type, Class III.*a* (Vogel); on certain other conditions it will take on the appearance of Secchi's fourth type, Class III.*b* (Vogel). There is now, however, no manner of doubt whatever that Secchi's Class III.*a* represents stars in which the temperature is increasing, and with conditions not unlike those of the nebulæ—that is to say, the meteorites are yet discrete, and that they are on their way to form bodies of Class II. and Class I. by the ultimate vaporization of all their meteoric constituents. There is equally no manner of doubt that the stars included in Class III.*b* have had their day; that their temperature has been running down, until owing to reduction of temperature they are on the verge of invisibility brought about by the enormous absorption of carbon in their atmospheres.

Pechüle was the first to object to Vogel's classification, mainly on the ground that Secchi's types 3 and 4 had been improperly brought together; and my work has shown how very just his objection was,[1] and how clear-sighted was his view as to the true position of stars of Class III.*b*.

II. Proposed New Grouping of all Celestial Bodies according to Temperature.

Having, then, gone over the various classifications of stars according to their spectra, I now proceed to consider the question of the classification of celestial bodies from a more advanced point of view. I pointed out in the year 1886 that the time had arrived when stars with increasing temperatures would require to be fundamentally distinguished from those with decreasing temperatures, but I did not then know that this was so easy to accomplish as it now appears to be (NATURE, vol. xxxiv. p. 228); and as I have already stated, when we consider the question of classification at all, it is neither necessary nor desirable that we should limit ourselves to the stars; we must include the nebulæ and comets as well, and the question of variability does not really concern us, because it is as a rule in its extremest form the passage of a body giving one spectrum to a body giving another even if of a different type, owing to sudden changes of temperature.

[1] "M. Vogel a proposé une classification suivant les diverses phases de refroidissement indiquées par les spectres, dans laquelle il fait des types III. et IV. de Secchi deux subdivisions d'une même classe, III.*a* et III.*b*. Mais je trouve certaines difficultés négatives contre cette classification relativement au rôle qu'y joue la III.*b*. En effet, il est admis que le IV. type de Secchi se distingue nettement du III. type, non seulement par la position et la quantité des zones obscures, mais aussi par le fait très-remarquable, que les principales de ces zones sont bien définies et brusquement interrompues du côté du violette dans le III. type du côté du rouge dans le IV. Or, si le IV. type doit représenter une des phases de refroidissement, par lesquelles passent les étoiles, on peut faire deux hypothèses. La première est que le spectre du IV. type soit coordonné au spectre du III. type, de manière qu'il ait des étoiles, qui passent de la phase représentée par le II. type, à la phase représentée par le III. type, et d'autres, qui passent directement du II. type au IV. Mais cette hypothèse est inadmissible. Car on connaît de spectres entremédiaires entre le I. et le II. type, et entre le II. et III.; mais on ne connaît pas, à ce que je sache, de spectres du II. type tendant au IV. Reste donc l'hypothèse, que la phase de refroidissement, représentée par le spectre du IV. type, soit postérieure à la phase représentée par le III. type, de manière que les spectres des étoiles passent du III. au IV. type. Si ce passage se fait peu à peu, il devrait avoir des spectres entremédiaires entre le III. et le IV. type; mais quoique Secchi par exemple le 17 Jan., 1868, ait déterminé le spectre de l'étoile 273 Schjell., comme semblant entremédiaire entre le III. et le IV. type, il l'a plus tard reconnu du IV. type, et l'existence de spectres du III.-IV. type n'est nullement prouvée. On pourrait objecter que les étoiles du IV. type sont peu nombreuses et en général si petites que leurs spectres sont difficiles à voir, et que par conséquent il pourrait y avoir parmi ces spectres quelques-uns, qui se rapprochassent du III. type. Mais je réponds à cette remarque, que les spectres du III.-IV. type, indiquant une phase moins refroidie, devraient au contraire en général appartenir à des étoiles plus grandes que celles ayant des spectres du IV. type. Si on veut supposer que le passage du III. au IV. type se fasse subitement, ou par une catastrophe, pendant laquelle apparaissent des lignes brillantes, cette supposition même constituerait une différence physique bien plus distincte entre le III. et le IV. type, qu'entre le II. et le III.; et le IV. type représenterait une phase bien distincte, la dernière peut-être avant l'extinction totale. Le rôle physique du IV. type est donc encore si mystérieux, que j'ai cru pouvoir encore me conformer à l'exemple de d'Arrest, en suivant la classification formelle de Secchi."—C. F. Pechüle, "Expédition Danoïse pour l'Observation du Passage de Venus, 1882," p. 25 (Copenhagen, J. H. Schultz, 1883).

In the first classification on these lines, which is certain to be modified as our knowledge gets more exact, it is desirable to keep the groups as small in number as possible; the groups being subsequently broken up into sub-groups, or, as I prefer to call them, species, as the various minute changes in spectra brought about by variations of temperature are better made out.

In my paper of November 17 (NATURE, vol. xxxvii. p. 84), I gave a diagram of the "temperature curve," on which is shown the distribution of nebulæ and of stars as divided into classes by Vogel, on the two arms of the curve.

On one arm of this we have those stages in the various heavenly bodies in which in each case the temperature is increasing, while on the other arm we have that other condition in which we get first vaporous combination, and then ultimately the formation of a crust due to the gradual cooling of the mass in dark bodies like, say, the companion to Sirius. At the top we of course have that condition in which the highest temperature must be assumed to exist.

To begin, then, a more general classification with the lowest temperatures, it is known that the nebulæ and comets are distinguished from most stars by the fact that we get evidence of radiation. Absorption has been suspected in the spectra of some nebulæ,[1] and has been observed beyond all doubt in some comets.[2] But there are some stars in which we also get radiation, accompanied by certain absorption phenomena; but there is no difficulty in showing that these bodies are more special on account of their bright lines than on account of their absorption bands. We may therefore form the first group of bodies which are distinguished by the presence of bright lines or flutings in the spectrum.

The presence or absence of carbon will divide this group into two main divisions, which, however, we may neglect in the following very brief sketch which I give in advance of a more detailed treatment.

The first species in this group would contain the nebulæ, in which only the spectrum of the meteoric constituents is observed. In the second species we find the spectrum of hydrogen added.

Another early species would contain those bodies in which the nebula spectrum gets almost masked by a continuous one, such as Comets 1866 and 1867, and the great nebula in Andromeda.

In the second division will be more condensed swarms still, in which, one by one, new lines are added to the spectra, and carbon makes its appearance; while probably the last species in this group would be bodies represented by γ Cassiopeiæ.

The great distinction between the first group and the second would be that evidences of absorption now become prominent, and side by side with the bright flutings of carbon and occasionally the lines of hydrogen we have well-developed fluting absorption.

The second group, therefore, is distinguished from the first by mixed flutings—that is to say, the presence of bright and dark flutings as well as lines in the spectrum.

I give a detailed examination into the species of this group in the next part of this memoir.

[1] "Nebula [No. 117, 51h. 32 M. R.A. 0h. 35m. 5·3s.; N.P.D. 49° 54′ 12″·7. Very, very bright; large, round; pretty suddenly much brighter in the middle].—This small but bright companion of the great nebula in Andromeda presents a spectrum exactly similar to that of 31 M [the great nebula in Andromeda]. The spectrum appears to end abruptly in the orange; and throughout its length is not uniform, but is evidently crossed either by lines of absorption or by bright lines" (Huggins, *Phil. Trans.* vol. cliv. p. 441).

[2] "A dark band was noticed at wave-length 567·9" (Copeland, Comet III., 1881, *Copernicus*, vol. ii. p. 226).

"May 20.—With none of these dispersions could any bright bands, properly so called, be distinguished; but two faint broad *dark* bands, or what gave that impression, crossed the spectrum. . . . A third dark band was suspected near D on the blue side of that line" (Maunder, Comet α 1882 (Wells), "Greenwich Spectroscopic Observations, 1882," p 34).

The dark bands were observed again, and their wave-lengths measured on May 31" (*ibid.* p. 35).

The passage from the second group to the third brings us to those bodies which are increasing their temperature, in which radiation and fluting absorption have given place to line absorption.

At present the observations already accumulated have not been discussed in such a way as to enable us to state very definitely the exact retreat of the absorption, by which I mean the exact order in which the absorption lines fade out from the first members to the last in the group. We know generally that the earlier species will contain the line absorption of those substances of which we get a paramount fluting absorption in the prior group. We also know generally that the absorption of hydrogen will increase while the other diminishes.

The next group, the fourth, brings us to the stage of highest temperature, to stars like α Lyræ; and the division between this group and the prior one must be more or less arbitrary, and cannot at present be defined. One thing, however, is quite clear, that no celestial body without all the ultra-violet lines of hydrogen discovered by Dr. Huggins can claim to belong to it.

We have now arrived at the culminating point of temperature, and now pass to the descending arm of the curve of temperature. The fifth group, therefore, will contain those bodies in which the hydrogen lines begin to decrease in intensity, and other absorptions to take place in consequence of reduction of temperature.

One of the most interesting problems of the future will be to watch what happens in bodies along the descending scale, as compared with what happens to the bodies in Group III. on the ascending one. But it seems fair to assume that physical and chemical combinations will now have an opportunity of taking place, thereby changing the constituents of the atmosphere; that with every decrease of temperature an increase in the absorption lines may be expected, but it will be unlikely that the last species in this group will resemble the first one in Group III.

The next group, the sixth, is Secchi's type IV. and Vogel's Class III.*b*, its distinct characteristics being the absorption flutings of carbon. The species of which it will ultimately be composed are already apparently shadowed forth in the map which accompanies Dunér's volume, and they will evidently be subsequently differentiated by the gradual addition of other absorptions to that of carbon, while at the same time the absorption of carbon gets less and less distinct.

To sum up, then, the classification I propose consists of the following groups:—

GROUP I.—Radiation lines and flutings predominant. Absorption beginning in the last species.
GROUP II.—Mixed radiation and absorption predominant.
GROUP III.—Line absorption predominant, with *increasing* temperature. The various species will be marked by increasing simplicity of spectrum.
GROUP IV.—Simplest line absorption predominant.
GROUP V.—Line absorption predominant, with *decreasing* temperature. The various species will be marked by decreasing complexity of spectrum.
GROUP VI.—Carbon absorption predominant.
GROUP VII.—Extinction of luminosity.

It will be seen from the above grouping that there are several fundamental departures from previous classifications, especially that of Vogel.

The presence of the bright flutings of carbon associated with dark metallic flutings in the second group, and the presence of only absorbing carbon in the sixth, appears to me a matter of fundamental importance, and to entirely invalidate the view that both groups (the equivalents of III.*a* and III.*b* of Vogel) are produced from the same mass of matter on cooling.

This point has already been dwelt upon by Pechüle.

Another point of considerable variation is the separation of stars with small absorption into such widely different groups as the first and fourth, whereas Vogel classifies them together on the ground of the small absorption in the visible part of the spectrum. But that this classification is unsound is demonstrated by the fact that in these stars, such as γ Cassiopeiæ and β Lyræ, we have intense variability. We have bright hydrogen lines instead of inordinately thick dark ones; and on other grounds, which I shall take a subsequent opportunity of enlarging upon, it is clear that the physical conditions of these bodies must be as different as they pretty well can be.

It will be seen also that, with our present knowledge, it is very difficult to separate those stars the grouping of which is determined by line absorption into the Groups III. and V., for the reason that so far, seeing that only one line of temperature, and that a descending one, has been considered, no efforts have been made to establish the necessary criteria. I made this point in the paper to which I have already referred in connection with the provisional curve, and for purposes of completeness I introduce here the chief part of what I wrote on that occasion.

(*To be continued.*)

THE HITTITES, WITH SPECIAL REFERENCE TO VERY RECENT DISCOVERIES.[1]

V.

SOME months ago the Rev. Greville J. Chester brought to this country a quadrangular hæmatite seal found near Tarsus. Though this seal shows, in certain particulars, some analogy with the Yuzgât seal, yet it gives little or no additional aid in the decipherment of the inscriptions. It presents, nevertheless, features of very great interest. Prof. Sayce scarcely goes beyond the merits of the seal when he says that it possesses a "unique and splendid character; nothing like it has ever before been brought to the notice of European scholars."[2] The seal is engraved not only on the base (1), but also on the four sides, while opposite the base the stone was so cut as to serve the purpose of a handle. On four out of the five engraved faces are to be seen two figures—one seated and one standing. These may be supposed to represent men or deities, or possibly, in some cases, ideal personages. At first sight it may seem difficult to discern any general aim or connected purpose in the curious figures depicted. On more attentive examination, however, there is seen to be exhibited a pervading principle of *tri-unity*, especially as exemplified in the triangle and the trident. Moreover, while on three faces of the seal (1, 2, 5) there are figures with the "pig-tail" (an appendage which suggests a connection with the Hittites), it appears tolerably evident that the engraver of the seal intended to represent the personages with this appendage as destitute of the valuable knowledge and power connected with the mysterious three-in-oneness of the triangle and the trident. This is entirely in accordance with the position that the wearers of the pig-tail were still regarded as aliens and intruders when the seal was engraved.

On the base (1), a figure standing or advancing holds in the left hand a trident-like object, which is probably to be understood as a plant; though, like the curious symbols on the Boghaz-Keui bas-relief (*supra*, pp. 513, 514), it must be somewhat idealized. Certainly, it would seem

[1] Based on Lectures delivered by Mr. Thomas Tyler at the British Museum in January 1888. Continued from p. 593.

[2] *Archæological Journal*, December 1887. Prof. Sayce's paper is accompanied by an autotype representation of the seal. I may here mention, also, that impressions of this seal, as also of the Yuzgât seal and the seal of Tarkutimme, may be obtained at a small cost from Mr. A. Ready, of the British Museum.

difficult or impossible to identify it with any known vegetable production. And it would be equally difficult to determine what is the plant held in the hand of the sitting figure wearing the pig-tail,[1] though there seems to be a flower with a long depending and somewhat fibrous root. The two objects apparently are presented in comparison or competition, while that in the hand of the standing figure has the superiority.

On the second face a very curious scene is depicted. Above a kind of altar in the centre is a trident-like object, evidently identical with that already described. The trident-like object is between two symbols of remarkable form, capped with equilateral triangles. On these remarkable symbols, which probably represent life in general, or particularly human life, something more must be said directly. A figure, probably that of a deity, with the head of a hawk or eagle,[2] is pouring out a libation at the foot of the altar, and thus, we may presume, is confessing the superiority of the sacred objects above. On the other side of the altar is, it may be supposed, another deity, having above his head the winged solar disk, and in his left hand a double three-forked thunderbolt, introduced here, it may be supposed, as another emblem of tri-unity.

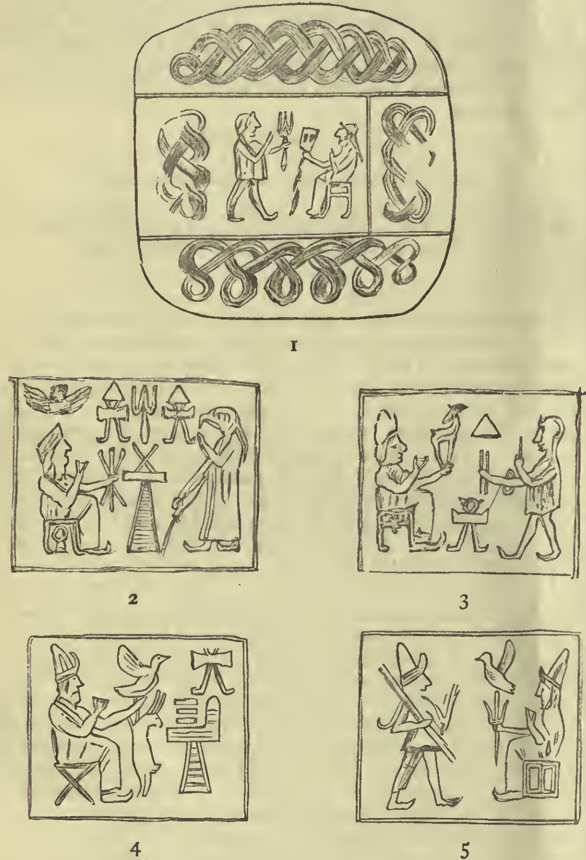


FIG. V.—The Tarsus seal (enlarged).

On the third face there is no personage wearing the pig-tail. Both the seated and the standing figures appear to be occupied with the mystery of the triangle. The engraver of the seal, moreover, as though determined that we should not mistake his meaning, actually represents the seated figure as forming a triangle with one hand. On face (4) the triangle formed by the hand is particularly clear in the impression of the seal; but there can scarcely be a doubt that the intention is the same also on this face (3) as well as on (2) and (5). How the triangle is supposed to be formed by the hand I am unable to say. By comparing the two hands of the seated figure in (3) it becomes evident that the goat standing on the left hand is here introduced as forming a triangle by his position. But still more remarkable and interesting is the personage standing, if considered together with the associated objects. This personage is supporting, apparently by a cord, a figure similar to those spoken of in connection with the second face as probably representing life in general, or more particularly the principle of human life. From the circular head of the figure are projecting what look like ears, but the triangular cap with which the head is covered on the second face is now seen above. The personage supporting the figure has in his left hand one rod held vertically, and in the right two vertical and parallel rods, thus suggesting the triangular number, three, a number regarded in antiquity as especially sacred.

The fourth face presents a single seated figure, making, as said just above, a triangle with the right hand. The left hand holds captive a hare as well as a bird with wings extended. The intention would seem to be to set forth the subjugation of the lower animals through the influence of such supposed occult and mysterious powers as those of the triangle. In front is an altar or table with objects upon it, which, it should be observed, are three in number. Above is a symbol generally identical with those spoken of in connection with faces (2) and (3), but here it is imperfect.

On the last face (5) we have apparently a competition between a pig-tailed figure standing or advancing and another figure seated. The pig-tailed figure holds two parallel rods or spears; and it would certainly appear that he is to be regarded as unequal in power to the seated figure, who is making a triangle with the left hand, while in the right hand is that symbol of tri-unity, the trident, now of more usual form, and differing considerably from the trident-like objects of (1) and (2). On the middle point of the trident is a bird with wings expanded. In this last respect the intention would seem to be somewhat similar to that expressed by the hare and bird held captive on face (4).

The Tarsus seal is probably less ancient than the Yuzgât seal; but there are nevertheless important points of resemblance, which may be reasonably taken as indicating a relationship more or less close. On both seals are to be seen the triangle and the trident, though on the Tarsus seal the form of the latter has become greatly changed. Both seals, also, have the winged solar disk. The wearing a horn in front of the head is another mark of resemblance; and the figures on both seals have the turned-up toes of the so-called "Hittite boots." The eagle-headed figure making the libation has a good deal of similarity to what, as depicted on the Yuzgât seal, I regard as a woman closely veiled, with some object, probably a baby, suspended from her arm (*supra*, p. 560). Notwithstanding any superficial resemblance, however, the objects delineated are certainly very different. The explanation probably is, that the respective engravers had in view a common typical form, which was in each case modified as the particular purpose required. A similar remark may be made with respect to the table or altar on (4), and the object before the king on the Yuzgât seal.

Whether the Tarsus seal will be found of importance with regard to the history of geometry, it would be difficult to say. This may to some extent depend on the date

[1] Prof. Sayce has rightly recognized the presence of the "pig-tail," but when he says that this appendage "characterizes Hittite female figures" (*op. cit.* p. 348), I fail to see any adequate grounds for the assertion. This, I should say, is not the mode of wearing the hair seen on the Boghaz-Keui bas-relief; and I am not acquainted with other evidence which would in any way justify the statement.

[2] The form of this deity suggests a possible relation with the eagle-headed deity on the Assyrian monuments, concerning which Assyriologists have been hitherto unable to give any adequate explanation. Perhaps some fresh light may be eventually derived from the "pig-tail" here appended.

to which the seal is to be referred. But, whatever may be the case with respect to the general history of geometry, certainly there are indications of something very like Pythagoreanism, such as we should by no means have expected to find on a Hittite or Asiatic monument. Still, however unexpected these indications may be, the scientific spirit requires that we should be loyal to facts. Among such indications may perhaps be placed the mysterious powers or properties apparently associated with vegetable forms on the Tarsus seal, as also on the Boghaz-Keui sculpture. But still greater importance and interest attach to the evidence of the seal as to the attribution of occult significance to number and to geometrical form. By the vertical rods of face (3) we are reminded of the Pythagorean doctrine concerning duality and unity, the even and the odd. (Plutarch, *De Is.* 48.) Moreover, we can scarcely mistake the sinister character of duality when we observe that the two parallel rods are carried on face (5) by the pig-tailed figure. Very probably the indications on the seal point to one of the sources whence were derived the doctrines attributed to Pythagoras. And such a view accords very well with the ancient tradition concerning the travels of Pythagoras, and the composite nature of Pythagoreanism.

But some additional consideration requires to be given to the figure on the Tarsus seal (faces 2, 3, 4), which I have spoken of as a symbol of life. In investigating the significance of this figure the most convenient method may be to compare it with the symbol most nearly resembling it which can be found elsewhere. This is to be seen on the coinage of Cyprus (Fig. W, 2). Here we have

1 2 3 4

FIG. W.—1, Symbol on Tarsus seal; 2, symbol on Cypriote coinage 3, *crux ansata*; 4, symbol on Indo-Scythian coin.

the rounded head (though without the projections on the symbol of the Tarsus seal), the horizontal stroke or body, and the divergent legs. True, on the seal there are slight projections at the ends of the horizontal piece, and at the ends of the divergent legs there are the "Hittite boots"; but in this last particular the symbol on the seal resembles the mandrake at Boghaz-Keui (*supra*, p. 514), the ends of the root being similarly turned up and metamorphosed.[1] As to the meaning of the symbol on the Cypriote coinage, we can make a reasonable inference from the fact that it seems to be introduced as an alternative symbol in place of the *crux ansata*, or symbol of life, which, indeed, is quite common on Cypriote coins.[2] The *crux ansata* was possibly derived from Egypt, but still it may very well be regarded as giving an indication of the meaning of the other symbol. If, however, the divergent legs of (2) are supposed to collapse, we have at once a *crux ansata* (3). The evidence so far would go towards the conclusion that the symbol on the Tarsus seal is a symbol of life. But by tracing the Cypriote symbol to its probable origin the evidence may be greatly strengthened.

The coins on which the Cypriote symbol just alluded to occurs are Phœnician. Now there occurs on Phœnician, and especially on Carthaginian, monuments a symbol by which scholars have been much puzzled. It consists of a triangle, normally, as it would seem, equilateral, though varying at times a good deal from this form. At the

[1] The triangular cap of the symbol on face (2) shows a connection between the symbol and the equilateral triangle. But what may be exactly the difference in the significance of the symbol when capped with the triangle and when destitute of this covering it is scarcely possible to say, unless the added triangle is supposed to give power and vitality.

[2] See De Vogüé, "Mélanges d'Archéologie Orientale," plate xi., Figs. 13, 16, 17, 18.

vertex of the triangle is a horizontal stroke or bar, with projections at the ends, which may be taken for arms, or hands held up; and these also are found to present variations. Above is a head of circular form. This frequently occurring symbol,[1] which may be seen to the reader's left in Fig. X, some scholars have taken for a representation of a man or woman praying and holding up his or her hands. But M. Renan justly observes that the position in which the symbol is found on the monuments is not compatible with such an opinion; and in the figure it evidently appears as

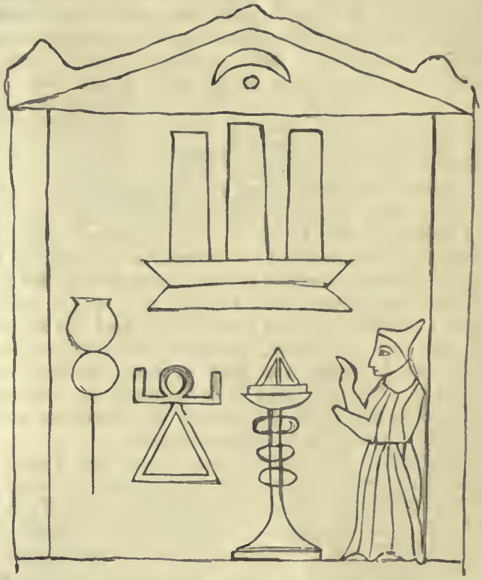

FIG. X.—Upper portion of stele of Lilybæum.

an object of worship. Regarded as denoting life, or as a sort of generalization of deity as the giver of life, its position on the stele becomes intelligible. It corresponds in form with the Cypriote symbol, except that the latter has lost the base of the triangle and the projections at the end of the horizontal piece, but indications of these being retained are clearly to be seen on the Tarsus symbol. M. Renan could make nothing of the triple object above the altar in Fig. X.[2] But when we look at the trident-like object of worship above the altar on face (2) of the Tarsus seal, the problem receives a good deal of light; and we recognize in the mysterious tripartite object of the stele a modification of the trident, expressing, like the triangle, the idea of tri-unity.

1 2

FIG. Y.—1, Portion of broken tablet in the British Museum; 2, archaic cuneiform character, *din*, "life."

With respect to the loss of the base of the triangle in the Cypriote symbol, and the import of this and other symbols before mentioned, we have evidence on a unique tablet in the British Museum. Though it is unfortunately broken, its testimony is still very important. The tablet

[1] M. Renan observes of this symbol: "Præcipua inter figuras religiosas est imago quâ nihil apud Phœnicas et Pœnos frequentius" ("Corp. inscr. sém.," vol. i. p. 281).

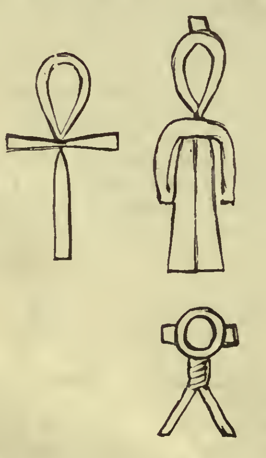
[2] He observes: "Supra figura cernitur tripartita, tribus cippis imparibus constans, cum basi duplici, quæ quid sibi velit non apparet" (*op. cit.* vol. i. p. 179). Fig. X. is a little reduced from the figure in the "Corpus."

gave the ancient hieroglyphic or hieratic forms of some cuneiform characters, with their values. Among these is a triangle the sides of which are represented by doubled lines carefully finished off, while the base, which is to a certain extent dissevered, is represented only by a single line or wedge. We thus see a tendency already to that dropping of the base exemplified in the Cypriote symbol. But is the meaning the same? The cuneiform character giving the value is unfortunately gone, except a small portion of a single wedge, which alone would yield but slender grounds for determining the import of the triangle. We are able, however, to take, together with the small portion of the wedge, the archaic cuneiform character denoting "life," and still retaining the semblance of an equilateral triangle. The value of "life" was that assigned to the triangle as it appears on the broken tablet, by M. Menant; and Mr. Pinches, of the British Museum, is also of opinion that the fragment of the wedge remaining is entirely in accordance with this view.

Whence the idea originated that the primordial source of life was of triangular form, it is of course impossible to say. This was, however, an idea which prevailed very widely indeed in the East. A distinguished scholar and archæologist has directed my attention to symbols found on Indo-Scythian coins as being analogous to the Hittite and Cypriote symbols (see Fig. V, 4). It is not difficult to discern the two sides of the triangle and the horizontal stroke or bar. Instead, however, of the circular or rounded head, there are four vertical strokes, which there can be little difficulty in recognizing as a symbol of fire, a symbol which, in the case of Zoroastrians and fire-worshippers, would be entirely suitable.

In connecting the Hittite symbol of the Tarsus seal with the Babylonian hieroglyphic triangle, we have gone back to an antiquity very remote indeed. But if we are to regard the symbols already discussed as connected also with the well-known Egyptian symbol of life, the *ankh*, and with other Egyptian symbolic forms, our demand on time must probably be much greater. That the Egyptian talismans (Fig. Z, 2, 3, 4) might have been evolved from

1 2 3



4

Fig. Z.—1, *Ankh*, Egyptian symbol of life, from coffin of Men-ka-ra, in the British Museum; 2, 3, 4, Egyptian talismans in the British Museum.

a form identical with, or resembling, the headed triangle of the Phœnician monuments, it requires no great stretch of imaginative power to discern.[1] But with regard to the *ankh* (1), so often seen in the hands of deities, though the points of resemblance are tolerably obvious,[1] yet it may seem difficult to understand how the triangle could have assumed the form of the vertical bar. True, the bar is pointed at the apex; and elsewhere on the Egyptian monuments an acute-angled triangle in the corresponding position is sufficiently common. But it is remarkable that this latter form is not seen on a monument so very ancient as the coffin of the king Men-ka-ra. Still, on the whole, it can scarcely be regarded as other than probable that the *ankh*, like the other Egyptian forms depicted, must be referred ultimately to the headed triangle. But, if this view is just, and the triangle had collapsed, as shown in the figure, when the coffin of Men-ka-ra was constructed, the period of man's existence on the earth in a condition of somewhat advanced civilization must be of exceedingly protracted duration.

As to the age of the greater Hittite monuments, it is impossible to speak. To argue that the Hittite hieroglyphs could not have remained long in use by the side of either the cuneiform syllabary or the Phœnician alphabet would be somewhat perilous. A better argument for their great antiquity is furnished by the total absence, so far as can be seen, of any indication of horses or chariots. Yet, in the wars with the Egyptians some fifteen or sixteen centuries before Christ, the Hittites appear well equipped with this kind of forces, in a state of organization from which lengthened usage may be reasonably inferred.

What has been said may suffice to show the extremely great interest of the questions suggested by the Hittite monuments. Unfortunately the material for investigation is at present but scanty, though there are probably hundreds, perhaps thousands, of monuments awaiting the spade of the excavator. The very important results obtained by the British Museum from the excavations at Jerablûs have not prevented these excavations from being for a considerable time wholly suspended. That this should be the case is certainly matter for regret; for I hope that I have at least succeeded in showing that the idea that the solution of the Hittite problem is hopeless is one which cannot be reasonably entertained.

CLASS EXPERIMENTS.

THE following is a brief account of some experiments shown to the students of the Natural Philosophy Class in the University of Glasgow during the present Session. It is communicated to NATURE with the permission of Sir W. Thomson.

I. (1) Suspend a heavy ball by a long wire, as shown in Fig. 1. To the middle of the ball attach a worsted thread, A D. Pull the thread in the direction of the arrow-head, with a pull that will not break it, and let the pull be finished before the ball is sensibly displaced. Observe the greatest subsequent displacement of the ball.

(2) Bring the ball to rest. Pull it now with a pull sufficient to break the thread. Note that the displacement is smaller than in case (1).

(3) Bring the ball to rest once more. Give a very sudden pull to the thread: it breaks, and the displacement of the ball is hardly perceptible.

In each of the three cases the momentum is equal to $\int F dt$ for the whole duration of the pull. The pull in case (1) is smaller than the pull in cases (2) and (3), but the duration of the pull is greater in a greater ratio; hence the momentum communicated, being the time integral of the pull, is the greatest for case (1). Although the pull in case (2) is equal to the pull in case (3), still its

[1] The distinguished Egyptologist, Mr. Le Page Renouf, now Keeper of Oriental Antiquities at the British Museum, tells me that, while (2) and (3) may not be earlier than the eighteenth dynasty, (4) is of very great antiquity, occurring in the name of Hor-em-sa-f, one of the Pyramid kings.

[1] The connection with, or analogy between, the Tarsus and Cypriote symbols and the *ankh* was suggested by Mr. Pinches, and subsequently, with respect to the Tarsus symbol, on different grounds, by Prof. Sayce.

duration is so exceedingly small in case (3) that the momentum communicated is very small.

II. Support a cylinder with a fly-wheel, as shown in Fig. 2. E E are two pieces of wood, both screwed at the

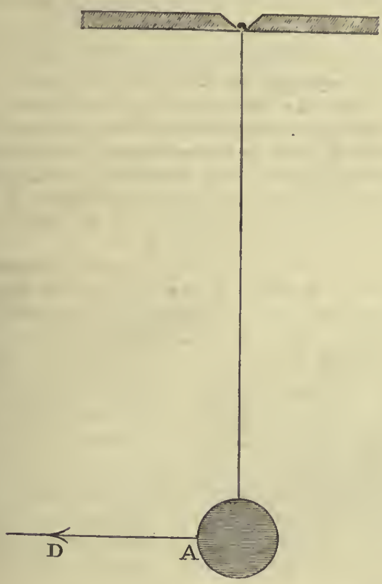


FIG. 1.

top to another piece of wood, L, of convenient thickness. Each has a slot cut along its centre, in which fits a ball, F, to which is attached a stiff wire, a string, and a weight, as shown in the figure. H is an india-rubber band, which presses E E together with a pressure at least sufficient to

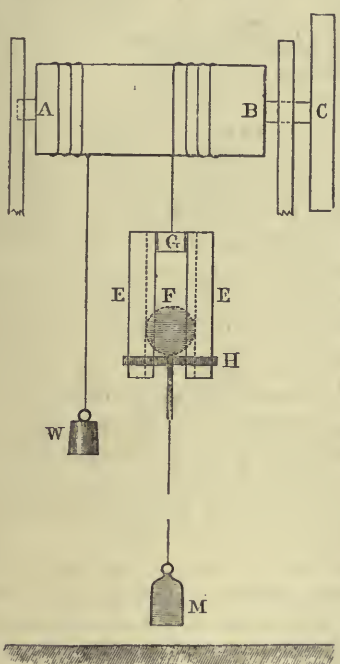

FIG. 2.

cause the ball F not to slip when the weight M is hung on to its string. Another string is wound round the end A of the cylinder, and a weight attached to it so as to balance the weight of the two pieces of wood, E E. The fly-wheel has a friction-brake upon it, and if the retarding force of the brake be constant, the angular displacement of the fly-wheel is proportional to the square of the momentum communicated.

(1) Lift the weight M a distance of about half an inch, and let it fall. The cylinder goes round through a certain angle, and the ball F is not pulled out of its slot.

(2) Lift the weight M through 2 or 3 inches, and let it fall. The ball F is pulled out of its slot; the cylinder goes round, but through a smaller angle than in case (1).

(3) Let the weight M fall through a height of 4 or 5 feet. The ball F is pulled out of its slot, and the angular displacement of the cylinder is barely perceptible.

The same explanations are applicable to the results of II. as were made concerning the results of I., provided couple be substituted for force, and moment of inertia for mass.

III. The following, though somewhat inconvenient as a class experiment, illustrates the same subject. Fix up

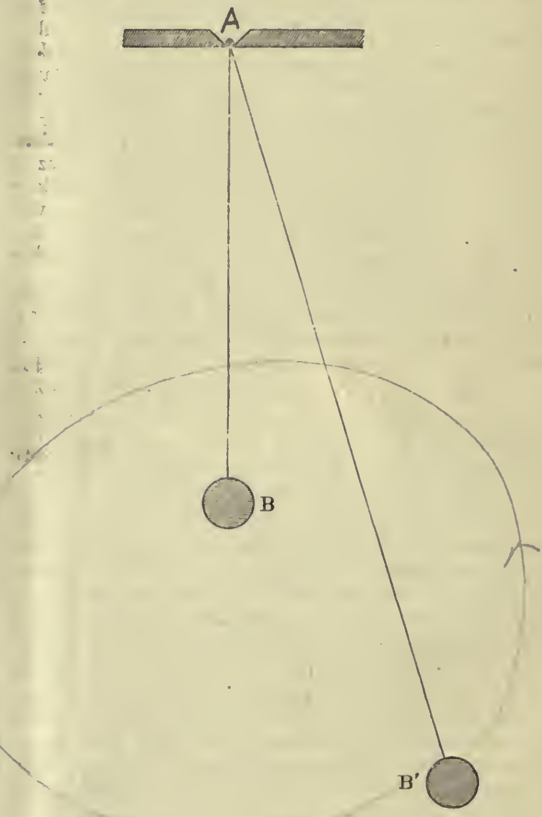

FIG 3.

a plain deal or other board in the manner of Robins' ballistic pendulum. From a rifle with a small charge of powder, fire a bullet into the board, at right angles to its plane, and as near as possible to its centre of inertia. The bullet lodges in the board, which is deflected through a large angle. Increase the charge of powder, so that the bullet pierces the board. The deflection of the board is now smaller. Put the maximum charge of powder in the rifle, and the deflection of the board on firing the bullet into it is exceedingly small.

IV. Suspend a light ivory or other ball by a long india-rubber thread several feet long, as shown in Fig. 3. Pull the ball into the position A B', and let it go. Looking at it as seen in the figure, it first begins to describe a curve against the hands of a watch. After two or three periods it begins to go round in a direction with the hands of a watch.

Bring the ball to the position B′ again, and project it at right angles, or at any angle, to the plane B A B The ball now illustrates three-dimensional motion. The period is slow, and the experiments are very interesting and instructive. MAGNUS MACLEAN.

NOTES.

THE bi-centenary of the publication of Newton's "Principia" was celebrated on Thursday last at Trinity College, Cambridge. A long and admirable address was read by Dr. Glaisher to a distinguished audience which had been invited to Cambridge by the Master and Fellows of the College. At a numerously attended dinner in Hall in the evening, speeches were made by the Master, the President of the Royal Society, the Astronomers-Royal for England and Ireland, and other distinguished guests.

AMONGST the missions just approved by the Special Commission of the French Ministry of Public Instruction are the following: M. Nicklès, mining engineer, to carry out in the provinces of Valencia and Alicante, in Spain, geological investigations; Dr. Morisse, to undertake various medical and natural history studies in the basins of the Upper Orinoco and Amazon; the Abbé Hyvernat, to proceed to Armenia to copy the cuneiform inscriptions on the shores of Lake Van, to investigate the art of Assyria, and to study on the spot the Neo-Syriac dialects spoken in the basin of Lake Urumiyah; M. Gay, to undertake a mission to Nicaragua, Columbia, and Venezuela, to study the natural history, and make collections for the State Museums; M. Thoulet, Professor of Mineralogy in the Faculty of Sciences at Nancy, to study the organization of the Observatory of Christiania, and of the Scottish Marine Biological Station at Edinburgh.

THE Bill to provide for technical education in England and Wales, prepared and brought in by Sir H. Roscoe, Sir U. Kay-Shuttleworth, Sir B. Samuelson, Mr. G. Dixon, and Mr. A. Acland, has been printed. It provides (1) that any School Board may make provision for giving technical education in any school under their management, and either by day or evening classes, or both, as may seem fit, having regard to the daily occupations of the persons to be benefited thereby; (2) that if no such provision is made, or if it is insufficient, and if the local authority by special resolution determine that provision or further provision ought to be made, they may themselves make such provision. The Bill also provides for the rendering of aid by School Boards or local authorities to voluntary schools in which technical instruction may be given; and two sections define the conditions under which Parliamentary grants shall be made for the encouragement of such instruction both in voluntary schools and in Board schools. It is proposed that any School Board or local authority, should they think fit, may institute an entrance examination in reading, writing, and arithmetic, for persons desirous of attending technical schools or classes under their management, or to which they contribute.

THE *Colonies and India*, commenting on the movement in favour of technical education in the colony of Victoria, says it will not be the fault of the Victorian Government if technical education is neglected, as there is a feeling in the Cabinet that if the country is to progress the rising generation should have the advantage of technical teaching. The Minister of Public Instruction has issued a minute on the policy of founding a Victorian Technical University, which is a digest of some of the evidence given before our own Royal Commission on Technical Instruction. Mr. Pearson estimates the initial expenditure involved in the foundation of a separate technical University at from £500,000 to a million, besides a yearly endowment of at least £30,000. The latter sum appears out of proportion to the average endowments of such institutions in Europe and America. It is not doubted that the money required will be freely voted.

THE following resolution was passed at a meeting of the American Philosophical Society on January 6, and has just been received by some of the scientific Societies of Great Britain in a circular dated March 12:—"*Resolved*, That the President of the American Philosophical Society be requested to address a letter to all learned bodies with which this Society is in official relations, and to such other Societies and individuals as he may deem proper, asking their co-operation in perfecting a language for learned and commercial purposes, based on the Aryan vocabulary and grammar in their simplest forms; and to that end proposing an International Congress, the first meeting of which shall be held in London or in Paris."

THE general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, May 3, and Friday afternoon, May 4. The chair will be taken by the President, Mr. Carbutt, at 7.30 p.m. on Thursday evening, and at 2.30 p.m. on Friday afternoon. The following papers will be read and discussed as far as time permits:—Third Report of the Research Committee on Friction: experiments on the friction of a collar bearing; description of the emery testing machine, by Mr. Henry R. Towne, of Stamford, Connecticut; and supplementary paper on the use of petroleum refuse as fuel in locomotive engines, by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South-east Russia.

SURGEON-MAJOR F. S. B. FRANÇOIS DE CHAUMONT, F.R.S., Professor of Military Hygiene at the Army Medical School, Netley, died at his residence at Woolston, near Southampton, on the 18th inst. He was fifty-five years of age.

AT the meeting of the Society of Arts on the 18th inst., Sir Howard Grubb read a paper on telescopes for stellar photography. His object was to discuss and describe a few of the more important mechanical details of the instruments which are to be used for the international photographic survey of the heavens. The paper is printed in the current number of the Journal of the Society of Arts.

ON March 31, about 10 p.m., a splendid meteor was seen at Asker, in Nerice, in Sweden. It appeared in the southern sky, increasing in brilliancy in its descent. Finally it seemed to burst into three parts, each of which left a trail in the sky observable a few seconds. The colour was intense bluish-white.

SEVERE shocks of earthquake were felt at Oldenburg on April 12. Several houses fell in at Eisenstadt. Shocks were also noticed at Pottendorf, in Lower Austria.

A HYDROGRAPHICAL BUREAU has been opened in Würtemberg, under the direction of Herr von Marten.

WE are glad to hear that a regular meteorological organization is to be established in Spain. The Director, appointed by "competitive examination," is Señor Augusto Arcimis, formerly of the Institution Libre de Ensenanza, Madrid. M. Arcimis has long been known as a meteorologist.

MM. MOHN AND HILDEBRANDSSON have published an important discussion on the "Thunderstorms of Scandinavia" (Upsal, 1888, 55 pp. and 12 plates). The first network of thunderstorm stations was established in France by Leverrier in 1865, and his plan has been adopted in most other countries, almost without change. Norway followed next, in 1867, and Sweden in 1871. The storms are divided into two classes: (1) heat thunderstorms, which occur generally in summer, and mostly originate in the central and eastern parts of the Scandinavian peninsula 2) cyclonic thunderstorms, which generally

occur in winter, on the western coasts, and accompany a barometric depression coming from the Atlantic. An attempt is made at fixing the heights of thunderstorm clouds, but these vary very much with different times and localities; it seems proved, however, that the movements of the cirrus clouds are in no way affected by the storms. The summer storms occur most frequently in the afternoon, and most rarely between 2 and 4 a.m. But on the coast of Norway the maximum frequency occurs about 8 p.m., and the winter storms occur more frequently in the night. These facts have also been pointed out by Dr. Buchan with regard to the storms of the north-west of Scotland. In the annual period the storms occur most frequently in July and August, but there is also a secondary maximum in January. The work contains much that would repay careful study.

THE monthly meteorological notes and rainfall statistics for South Australia, published by Mr. C. Todd, the Government Astronomer, contain very useful climatological data and notices of miscellaneous phenomena. Mr. Todd has taken advantage of his position as Postmaster-General to establish meteorological or rainfall stations at a great number of telegraph offices; the number of reports published for February 1887 is 298, together with the means for all stations having at least seven years' record. The observations in their present form seem to date from 1883, when 235 records were published, but the work commenced as as far back as 1857, since which time it has been steadily pursued. For Adelaide itself, the records of Sir G. S. Kingston extend back as far as 1839, and these observations have been used by Mr. Todd in his excellent article on the climate of the colony in the "Hand-book of South Australia." It is stated in this work that local features are apparently insufficient to explain the large differences in the yearly averages of the rainfall; Mr. Todd's continued exertions must tend to elucidate this subject.

A NEW series of isomorphous double chlorides of the metals of the iron and alkali groups have been prepared by Dr. Neumann (*Liebig's Annalen*). The general formula of the system is $4RCl . M_2Cl_6 + 2H_2O$, where R may represent any member of the group of alkali metals, and M either iron, chromium, or aluminium. Magnesium and beryllium are also included in the series, $2MgCl_2$ or $2BeCl_2$ replacing $4RCl$. They all crystallize in forms belonging most probably to the regular system, generally in octahedrons or rhombic dodecahedrons. The iron salts especially are remarkably beautiful, $4KCl . Fe_2Cl_6 + 2H_2O$ forming octahedrons and dodecahedrons of reddish-brown tint, while crystals of the corresponding ammonium compound possess a magnificent garnet-red colour; the rubidium and magnesium salts are yellow, and the chloride of beryllium and iron separates in fine orange crystals. These iron salts, the first two of which have been known some time, are prepared comparatively readily by dissolving ferric chloride in concentrated hydrochloric acid, adding the necessary quantity of the alkaline chloride, and crystallizing. But Dr. Neumann, in attempting to complete the series, found considerable difficulty in preparing the corresponding chromium and aluminium salts. He eventually succeeded completely, in the case of chromium, by dissolving the chromium chloride in warm 96 per cent. alcohol, adding a proportionately small quantity of the other chloride and passing a rapid stream of hydrochloric acid gas, the whole being gently boiled for some time, using a reflux condenser. It was found that the 4 per cent. of water, together with that liberated during the formation of ethyl chloride, was just sufficient to supply the water of crystallization, hence on cooling the double salt crystallized out in microscopic crystals resembling in shape those of their ferric brethren. These chromium salts are of various shades of violet, are deliquescent like all other members of the series, and are likewise decomposed by water. The only aluminic member of the series yet prepared by Dr. Neumann is the potassium compound $4KCl . Al_2Cl_6 + 2H_2O$, which, however, is one of the finest of the whole class; it crystallizes in splendid octahedrons, resembling large diamonds and refracting light with similar brilliancy. Crystals will ever remain among the choicest fruits of the chemist's labour, and form an inexhaustible source of pleasure to lovers of the beautiful. The new isomorphous group is of great theoretical interest, and will take its rank with the well-known alums and the double sulphates of the ferrous-ammonium type.

A MOST interesting account of the work in mound-exploration carried on by the United States Bureau of Ethnology, has been issued by the Smithsonian Institution. The writer is Mr. Cyrus Thomas. It seems that over two thousand mounds have been explored, including almost every known type as to form, from the low, diminutive, circular burial tumulus of the north, to the huge, truncated, earthen pyramid of the south, the embankment, the effigy, the stone cairn, house site, &c. Every hitherto known variety as to construction, as well as a number decidedly different in details, has been examined. Some of the latter are very interesting and furnish important data. Particular attention has been paid to this branch of the work, because the mode of construction and the methods of burial in the ordinary conical tumuli furnish valuable data in regard to the customs of the builders, and aid in determining the archæological districts. Many ancient graves and cemeteries and several *caches* and cave deposits have also been explored. The number of specimens obtained by the division since its organization is not less than thirty-eight thousand. The specimens procured by the field assistants in person constitute by far the most valuable portion of the collection, since the particulars regarding their discovery and surroundings are known. Not a single stone or tablet with anything like letters or hieroglyphics inscribed on it, by which linguists might be able to judge of the language of the mound-builders, has been discovered.

A SECOND Laura Bridgman is at present attracting the attention of American psychologists. Her name is Helen Keller. Although blind and deaf, she makes rapid progress in her studies. *Science* (April 6) gives her portrait and that of her teacher, Miss Annie Sullivan, a graduate of the Perkins Institute at Boston, and also reproduces in *facsimile* a letter written by Helen Keller to A. Graham Bell, of Washington. It was only in March 1887 that Miss Sullivan was engaged to give the first instruction to her pupil, who was then six years old. In a month the little girl learned to spell about 400 words, and in less than three months could write a letter, unaided by anyone. In six weeks she mastered the Braillé (French) system, which is a cipher for the blind, enabling them to read what they have written. She has also mastered addition, multiplication, and subtraction, and received lessons in geography. She is trained solely through the sense of touch.

THE new number of the "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland" (Griffin and Co.) has just been published. This is the fifth annual issue. It comprises lists of papers read during 1887 before Societies engaged in all departments of research, with the names of their authors. There is also an appendix, presenting a list of the leading scientific Societies throughout the world. The work is a useful one, but it ought to have been more thoroughly revised. On the very first page, in the list of the members of the Council of the Royal Society, two names are wrongly given: Sir A. (instead of W.) Bowman, and R. (instead of W.) T. Thiselton Dyer.

A PAPER entitled "Additional Records of Scottish Plants for the Year 1887," by Mr. Arthur Bennett, has been sent to us. It consists of a list of the new county botanical records which came under Mr. Bennett's notice during 1887, and forms a con-

tinuation of the lists which appeared in the *Scottish Naturalist* for 1886 and 1887. Mr. Bennett says that the results during the year 1887 were probably richer than in any former year, not only in the large number of comital records, but in the new species added to the Scottish flora.

We have received several numbers of the *Annales de la Faculté des Sciences de Toulouse* (Paris: Gauthiers-Villars). This new publication (which is well printed on good paper, with wide margins) consists chiefly of memoirs relating to physics, chemistry, and mathematics pure and applied. It contains also articles on questions of general scientific interest. To papers of the latter class the authors append lists of books on the questions discussed.

According to a paper in the *Board of Trade Journal* for April, the production of attar of roses constitutes one of the most important branches of native industry in Bulgaria. The valley of Kezanlyk, known as the Vale of Roses, is the centre of this production, which extends as far as Carlovo, and the villages which lie sheltered from the north wind by the vast chain of the Great Balkans. In 1885, and no later statistics have been published, the manufacture of attar of roses in the district indicated amounted to a value of 1,100,000 francs. The prosperous condition of the valley of Kezanlyk has led other districts of Bulgaria to develop the same industry, and particularly the inhabitants of Strema, and of Toundja, at the foot of Mount Rhodope. It is not yet certain that the attar from these new countries will equal in quality the famous product of Kezanlyk. The Government, however, is anxious to encourage this movement, and the Department of the Interior has lately authorized the purchase of a certain quantity of attar prepared at Strema and at Toundja. Specimens of each are to be sent for examination at the laboratory of the University of Moscow, and the result is to be published.

From an official report just published it appears that in 1886 there were killed in Norway 114 bears, 37 wolves, 5618 foxes, 950 eagles, 5100 hawks, and 108 other animals of prey. The number of bears was slightly below that of 1885, but above the numbers of previous years, whilst the number of wolves was twice that of 1885. The number of foxes, on the other hand, was only half that of the previous year, whilst those of eagles and hawks were about the same.

In last week's Nature (p. 581), near the middle of the second column, for "Ekholm *of* Hagström," read "Ekholm *and* Hagström."

The additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-East Brazil, presented by Mrs. Leighton; a Striped Hyæna (*Hyæna striata*) from Morocco, presented by Mr. Herbert E. White; an Indian Wolf (*Canis pallipes* ♂), two —— Foxes (*Canis* ——), a —— Hawk Eagle (*Spizaetus* ——) from India, presented by Colonel Alex. A. A. Kinloch, C.M.Z.S.; two Rock-hopper Penguins (*Eudyptes chrysocome*) from Auckland, New Zealand, presented by Captain Sutcliff, R.M.S.S. *Aorangi*; a Gannet (*Sula bassana*), British, presented by Miss Serrell; three Common Swans (*Cygnus olor*), British, purchased; a Chinchilla (*Chinchilla lanigera*), a Barbary Wild Sheep (*Ovis tragelaphus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Photography in the Determination of the Motions of Stars in the Line of Sight.—Of the many developments of spectroscopy, one of the most interesting is that first made a practical branch of observation by the skill and patience of Dr. Huggins, viz. the determination of the motions of stars in the direction of the visual ray by measures of the displacement of the more prominent lines in their spectra. The research has, however, always been beset with many practical difficulties, one of the most serious being the manner in which the stellar lines seem to elude the sight when the air is disturbed. This hindrance has been especially felt at Greenwich, where this kind of work has been adopted as part of the ordinary routine, and where, in consequence, it has not been possible, as would be the case in a private observatory, to confine observation to nights of faultless definition. Many of the observations have, therefore, been exceedingly rough, or even discordant. Prof. H. C. Vogel, who had made some successful measures of the displacements of lines in three or four of our brightest stars soon after Huggins's first observations, has recently turned his attention to photography as a means of overcoming this difficulty, and his first results, given in a paper read before the Royal Prussian Academy on March 15, are very promising. Prof. Vogel finds that the atmospheric tremors, so wearisome to the eye, exercise no influence upon the photograph, which possesses the additional advantage of being free from all bias or predisposition. Dr. Scheiner, who has been carrying out these experiments, has examined seven spectra, viz. those of Sirius, Procyon, Castor, Arcturus, Aldebaran, Pollux, and Rigel. Of these, Sirius showed a slight displacement to the red, Procyon a decided displacement, and Rigel very large in the same direction, whilst Arcturus showed a considerable displacement towards the violet. The observations were made on the third line of hydrogen, Hγ, a train of two prisms of high dispersion being used.

The Total Lunar Eclipse of January 28.—Dr. E. Lindemann sends the following list of the number of occultations observed at different Observatories during this eclipse, in addition to the lists given already: Albany (U.S.), 7; Christiania, 28; Milan, 23; Bonn, 7; Durban (Natal), 17; Oxford (Radcliffe), 9; Bruxelles, 14; Liège, 5; Palermo, 8; Cape of Good Hope, 21; Madras, 10. The weather was cloudy at Warsaw.

New Minor Planets.—Herr Palisa discovered a new minor planet, No. 274, on April 3, and another, No. 275, on April 13. The latter is his sixty-third discovery. No. 269 has received the name of Justitia.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *APRIL* 29—*MAY* 5.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 29

Sun rises, 4h. 36m.; souths, 11h. 57m. 10·3s.; sets, 19h. 18m.: right asc. on meridian, 2h. 28·7m.; decl. 14° 41′ N. Sidereal Time at Sunset, 9h. 51m.

Moon (at Last Quarter May 3, 0h.) rises, 22h. 21m.*; souths, 2h. 46m.; sets, 7h. 6m.: right asc. on meridian, 17h. 15·7m.; decl. 19° 30′ S.

GEOGRAPHICAL NOTES.

THE Founder's Medal of the Royal Geographical Society has been awarded to Mr. Clements R. Markham, C.B., F.R.S., on his retirement, after twenty-five years' service, from the Honorary Secretaryship of the Society, during which he has done so much for the promotion of geography. The announcement of Mr. Markham's retirement will be received with regret by all who know the value of the work he has done, both in connection with the Society and otherwise. But as he is still in his vigour we may look for many more years' good work from him. The Royal Medal has been awarded to Lieut. Wissmann, who has twice crossed Africa, and done a great amount of excellent exploring work in the region south of the Congo. The Murchison Grant has been awarded to Mr. James McCarthy, Superintendent of Surveys in Siam; the Gill Premium to Mr. Charles M. Doughty, for his explorations in Arabia; and the Cuthbert Peek Grant to Major Festing for his services as cartographer on the Gambia River. As honorary corresponding members, have been selected Dr. G. Radde, of Tiflis, Dr. H. Rink, of Copenhagen, and Dr. Rein, Professor of Geography at Bonn University.

Two papers were read at Monday's meeting of the Royal Geographical Society, one by the Rev. T. S. Lea, on the Island of Fernando Noronha, and the other by Colonel Sir Marshall Clarke, on Basuto Land. Mr. Lea accompanied Mr. H. N. Ridley on his mission to Fernando Noronha last year. The islands are 290 miles north-east of Pernambuco. The total length of the whole group from north-east to south-west is about 6¼ geographical miles, and the maximum width of Fernando itself 1½ mile. The north-east cape of that island is very rugged and precipitous, though of no great height. Boobie Island and Egg Island are also raised masses of reef rock, which again appears on the top of the basalt of Platform Island. Mount St. Michael is a phonolite peak on which the weed invasion has hardly found a footing, and the native plants still flourish. This phonolite is a gray, close-grained columnar rock, and it seems to be the key to the very interesting geology of the island. Platform Island and Egg Island have a connection at low water with the main island, a small mass of reef rock. Morro do Chapeo, or the Hat Rock, seems to represent the residue of a larger block. The north cape of the main island is stony, and there is no great wealth of vegetation, though even here many of the endemics may be found. There is a patch of blown sand at San Antonio over which the *Ipomœa pes-capræ* trails, and beyond that the ground rises towards the basaltic height on which the town is built. The basalt is more inclined to be nodular than columnar. Descending from the town hills, the peak stands out clear against the northern sky. It is a huge mass of columnar phonolite, with a talus of *débris* around it, in shape not unlike a church with a tower. About the centre of the plain rises a round mass of phonolite. On the south coast, like bastions, stand two other phonolite masses, with a ridge of basalt between them, steep on its seaward side, but sloping gradually landwards. The islands of the south coast, with the exception of the minute I. Jones, are also phonolite. Tobacco Point is basaltic, and Morro Branco, in Leâo Bay, altered phonolite. There are raised beaches of reef rock on Tobacco Point and to the east of Look-out Hill. Mr. Lea hazards the following observations with regard to the structure and possible history of the main island. Though undoubtedly volcanic in origin, the date at which it was in any way active must be exceedingly remote. No hot springs, or any trace of them, occur; no earthquakes or tidal waves are felt. No site of a crater can be pointed to with certainty, and indeed any attempt to reconstruct its pristine shape from the attenuated remains that are left us must be undertaken with extreme diffidence. As the island is surrounded by deep sea, and as nothing volcanic occurs, as far as he is aware, on the coast of Brazil in its neighbourhood, he is inclined to think that it marks the site of an isolated vent. The number of species of plants, &c., peculiar to the island seems also to point to this, or at any rate to the extreme remoteness of any connection with other land. But there is at least one thing which may throw some light on this matter. All round the island, though interrupted in places, especially on the northern coast, there is a sort of reef formation laid bare at low water, and closely resembling the Recife of Pernambuco. At certain points a very similar rock is found at considerable heights above the sea. On Rat Island this reef attains no great elevation. It rests upon a beach of rounded boulders near the landing, which may be seen underlying it. Boobie Island and Egg Island also have it, and there are traces of it at the summit of Platform Island. On basalt in Cotton-tree Bay, close by Look-out Hill, it occurs at a yet greater height, and again on Tobacco Point and I. Jones it also occurs above high-water mark. Raised beaches, therefore, seem only to exist on basalt, and in close connection with a phonolite peak. Mr. Lea suggests that the phonolite regions mark the sites of the ancient vents of the volcano, the phonolite itself being the plug which remained fixed during subsequent eruptions of lava. The scoria is all but gone, only remaining where the basalt covers it, but the harder phonolite still remains in its place, and the raised beaches show that beneath it lay the forces which manifested themselves in the last expiring efforts of the volcano. The flora and fauna of the group have already been very fully described by Mr. Ridley.

SIR MARSHALL CLARKE'S paper described an official tour he made in Basuto Land, last October, to visit the Baltokoa tribe settled among the mountains. He traversed 400 miles of country, a large proportion of which had never been visited by Europeans. The highest point attained was 10,750 feet; but from thence, both north and south, distant heights appeared at great elevations.

ANTAGONISM.[1]

SOME months ago, shortly after I had resigned my office of Judge of the High Court, I was expressing to a friend my fear of the effect of having no compulsory occupation, when he said, by way of consolation, "Never mind, 'for Satan finds some mischief still for idle hands to do.'" You may possibly in the course of this evening think he was right. I have chosen a title for my lecture which may not fully convey to your minds the scope of the views which I am going to submit to you. I propose to adduce some arguments to show that "antagonism," a word generally used to signify something disagreeable, pervades all things; that it is not the baneful thing which many consider it; that it produces at least quite as much good as evil; but that, whatever be its effect, my theory—call it, if you will, speculation—is that it is a necessity of existence, and of the organism of the universe so far as we understand it; that motion and life cannot go on without it; that it is not a mere casual adjunct of Nature, but that without it there would be no Nature, at all events as we conceive

[1] Lecture delivered at the Royal Institution, on April 20, by the Right Hon. Sir William R. Grove, F.R.S.

it; that it is inevitably associated with unorganized matter, with organized matter, and with sentient beings.

I am not aware that this view, in the breadth in which I suggest it, has been advanced before. Probably no idea is new in all respects in the present period of the world's history. It has been said by a desponding pessimist that "There is nothing new, and nothing true, and nothing signifies," but I do not entirely agree with him; I believe that in what I am about to submit there is something new and true in the point of view from which I regard the matter; whether it signifies or not is for you to judge.

The universality of antagonism has not received the attention it seems to me to deserve from the fact of the element of force, or rather of the conquering force, being mainly attended to, and too little note taken of the element of resistance unless the latter vanquishes the force, and then it becomes, popularly speaking, the force, and the former force the resistance.

There are propositions applying more or less to what I am going to say of some antiquity.

Heraclitus, quoted by Prof. Huxley, said: "War is the father and king of all things." Hobbes said war is the natural state of man, but his expressions have about them some little ambiguity. In Chapter I. of the "De Corpore Politico" he says "Irresistible might in a state of nature is right," and "The estate of man in this natural liberty is war." Subsequently he says: "A man gives up his natural right, for when divers men having right not only to all things else, but to one another's persons, if they use the same there arizeth thereby invasion on the one part and resistance on the other, which is war and therefore *contrary to the law of Nature, the sum whereof consisteth in making peace.*" I can only explain this apparent inconsistency by supposing he meant "law of Nature" to be something different from "the natural estate of man," and that the making peace was the first effort at contract, or the beginning of law; but then why call it the "*law of Nature*," where he says might is right? There is however some obscurity in the passage.

The Persian divinities, Ormuzd and Ahriman, were the supposed rulers or representatives of good and evil, always at war, and causing the continuous struggles between human beings animated respectively by these two principles. Undoubtedly good and evil are antagonistic, but antagonism, as I view it, is as necessary to good as to evil, as necessary to Ormuzd as to Ahriman. Zoroaster's religion of a Divine being, one and indivisible, but with two sides, is, to my mind, a more philosophical conception. The views of Lamarck on the modification of organic beings by effort, and the establishment of the doctrine of Darwin as to the effects produced by the struggle for existence and domination, come much nearer to my subject. Darwin has shown how these struggles have modified the forms and habits of organized beings, and tended to increased differentiation, and Prof. Huxley and Herbert Spencer have powerfully promoted and expanded these doctrines. To the latter we owe the happy phrase, "survival of the fittest," and Prof. Huxley has recently, in a paper in the *Nineteenth Century*, anticipated some points I should have adverted to as to the social struggles for existence. To be anticipated, and by a very short period, is always trying, but it is more trying when what you intended to say has been said by your predecessor in more terse and appropriate language than you have at your command.

I propose to deal with "antagonism" inductively, *i.e.* with facts derived from observation alone, and not to meddle with spiritual matters or with consequences.

Let us begin with what we know of the visible universe, viz. suns, planets, comets, meteorites, and their effects. These are all pulling at each other, and resisting that pull by the action of other forces.

Any change in this pulling force produces a change, or, as it is called, perturbation, in the motion of the body pulled. The planet Neptune, as you know, was discovered by the effect of its pulling force on another planet, the latter being deflected from its normal course. When this pulling force is not counterbalanced by other forces, or when the objects pulled have not sufficient resisting power, they fall into each other. Thus, this earth is daily causing a bombardment of itself by drawing smaller bodies—meteorites—to it; 20,000,000 of which, visible to the naked eye, fall on an average into our atmosphere in each twenty-four hours, and of those visible through the telescope, 400,000,000 are computed to fall within the same period. Mr. Lockyer has recently given reasons for supposing the luminosity of nebulæ, or of many of them, is due to collisions or friction among the meteorites which go to form them; but his paper on the subject is not yet published. You must get from Mr. Lockyer the details of his views. I hope he may, at one of these evening meetings, give you a *résumé* of them from the place I now occupy.

What is commonly called centrifugal force does not come from nothing; it depends upon the law that a body falling by the influence of attraction, not upon, but near to, the attracting body, whirls round the latter, describing one of the curves known as conic sections. Hence, a meteorite may become a planet or satellite (one was supposed to have become so to this earth, but I believe the observations have not been verified); or it may go off in a parabola as comets do; or, again, this centrifugal force may be generated by the gradual accretion of nebulous matter into solid masses falling near to, or being thrown off from, the central nucleus, the two forces, centrifugal and centripetal, being antagonistic to each other, and the relative movements being continuous, but probably not perpetual. Our solar system is also kept in its place by the antagonism of the surrounding bodies of the Kosmos pulling at us. Suppose half of the stars we see, *i.e.* all on one side of a meridian line, were removed, what would become of our solar system? It would drift away to the side where attraction still existed, and there would be a wreck of matter and a crash of worlds. It is very little known that Shakespeare was acquainted with this pulling force. He says, by the mouth of Cressida—

> "But the strong base and building of my love
> Is as the very centre of the earth
> Drawing all things to it"—

a very accurate description of the law of gravitation, so far as this earth is concerned, and written nearly a century before Newton's time.

But in all probability the collisions of meteorites with the earth and other suns and planets are not the only collisions in space. I know of no better theory to account for the phenomena of temporary stars, such as that which appeared in 1866, than that they result from the collision of non-luminous stars, or stars previously invisible to us. That star burst suddenly into light, and then the luminosity gradually faded, the star became more and more dim, and ultimately disappeared. The spectrum of it showed that the light was compound, and had probably emanated from two different sources. It was probably of a very high temperature. If this theory of temporary stars be admitted, we get a nebula of vapour or star dust again, and so may get fresh instances of the nebular hypothesis.

Let us now take the earth itself. It varies in temperature, and consequently the particles at or near its surface are in continuous movement, rubbing against each other, being oxidized or deoxidized, either immediately or through the medium of vegetation. This also is continuously tearing up its surface and changing its character. Evaporation and condensation, producing rain, hail, and storms, notably change it. Force and resistance are constantly at play. The sea erodes rocks and rubs them into sand. The sea quits them and leaves traces of its former presence by the fossil marine shells found now at high altitudes. Rocks crumble down and break other rocks or are broken by them; avalanches are not uncommon. The interior of the earth seems to be in a perpetual state of commotion, though only recurrent to our observation. Earthquakes in various places from time to time, and, doubtless, many beneath the sea of which we are not cognizant, nor of other gradual upheavals and depressions. Throughout it nothing that we know of is at rest, and nothing can move without changing the position of something else, and this is antagonism. Metals rust at its surface, and probably they or their oxides, chlorides, &c., are in a continuous state of change in the interior. Nothing that we know of is stationary. The earth as a whole seems so at first sight, but its surface is moving at the rate of some seventeen miles a minute at the equator; and standing at either of the Poles—an experiment which no one has yet had an opportunity of trying—a man would be turned round his own axis once in every twenty-four hours, while the earth's motion round the sun carries us through space more than a million and a half of miles a day.

The above changes produce motion in other things. The earth pulls the sun and planets, and in different degrees at different portions of its orbit.

Before I pass from inorganic to organized matter I had better deal with what may perhaps strike you as the most difficult part of my subject, viz. light. Where, you may say, is there antagonism

in the case of light? Light exercises its force upon such minute portions of matter that until the period of the discovery of photography its physical and chemical effects were almost unknown. Such effects as bleaching, uniting some gases, and affecting the colouring matter of vegetables, were partly known but little attended to; but photography created a new era: I shall advert to this presently. The theories of light, however, involved matter and motion. The corpuscular theory, as you well know, supposed that excessively small particles were emitted from luminous bodies, and travelled with enormous velocity. The undulatory theory, which supplanted it, supposed that luminous bodies caused undulations or vibrations in a highly tenuous matter called ether, which is supposed to exist throughout the interplanetary spaces and throughout the universe so far as we know it. Some suppose this ether to be of a specific character differing from that of ordinary gases, others that it is in the nature of a highly attenuated gas; but, whatever it be, it cannot be affected by undulations or vibrations without being moved, and when matter is moved by any force it must offer resistance to that force, and hence we get antagonism between force and resistance. Light also takes time in overcoming this resistance, *i.e.* in pushing aside the ether. It travels no doubt at a good pace—about 190,000 miles in a second; but even at this rate, and without being particular as to a few millions of miles, it takes three years and a quarter to reach us from the star which, so far as we know, is the nearest to us, viz. α Centauri. The ether, or whatever it may be called, tenuous as it is, is not unimportant, though it be not heavy. Without it we should have no light and possibly no heat, and the consequences of its absence would be rather formidable. I believe you have heard Dr. Tyndall on this subject. Supposing the visible universe to be as it is now supposed to be, *i.e.* in no part a mere vacuum, there can be no force without resistance in any part of it.

But photography carries us further, it shows us that light acts on matter chemically, that it is capable of decomposing or forcing asunder the constituents of chemical compounds, and is therefore a force met by resistance. In the year 1856 I made some experiments published in the *Philosophical Magazine* for January 1857, which seemed to me to carry still further what I may call the molecular fight between light and chemical affinity, and among them the following. Letters cut out of paper are placed between two polished squares of glass with tin-foil on the outsides. It is then electrized like a Leyden jar, for a few seconds, the glasses separated, the letters blown off, and the inside of one of the glasses covered with photographic collodion. This is then exposed to diffuse daylight, and on being immersed in the nitrate of silver bath the part which had been covered with the paper comes out dark, the remainder of the plate being unaffected. (This result was shown by the electric light lantern.) In this case we see that another imponderable force, electricity, invisibly affects the surface of glass in such a way that it conveys to another substance of definite thickness, viz. the prepared collodion, a change in the chemical relations of the substance (iodide of silver) pervading it, enabling it to resist that decomposition by light which but for some unseen modification of the surface of the glass plate it would have undergone, and no doubt the force of light being unable to effect its object was reflected or dispersed, and instead of changing its mode of motion in effecting chemical decomposition, it goes off on other business. The visible effect is in the collodion film alone. I have stripped that off, and the imprint remains on it, the surface of the glass being, so far as I could ascertain, unaffected. Thus in the film over the protected part, light conquers chemical affinity; in that over the non-protected part, chemical affinity resists and conquers light, which has to make an ignominious retreat. It is a curious chapter in the history of the struggles of molecular forces, and probably similar contests between light and chemical or physical attractions go on in many natural phenomena, some forms of blight and some healthy vegetable changes being probably dependent on the varying effects of light, and conditions, electrical or otherwise, of the atmosphere.

Let us now pass on to organic life. A blade of grass, as Burke, I believe, said as a figure of speech, is fighting with its neighbours. It is robbing them, and they are trying to rob it—no agreement or contract, simply force opposed to force. This struggle is good for the grass; if it got too much nutriment it would become diseased. The struggle keeps it in health. The rising of sap in trees, the assimilation of carbon, the process of growth, the strengthening themselves to resist prevalent winds, and many other instances might be given, which afford examples of the internal and external struggles in vegetable life.

I will now proceed to consider animal life, and in this case I will begin with the internal life of animals, which is a continual struggle. That great pump the heart is continuously beating—that is, conquering resistance. It is forcing the blood through the arteries, they assisting in squeezing it onwards. If they give way the animal dies; if they become rigid and resist too much, the animal dies. There must be a regulated antagonism, a rhythmical pulsation, the very term involving force and resistance. That the act of breathing is antagonistic scarcely needs argument. The muscular action by which the ribs are made to open out and close alternately, in order to inhale and exhale air, and other physiological changes which I cannot here go into, necessitate a continuous fight for life. So with digestion, assimilation, and other functions, mechanical and chemical forces and resistances come into play.

Since this lecture was written, I have heard of a discovery made, I am informed, by Prof. Metschnikoff, and which has brought to light a singular instance of internal antagonism. He is said to have proved that the white corpuscles of the blood are permanent enemies of Bacteria, and by inoculation will absorb poisonous germs; a recurrent war, as it appears, going on between them. If the corpuscle is the conqueror, the Bacteria are swallowed up, and the patient lives. If the corpuscles are vanquished, the patient dies, and the Bacteria live, at all events for a time. If the theory is founded, it affords a strong additional argument to the doctrine of internal antagonism. Possibly if there were no Bacteria, and the corpuscles had nothing to do, it would be worse for them and the animal whom they serve.

Let us now consider the external life of animals. I will take as an instance, for a reason which you will soon see, the life of a wild rabbit. It is throughout its life, except when asleep (of which more presently), using exertion, cropping grass, at war with vegetables, &c. If it gets a luxurious pasture it dies of repletion. If it gets too little it dies of inanition. To keep itself healthy it must exert itself for its food; this, and perhaps the avoiding its enemies, gives it exercise and care, brings all its organs into use, and thus it acquires its most perfect form of life. I have witnessed this effect myself, and that is the reason why I choose the rabbit as an example. An estate in Somersetshire, which I once took temporarily, was on the slope of the Mendip Hills. The rabbits on one part of it, viz. that on the hill-side, were in perfect condition, not too fat nor too thin, sleek, active, and vigorous. and yielding to their antagonists, myself and family, excellent food. Those in the valley, where the pasturage was rich and luxuriant, were all diseased, most of them unfit for human food and many lying dead on the fields. They had not to struggle for life, their short life was miserable and their death early, they wanted the sweet uses of adversity—that is, of antagonism.

The same story may be told of other animals. Carnivora, beasts or birds of prey, live on weaker animals; weaker animals herd together to resist, or, by better chance of warning, to escape, beasts of prey; while they, the Herbivora, in their turn are destroying vegetable organisms.

I now come to the most delicate part of my subject, viz. man (I include women of course!). Is man exempt from this continual struggle?

It is needless to say that war is antagonism. Is not peace so also, though in a different form? It is a common-place remark to say that the idle man is worn out by *ennui*, *i.e.* by internal antagonism. Kingsley's "Do-as-you-like" race—who were fed by a substance dropping from trees, who did no work, and who gradually degenerated until they became inferior to apes, and ultimately died out from having nothing to do, nothing to struggle with—is a caricature illustrative of the matter. That the worry of competition is nearly equivalent to the hardships and perils of military life seems proved to me by the readiness with which military life is voluntarily undertaken, ill as it is paid. If it were well paid, half our men would be in the military or naval service, and I am not sure that we should not have regiments of Amazons! The increased risk of life or limbs and the arduous nature of the work do not prevent men belonging to all classes from entering these services, little remunerative as they are. Others take the risks of travelling in the deserts of Africa or wintering in the Polar regions, of being eaten by lions or frozen to death, of falling from a Swiss mountain or foundering in a yacht, in preference to a life of tranquillity; and sportsmen elect the danger of endeavouring to kill an animal that can and may kill

them, to shooting tame pheasants at a *battue* or partridges in a turnip-field.

Then, in what is euphemistically called a life of peace, buyer and seller, master and servant, landlord and tenant, debtor and creditor, are all in a state of simmering antagonism; and the inventions and so-called improvements of applied science and art do not lessen it. Exercise is antagonism; at each step force is used to lift up our bodies and push back the earth; as the eminent Joseph Montgolfier said, that when he saw a company dancing, he mentally inverted his view and imagined the earth dancing on the dancers' feet, which it most unquestionably did. Indeed, his great invention of balloons was guessed at by his witnessing a mild form of antagonism between heat and gravitation. He, being a dutiful husband, was airing his wife's dresses, who was going to a ball. He observed the hot air from the fire inflated the light materials, which rose up in a sort of spheroidal form (you may some of you have noticed this form in dress!). This gave him the idea of the fire-balloon, which, being a large paper-maker at Annonay, he forthwith experimented on, and hence we got aërial navigation. This anecdote was told me by his nephew M. Seguin, also an eminent man. Even what we call a natural death is a greater struggle than that which other animals go through, and is, in fact, the most artificial of all deaths. The lower animals, practically speaking, do experience a natural death, *i.e.* a violent or unforeseen death. As soon as their powers decline to such an extent that they cannot take part in the struggle for existence, they die or are killed, generally quickly, and their sufferings are not protracted by the artificial tortures arising from the endeavours to prolong life.

Let us now pass from individuals to communities. Is there less antagonism now than of yore? Do the nations of Europe now form a happy family? Are the armaments of Continental nations, or is the navy of this country, less than in former years? The very expression "the Great Powers" involves antagonism.

As with wars and revolutions, so, as I have said, with regard to individuals, during our so-called peace, the fight is continuous among communities. If the water does not boil, it simmers. Not merely are there the struggles of poor against rich going on, but the battles for position and pre-eminence are constant. The subjugated party or sect seeks first for toleration, then for equalization, and then for domination.

We call contentment a virtue, but we inculcate discontent. A father reproaches his son for not exerting himself to improve his position, and at school and college and in subsequent periods of life efforts at advancement in the social scale are recommended. Individual antagonisms, class antagonisms, political, trading, and religious antagonisms take the place of war. Can war exhibit a more vigorous and persistent antagonism than competition does? Take the college student with ruined health; take the bankrupt tradesman with ruined family; take the aspirants to fashion turning night into day, and preferring gas or electric light to that of the sun: there is, to be sure, some excuse for this, as we so rarely see the latter. But our very amusements are of a combative character: chess, whist, billiards, racing, cricket, football, &c. And in all these we, in common parlance, speak of *beating* our opponent.

Even dancing is probably a relic and reminiscence of war, and some of its forms are of a military character. I can call to mind only one game which is not combative, and that is the game you are in some sort now playing, viz. "patience," and with, I fear, some degree of internal antagonism!

Take, again, the ordinary incidents of a day's life in London. 15,000 to 20,000 cabs, omnibuses, vans, private carriages, &c., all struggling, the horses pushing the earth back and themselves forwards, the pedestrians doing the same, but the horses compulsorily—they have not as yet got votes. The occupants of the cabs, vans, &c., are supposed to act from free will, but in the majority of cases they are as much driven as the horses. Insolvents trying to renew bills, rich men trying to save what they have got by saving half an hour of time. Imagine, if you can, the friction of all this, and add the bargaining in shops, the mental efforts in counting-houses, banks, &c., and road repair, now a permanent and continuous institution. Take our railways: similar efforts and resistances. Drivers, signal-men, porters, &c., and the force emanating from the sun millions of years ago, and locked up in the coal-fields, as Stephenson suggested, now employed to overcome the inertia of trains and to make them push the earth in this or that direction, and themselves along its surface. Take the daily struggles in commerce, law, professions, and legislation, and sometimes even in science and literature. Politics I cannot enter upon here, but must leave you to judge whether there is not some degree of antagonism in this pursuit. In all this there is plenty of useful antagonism, plenty of useless—much to please Ormuzd and much to delight Ahriman; but of the two extremes, over-work or stagnation, the latter would, I think, do Ahriman's work more efficiently than the former. We cry peace when there is no peace. Would the world, however, be better if it were otherwise? Is the Nirvana a pleasing prospect? Sleep, though not without its troubles and internal antagonism, is our nearest approach to it, but we should hardly wish to be always asleep.

Shakespeare not only knew something about gravitation, but he also knew something about antagonism. He says, by the mouth of Agamemnon—

> "Sith every action that hath gone before
> Whereof we have record, trial did draw
> Bias and thwart, not answering the aim,
> And that unbodied figure of the thought
> That gav't surmised shape."

In no case is the friction of life shown more than in the performance of "duty," *i.e.* an act of self-resistance, a word very commonly used; but the realization of it is by no means so frequent. Indeed, faith in its performance so yields to scepticism that it is said that when a man talks of doing his duty, he is meditating some knavish trick.

The words good and evil are correlative: they are like height and depth, parent and offspring. You cannot, as far as I can see, conceive the existence of the one without involving the conception of the other. In their common acceptation they represent the antagonism between what is agreeable or beneficial and what is painful or injurious.

An old anecdote will give us the notion of good and evil in a slenderly educated mind. A missionary having considered that he had successfully inculcated good principles in the mind of a previously untutored savage, produced him for exhibition before a select audience, and began his catechism by asking him the nature of good and evil. "Evil," the pupil answered, "is when other man takes my wife." "Right," said the missionary, "now give me an example of good." The answer was: "Good is when me takes other man's wife." The answer was not exactly what was expected, but was not far in disaccord with modern views among ourselves and other so-called civilized races. I don't mean as to running away with other men's wives! But we still view good and evil very much as affecting our own interests. At the commencement of a war each of the opposing parties view victory—*i.e.* the destruction of their enemies—as good, and being vanquished as evil. Congregations pray for this. Statesmen invoke the God of battles. Those among you who are old enough will call to mind the Crimean War. Each combatant nation gives thanks for the destruction of the enemy, each side possibly believing that they respectively are in the right, but in reality not troubling themselves much about that minor question. We (unconsciously perhaps) "compound for sins we are inclined to by damning those we have no mind to." So in the daily life of what is called peace. The stage-coach proprietor rejoiced when he had driven his rival off the road, railway directors and shareholders now do the same, so do publicans, shopkeepers, and other rivals. We are still permeated by the old notion of good and evil. But "antagonism," as I view it, not only comprehends the relation of good and evil, but, as I have said, produces both, and is as necessary to good as to evil. Without it there would be neither good nor evil. Judging of the lives of our progenitors from what we see of the present races of men of less cerebral development, we may characterize them as having been more impulsive than ourselves, and as having their joys and sorrows more quickly alternated. After the hunt for food, accompanied by privation and suffering, comes the feast to gorging. Their main evil was starvation, their good repletion. Even now the Esquimaux watches a seal-hole in the bitter cold for hours and days, and his compensation is the spearing and eating the seal. The good is resultant upon and in the long run I suppose equivalent to the evil. These men look not back into the past, and forward into the future as we do. We, by extending our thought over a wider area, are led to more continuing sacrifices, and aim at more lasting enjoyment in the result. The child suffers at school in order that his future life may be more prosperous. The man spends the best part of his life in arduous toil, physical or mental, in order that he may not want in his later years, or that his family may reap the benefit of his

labour. Further-seeing men spend their whole lives on work little remunerative that succeeding generations may be benefited. The prudent man transmits health and wealth to his descendants, the improvident man poverty or gout. One main element of what we call civilization is the capability of looking further back into the past, and further forward into the future; but, though measured on a different scale, the average antagonism and approximate equivalence appear to me to be the same.

Can we suppose a state of things either in the inorganic or the organic world which, consistently with our experience or any deduction drawn from it, would be without antagonism? In the inorganic world it would be the absence of all movement, or, what practically amounts to the same thing, movement of everything in the same direction, and the same relative velocity; for, as movement is only known to us by relation, movement where nothing is stationary or moving in a different direction or with a different velocity would be unrecognizable.

So in the organic but non-sentient world, if there were no no struggle, no absorption of food, no growth, nothing to overcome, there would be nothing to call life. If, again, in the sentient world there were no appetites, no hopes—for both these involve discontent—no fear, no good or bad, what would life be? If fully carried out, is not a life without antagonism no life at all, a barren metaphysical conception of existence, or rather alleged conception, for we cannot present to the mind the form of such conception?

In the most ordinary actions, such as are necessary to sustain existence, we find, as I have already pointed out, a struggle more or less intense, but we also find a reciprocal interdependence of effort and result. The graminivorous animal is during his waking hours always at work, always making a small but continuous effort, selecting his pastures, cropping vegetables, avoiding enemies, &c. The Carnivora suffer more in their normal existence; their hunger is greater, and their physical exertion when they are driven by hunger to make efforts to obtain food is more violent than with the Herbivora, if they capture their prey by speed or battle, or their mental efforts are greater if they capture it by craft. But then their gratification is also more intense, and thus there is a sort of rough equation between their pain and their pleasure, the more sustained the labour the more permanent is the gratification.

As, with food or exercise, deficiency is as injurious in one as is excess in another direction, so, as affecting the mind of communities, as I have stated it to be with individuals, the effect of a life of ease and too much repose is as much to be avoided as a life of unremitting toil. The Pitcairn islanders, who managed in some way to adapt their wants to their supply and to avoid undue increase of population, are said never to have reached old age. In consequence of the uneventful, unexcited lives they led, they died of inaction, not from deficiency of food or shelter, but of excitement. They should have migrated to England! They died as hares do when their ears are stuffed with cotton, *i.e.* from want of anxiety. We have hope in our suffering, and in the mid gush of our pleasures something bitter surges up.

> "We look before and after, and pine for what is not,
> Our sincerest laughter with some pain is fraught,
> Our sweetest songs are those which tell of saddest thought."

The question may possibly occur to you, Have we more or less antagonism now than in former times? We certainly have more complexity, more differentiation, in our mental characteristics, and probably in our physical, so far as the structure of the brain is concerned; but is there less antagonism? With greater complexity come increased wants, more continuous cares. Higher cerebral development is accompanied with greater nervous irritability, with greater social intricacies—we have more frequent petty annoyances, and they affect us more. With all our so-called social improvements, is there not the same struggle between crime and its repression? If we have no longer highway robberies, how many more cases of fraud exist, most of it not touched by our criminal laws? As to litigation I am perhaps not an impartial judge, but it seems to me that if law were as cheap as is desired, every next-door neighbour would be in litigation. It would seem as if social order had never more than the turn of the scale which is necessary to social existence in its favour when contrasted with the disorganizing forces. Without that there would be perpetual insurrections and anarchy. But though antagonism takes a different form it is still there. Are wars more regulated by justice than of yore? I venture to doubt it, though probably many may disagree with me. National self-interest or self-aggrandisement is, I think, the predominant factor, and is frequently admittedly so. I also doubt if the old maxim "If you wish for peace, prepare for war," is of much value. Large armaments and improvements in the means of destruction (whose inventors are more thought of than the discoverers of natural truths) are as frequently the cause of war as of its prevention. Are wars less sanguinary with 100-ton guns than with bows and arrows? I cannot enter into statistics on this subject, but a sensible writer who has, viz. Mr. Finlaison, came to the conclusion that wars ceased now as anciently, not in the ratio of the improvements in killing implements, but from exhaustion of men or means. Wars undoubtedly occur at more distant intervals, or the human race would become extinct. Probably the largely increased competition supplies their place: we fight commercially more and militarily less. It is a sad reflection that man is almost the only animal that fights, not for food or means of life or of perpetuating its race, but from motives of the merest vanity, ambition, or passion. War is, however, not wholly evil. It develops noble qualities—courage, endurance, self-sacrifice, friendship, &c.—and tends to get rid of the silly incumbrances of fashion and ostentation. But do the much be-praised inventions of peace bring less antagonism? Consider the enormous labour and waste of time due to competition in the advertizing system alone. Paper-making, type-founding, printing, pasting, posting or otherwise circulating, sandwich-men, &c., all at work for purposes which I venture to think are in great part useless; and those who might add to the productiveness of the earth, or to the enriching our knowledge, are helping to extend the limits of the black country, and wasting their time in interested self-laudation. And the consumer pays the costs. "Buy my clothing, which will never wear out." "Become a shareholder in our Company, which will pay cent. per cent." "Take my pills, which will cure all diseases," &c. These eulogies come from those highly impartial persons the advertisers, all promising golden rewards, but, as with the alchemists, on condition that gold be paid in advance for their wares; and the silly portion of the public, no small body, take them at their word. Though you may not fully agree in this my anathema of the advertising system, and though there may be some small modicum of good in it, I think you will agree that it affords a notable illustration of antagonism. If I were a younger man, I think I should go to Kamchatka to avoid the penny post; possibly I should not be satisfied when I got there. Civilization begins by supplying wants, and ends by creating them, and each supply for the newly-created want begets other wants, and so on "*toties quoties*."

As far as we can judge by its present progress, mankind seems tending to an automatic state. The requirements of each day are becoming so numerous as to occupy the greater portion of that day; and when telegrams, telephones, electro-motion, and numerous other innovations which will probably follow these, reach their full development, no time will be left for thought, repose, or any spontaneous individual action. In this mechanical state of existence, in times of peace, extremes of joy and sorrow, of good and evil, will become more rare, and the necessary uniformity of life will reduce passion and feeling to a continuous petty friction. The converse of the existence contemplated by the Stoics will be attained, and, instead of a life of calm contemplation, our successors will have a life of objectless activity. The end will be swallowed up in the means. It will be all pursuit and no attainment. Is there a *juste milieu*, a point at which the superfluous *commoda vitæ* will cease? None probably would agree at where that point should be fixed, and the future alone can show whether the human race will emancipate itself from being, like Frankenstein, the slave of the monster it has created. In the cases I have given as illustrations—and many more might be adduced—the evil resulting from apparently beneficial changes is not a mere accident: it is as necessary a consequence as reaction is a consequence of action. In the struggle for existence or supremacy, inevitable in all social growths, the invention, enactment, &c., intended to remedy an assumed evil will be taken advantage of by those for whom it is not intended; the real grievance will be exaggerated by those having an interest in trading on it, and the remedy itself will have collateral results not contemplated by those who introduce the change. I could give many instances of this by my own experience as an advocate and judge, but this would lead me away from my subject. Evils, indeed, result from the very change of habit induced by the alleged improvement. The carriage which saves fatigue induces listnessness, and tends to prevent healthy exercise. The knife and fork save the labour of mastication, but by their use

there is not the same stimulus to the salivary glands, not the full healthy amount of secretion, whereby digestion suffers; there is not the same exercise of the teeth whereby they are strengthened and uniformly worn, as we see in ancient skulls. It seems not improbable that their premature decay in civilized nations is due to the want of their normal exercise by the substitution of the knife and fork and stew-pan. According to the evolution theory, our organs have grown into what they are, or ought to be, by long use, and the remission of this tends to irregular development, or atrophy. Every artificial appliance renders nugatory some pre-existing mode of action, either voluntary or involuntary; and as the parts of the whole organism have become correlated, each part being modified by the functions and actions of the others, every part suffers more or less when the mode of action of any one part is changed. So with the social structure, the same correlation of its constituent parts is a necessary consequence of its growth, and the change of one part affects the well-being of other parts. All change, to be healthy, must be extremely slow, the defect struggling with the remedy through countless but infinitesimally minute gradations.

Lastly, so the forms of government give us any firm ground to rest upon as to there being less undue antagonism in one than in another form. Whether it is better to run a risk of, say, one chance in a thousand or more of being decapitated unjustly by a despot, or to have what one may eat or drink, or whom one may marry, decided by a majority of parish voters, is a question on which opinions may differ, but there is abundant antagonism in either case.

Communism, the dream of enthusiasts, offers little prospect of ease. It involves an unstable equilibrium, *i.e.* it consists of a chain of connection where a defect in one link can destroy the working of the whole system, and why the executive in that system should be more perfect than in others I never have been able to see. Antagonism, on the other hand, tends to stability. Each man working for his own interests helps to supply the wants of others, thus ministering to public convenience and order, and if one or more fail the general weal is not imperilled.

You may ask, Why this universal antagonism? My answer is, I don't know; Science deals only with the How? not with the Why? Why does matter gravitate to other matter, with a force inversely as the square of the distance? Why does oxygen unite with hydrogen? All I can say is that antagonism is, to my mind, universal, and will, I believe, some day be considered as much a law, as the law of gravitation. If matter is, as we believe, everywhere, even in the interplanetary spaces, and if it attracts and moves other matter, which it apparently must do, there must be friction or antagonism of some kind. So with organized beings, Nature only recognizes the right, or rather the power, of the strongest. If twenty men be wrecked on a secluded island which will only support ten, which ten have a right to the produce of the island? Nature gives no voice, and the strongest take it. You may further ask me, *Cui bono?* what is the use of this disquisition? I should answer, If the views be true, it is always useful to know the truth. The greatest discoveries have appeared useless at the time. Kepler's discovery of the relations of the planetary movements appeared of no use at the time; no one would now pronounce it useless. I can, however, see much probable utility in the doctrine I have advocated. The conviction of the necessity of antagonism, and that without it there would be no light, heat, electricity, or life, may teach us (assuming free will) to measure effort by the probable result and to estimate the degree of probability. It may teach us not to waste our powers on fruitless objects, but to utilize and regulate this necessity of existence; for, if my views are correct, too much or too little is bad, and a due proportion is good (like many other useful things, it is best in moderation), to accept it rather as a boon than a bane, and to know that we cannot do good without effort—that is, without some suffering.

I have spoken of antagonism as pervading the universe. Is there, you may ask, any limit in point of time or space to force? If there be so, there must be a limit to antagonism. It is said that heat tends to dissipate itself, and all things necessarily to acquire a uniform temperature. This would in time tend practically, though not absolutely, to the annihilation of force and to universal death; but if there be evidence of this in our solar system and what we know of some parts of the universe, which probably is but little, is there no conceivable means of reaction or regeneration of active heat? There is some evidence of a probable zero of temperature for gases as we know them, *i.e.* a temperature so low that at it matter could not exist in a gaseous form; but passing over gases and liquids, if matter becomes solid by loss of heat, such solid matter would coalesce, masses would be formed, these would gravitate to each other, and come into collision. It would be the nebular hypothesis over again. Condensation and collisions would again generate heat; and so on *ad infinitum.*

Collisions in the visible universe are probably more frequent than is usually supposed. New nebulæ appear where there were none before, as recently in the constellation of Andromeda. Mr. Lockyer, as I have said, considers that they are constant in the nebulæ; and if there be such a number of meteorites as are stated to fall daily into the atmosphere of this insignificant planet, what numbers must there be in the universe? There must be a sort of fog of meteorites, and this may account, coupled with possibly some dissipation of light or change of it into other forces, for the smaller degree of light than would be expected if the universe of stellar bodies were infinite. For if so, and the stars are assumed to be of an equal average brightness, then if no loss or obstruction, as light decreases as the square of the distance and stars increase in the same ratio, the night would be as brightly illuminated as the day. We are told that there are stars of different ages—nascent, adolescent, mature, decaying, and dying; and when some of them, like nations at war, are broken up by collision into fragments or resolved into vapour, the particles fight as individuals do, and like them end by coalescing and forming new suns and planets. As the comparatively few people who die in London to-night do not affect us here, so in the visible universe one sun or planet in a billion or more may die every century and not be missed, while another is being slowly born out of a nebula. Thus worlds may be regenerated by antagonism without having for the time more effect upon the Kosmos than the people now dying in London have upon us. I do not venture to say that these collisions are in themselves sufficient to renew solar life; time may give us more information. There may be other modes of regeneration or renewed activity of the dissipated force, and some of a molecular character. The conversion of heat into atomic force has been suggested by Mr. Crookes. I give no opinion on that, but I humbly venture to doubt the mortality of the universe.

Again, is the universe limited? and if so, by what? Not, I presume, by a stone wall! or if so, where does the wall end? Is space limited, and how? If space be unlimited and the universe of suns, planets, &c., limited, then the visible universe becomes a luminous speck in an infinity of dark vacuous space, and the gases, or at all events the so-called ether, unless limited in elasticity, would expand into this vacuum—a limited quantity of ether into an infinite vacuum! If the universe of matter be unlimited in space, then the cooling down may be unlimited in time. But these are perhaps fruitless speculations. We cannot comprehend infinity, neither can we conceive a limitation to it. I must once more quote Shakespeare, and say in his words, "It is past the infinite of thought." But whatever be the case with some stars and planets, I cannot bring myself to believe in a dead universe surrounded by a dark ocean of frozen ether.

Most of you have read "Wonderland," and may recollect that after the Duchess has uttered some ponderous and enigmatical apophthegms, Alice says, "Oh!" "Ah," says the Duchess, "I could say a good deal more if I chose." So could I; but my relentless antagonist opposite (the clock) warns me, and I will only add one more word, which you will be glad to hear, and that word is—Finis.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The list of Physical Science lectures this term includes Prof. Liveing on Spectroscopic Chemistry, Mr. Robinson on Agricultural Chemistry, Mr. Ruhemann on Gas Analysis and on Aromatic Compounds, Mr. Shaw on Electrolysis, Mr. Wilberforce on Dynamo-electric Machines, Mr. Lyon on Machine Construction.

Prof. Stokes lectures on Hydrodynamics, Dr. Besant on Differential Equations and Solid Geometry, Dr. Glaisher on Theory of Errors, Mr. Stearn on Attractions and Theory of Potential.

In Biology, Mr. Langley is lecturing on the Central Nervous System, Prof. Macalister on the Rudimental Structures of the Human Body, Mr. Gadow on the Morphology of Mammalia recent and extinct, Mr. F. Darwin on the Physiology of Plants (advanced demonstrations).

In Geology, Prof. Hughes lectures on the geology of the

neighbourhood of Cambridge, Mr. Marr on Advanced Physical Geology, Mr. Roberts on the Crinoidea.

The above are only a selection out of a long list.

Mr. J. G. Adams, of Christ's College, has been appointed Demonstrator of Pathology on Mr. Rolleston's resignation.

SCIENTIFIC SERIALS.

American Journal of Science, April.—The absolute wave-length of light, by Louis Bell. The final results are here given of the research partially reported in the *Journal* for March 1886. Owing to the wide discrepancies in the value of this constant as determined by various observers and methods, the author gives a brief historical summary of the subject, with a critical discussion of the standards of length, methods, and apparatus employed in the present investigation. The details of the experimental work, together with some remarks on the final results, and some questions of theoretical and practical interest connected with the work of recent experimenters in this field, are reserved for a future number.—History of the changes in the Mount Loa craters; Part 1, Kilauea (continued), by James D Dana. Here are discussed questions connected with the ascensive action in the conduit lavas, the effects of heat, the hydrostatic and other gravitational pressure.—The electromotive force of magnetization, by Edward L. Nichols and William S. Franklin. At the Ann Arbor meeting of the American Association for the Advancement of Science the authors described some singular modifications in the relation of iron to acids which occur when the reaction takes place within the magnetic field. In the present paper, which was read at the New York meeting of the Association in 1887, they deal with the behaviour of iron when that metal acts as one electrode in a voltaic circuit, and is at the same time subjected to magnetization.—Notes on certain rare copper minerals from Utah, by W. F. Hillebrand. A series of rare copper ores, including olivenite, erinite, tyrolite (?), chalcophyllite, clinoclasite, mixite (?), and bronchantite, are here subjected to careful chemical and physical examination.—The Taconic system of Emmons, and the use of the name Taconic in geological nomenclature (continued), by Chas. D. Walcott. The main subject of this paper is the geology of the Taconic area as known to Dr. Emmous, with a comparison of its area as now known. As a result of this comparative study, the author finds that the Lower Taconic is essentially a repetition of the Lower Silurian (Ordovician) of the Champlain Valley, while the Upper Taconic appears to be conformably subjacent to the Stockbridge Limestone of the Lower Taconic, and to include the Potsdam horizon at or near its upper portion.—Three formations of the Middle Atlantic Slope (continued), by W. J. McGee. This paper is occupied with the Appomattox formation, its character, and distribution.—W. Le Conte Stevens describes a new lecture apparatus of an extremely simple character for the demonstration of reflection and refraction phenomena.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 8.—"Further Observations on the Electromotive Properties of the Electrical Organ of *Torpedo marmorata*." By Francis Gotch, Hon. M.A. Oxon., B.A., B.Sc. London, M.R.C.S. Communicated by Prof. J. Burdon Sanderson, F.R.S.

In the present treatise the author details the results of further observations as to the electromotive properties of the electrical organ of Torpedo, the experiments being carried out in October, 1887, at the laboratory of the Société Scientifique d'Arcachon.

I. The first part of the work deals entirely with the phenomena of "irreciprocal conduction" in the organ of Torpedo, as described by du Bois-Reymond.

From du Bois Reymond's experiments it would appear that the organ possesses the remarkable property of conducting an intense current of short duration, led lengthwise through its columns, better when the current is directed from its ventral to its dorsal surface than when directed the reverse way. The former direction coincides with that of the current of the shock of the organ, and is therefore termed by him "homodromous," the latter, being opposite in direction, is termed "heterodromous." The evidence rests upon the value of the galvanometric deflections obtained when both currents are allowed to traverse a strip of organ and a galvanometric circuit. The deflections are markedly unequal, particularly when induced currents are used, the homodromous effect being always much greater than the heterodromous. The homodromous current must therefore either encounter less resistance than the heterodromous, or its electromotive force must be suddenly strengthened, and that of the heterodromous current weakened, by the sudden establishment in the tissue of a new source of electromotive energy. The first is the view taken by Prof. du Bois-Reymond.

(1) The present rheotome experiments reveal (*a*) the new fact that the passage of such intense currents of short duration is always followed by an excitatory response (shock) in the tissue; (*b*) that if the intense current due to this response is allowed to affect the galvanometer as well as the induced or other exciting current, then by obvious algebraic summation the homodromous deflection must be much larger than the heterodromous; (*c*) and that when by means of a fast-moving rheotome the induction shock only is allowed to affect the instrument, no irreciprocity is found.

The author therefore assumes that the phenomena of irreciprocal conduction are in reality excitatory phenomena, the nature of which, from the methods of investigation used, have not been recognized.

(2) The time relations of this response of the isolated strip of the organ to direct stimulation by the traversing induction shock are now for the first time investigated, by means of the rheotome, and the influence of temperature and other conditions upon these is shown by experimental evidence.

II. The second part deals with entirely novel phenomena—namely, the excitation of the organ by the current of its own excitatory state. It is shown that in vigorous summer fish every response of the whole or part of the organ to a single excitation of its nerves is followed by a second response, due to the passage through its own substance of the intense current of the first response. In other words, the shock of the organ excites its own nerve fibres and nerve endings, producing a feebler second shock, which in a similar manner evolves a feebler third shock; this a fourth, and so on.

The response of the isolated organ to nerve excitation is thus multiple; a primary, secondary, tertiary response following the application to the nerve of a single stimulus. Since all these responses produce currents similarly directed through the columns of the organ, each column during its activity must reinforce by its echoes the force of the primary explosion, both in its own substance and also in that of its neighbours.

Linnean Society, April 5.—Mr. W. Carruthers, F.R.S., President, in the chair.—Amongst the exhibitions of the evening Mr. D. Morris (Kew) showed a curious native bracelet from Martinique. Although formed apparently of seeds, or beads of wood, or bone, its real composition had puzzled both botanists and zoologists, and until microscopically examined could not be determined.—Mr. J. G. Baker, F.R.S., exhibited a series of specimens of *Adiantum Fergusoni* and *Capillis Veneris*, and offered some remarks upon their specific and varietal characters.—Mr. J. E. Harting exhibited a specimen of a rare British animal, the pine-marten, which had been trapped in Cumberland; and made some observations on the present distribution of the species in the British Islands.—Mr. Clement Reid exhibited a series of fruits and seeds obtained by Mr. J. Bennie from inter-glacial deposits near Edinburgh, affording evidence of a colder climate formerly than that now prevailing in the Lowlands of Scotland.—Mr. F. Crisp exhibited some fragmentary remains of a wild goose shot in Somersetshire, which had been reported as the lesser whitefronted goose (*Anser erythropus*, Linn.), but which was apparently an immature specimen of *Anser albifrons*, Scopoli.—In the absence of the author, a paper by Mr. A. W. Waters, on some ovicells of the Cyclostomatous Bryozoa, was read by the Zoological Secretary, Mr. W. Percy Sladen; and after an interesting discussion, the meeting adjourned.

Chemical Society, March 28.—Annual General Meeting.—Mr. W. Crookes, F.R.S., in the chair.—The President delivered an address on which we have already commented.—The following Officers and Council were elected for the ensuing session:—President: Mr. W. Crookes, F.R.S. Vice-Presidents who have filled the office of President: Sir F. A. Abel, F.R.S.; Dr. Warren de la Rue, F.R.S.; Dr. E. Frankland, F.R.S.; Dr. J. H. Gilbert, F.R.S.; Dr. J. H. Gladstone, F.R.S.; Dr. A. W. Hofmann, F.R.S.; Dr. H. Müller, F.R.S.; Prof. Odling, F.R.S.; Dr. W. H. Perkin, F.R.S.; Sir Lyon Playfair, F.R.S.; Sir H. E. Roscoe,

F.R.S., and Dr. A. W. Williamson, F.R.S. Vice-Presidents: Prof. G. Carey Foster, F.R.S.; Mr. David Howard; Prof. J. W. Mallet, F.R.S.; Prof. H. McLeod, F.R.S.: Mr. Ludwig Mond; and Prof. Schorlemmer, F.R.S. Secretaries: Prof. H. E. Armstrong, F.R.S., and Prof. J. M. Thomson. Foreign Secretary: Dr. F. R. Japp, F.R.S. Treasurer: Dr. W. J. Russell, F.R.S. Ordinary Members of Council: Prof. T. Carnelly, Mr. A. H. Church, Prof. Clowes, Prof. Dunstan, Dr. P. F. Frankland, Mr. R. J. Friswell, Mr. C. W. Heaton, Mr. E. Kinch, Dr. H. F. Morley, Dr. R. T. Plimpton, Prof. Purdie, and Prof. Ramsay.

April 5.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Researches on the constitution of azo- and diazo-derivatives; part iii., compounds of the naphthalene β-series, by Prof. R. Meldola, F.R.S., and Mr. F. J. East.—The action of finely divided metals on solutions of ferric salts, and a rapid method for the titration of the latter, by Mr. D. J. Carnegie.

Anthropological Institute, April 10.—Francis Galton, F.R.S., President, in the chair.—Captain Strachan exhibited a young Papuan boy brought by him from the north-west coast of New Guinea.—Mr J. Allen Brown read a paper on some small highly specialized forms of stone implements, found in Asia, North Africa, and Europe.—A paper by MM. Henri and Louis Siret, on the early age of metal in the south-east of Spain, was read.

PARIS.

Academy of Sciences, April 16.—M. Janssen, President, in the chair.—On the spectra of oxygen, by M. J. Janssen. Attention is called to Olszewski's recent experiments with liquefied oxygen, which fully confirm the results of the author's researches on the phenomena of elective absorption in oxygen gas. The bands already determined by him have been observed by Olszewski with a thickness of 7 millimetres of liquid oxygen, while a thickness of from 4 to 5 millimetres would be required to detect the presence of the strongest band, which occurs in the neighbourhood of D. This is a remarkable confirmation of the law of the product of the thickness by the square of the density regulating one of the two systems of bands described by M. Janssen.—On the relations of atmospheric nitrogen to vegetable soil, by M. Th. Schlœsing. This is a reply to the objections recently urged by M. Berthelot against the character of the author's researches, and the general conclusions based on them. He denies the validity of M. Berthelot's criticisms, and insists that he does not deny the fixation of atmospheric nitrogen in vegetable soils. He maintains, however, that the phenomenon is neither determined by his own experiments nor demonstrated with sufficient accuracy by M. Berthelot's analyses.—On a source of algebraic equations whose roots are all real, by M. G. Fouret. An algebraic process is explained, by means of which equations, all of whose roots are real, may be combined in such a way as to obtain from them fresh equations possessing the same property. The following theorem is proposed and discussed: If the equation

$$F(x) \equiv a_0 x^n + a_1 x^{n-1} + a_2 x^{n-2} + \ldots + a_{n-1} x + a_n = 0$$

has all its roots real, then the equation

$$\phi(x) \equiv a_0 f(x) + a_1 f'(x) + a_2 f''(x) + \ldots + a_{n-1} f^{(n-1)}(x) + a_n f^{(n)}(x) = 0,$$

in which $f(x)$ represents an entire polynome of equal or higher degree to n, has at least as many real roots as the equation $f(x) = 0$; and if it has more, the excess is an even number.—On Foucault's gyroscope, by M. E. Guyou. An elementary solution is given of the problem connected with the rotation of a solid body suggested by the movement of this apparatus.—On a new method of measuring the heat of evaporation of liquefied gases, by M. E. Mathias. The calorimetric methods usually employed are either those of *variable* temperature or of the *fixed* temperature of melting ice. But for the purpose of his researches the author has had to employ one of *constant* temperature, the nature and advantages of which are here described. It is specially applicable in the case of gases which, like ethylene, carbonic acid, and the protoxide of nitrogen, have their critical point at the ordinary temperature.—On a class of electric currents set up by the ultra-violet rays, by M. A. Stoletow. Hertz, Wiedemann, and others having shown the influence of the ultra-violet rays on electric discharges at high tension, the author here inquires whether a similar effect may not be obtained with electricity of feeble potential.—On a regulator of electric light, by M. Charles Pollak. In the apparatus here described the movement required to be communicated to the carbons in order to supply and maintain the electric arc is obtained by the thermic expansion of the conducting wires. This appliance, which regulates the electric arc for a period of three hours consecutively, has the advantage of extreme simplicity, dispensing with all intricate mechanism, as well as with electro-magnets.—On a sodico-potassic carbonate, by MM. L. Hugounenq and J. Morel. The authors have obtained this substance by exposing to the open air at a temperature of 12° to 15° C. a solution of carbonate of soda containing carbonate of potassa in the presence of a great excess of iodide of potassium mixed with phosphate and chloride of sodium. It approaches the formula—

$$CO_3K_2,6H_2O + (CO_3Na_2,6H_2O).$$

These researches show generally that the carbonates of soda and of potassa may crystallize together, yielding isomorphous mixtures, which can scarcely be represented by definite formulas.—New experiments on inoculation against rabies, by M. G. Galtier. These experiments, made on sheep and goats, show that herbivorous animals may be successfully preserved from the bite of mad dogs by the usual processes of inoculation, whether applied before or immediately after the attack.—A communication was received from the Minister of Public Instruction announcing the results of the measures recently taken to determine the exact superficial area of France calculated by the planimetric method. This estimate gives 536,408 square kilometres, which is ·8012 more than that indicated by the Bureau of Longitudes, and 2929 more than that of the Russian General Strelbitsky.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Outlines of Qualitative Analysis: G. W. Slatter (Murby).—Text-book of Biology: J. R. A. Davis (Griffin).—British Birds: Key List: Colonel L. H. Irby (Porter).—In Pursuit of a Shadow: A Lady Astronomer (Trübner).—A Treatise on Alcohol, 2nd edition: Dr. T. Stevenson (Gurney and Jackson).—Allgemeine Geologie: Dr. Karl von Fritsch (Engelhorn, Stuttgart).—Arithmetic for Beginners: Rev. J. B. Lock (Macmillan).—Nature Readers, Sea-Side and Way-Side, No. 1: J. W. Wright (Heath, Boston).—Mr. Tebbutt's Observatory, Windsor, New South Wales: J. Tebbutt (Sydney).—Bulletin du Musée Royal d'Histoire Naturelle de Belgique, Tome v. No. 1.
